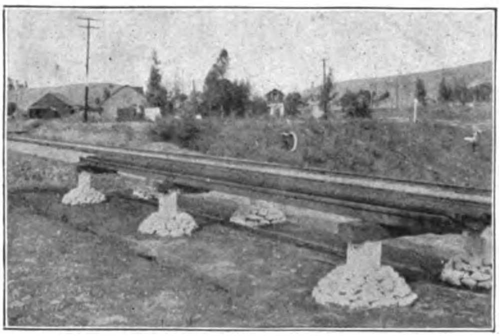
The style of rail rest shown in Fig. 260 is used on the Southern California Ry. It consists simply of posts and caps made from old switch or bridge ties set up on a piece of leveled ground and neatly embellished with a paving of whitewashed stones around each post. The capacity for spare rails is larger than is usually the case with a rest consisting of vertical or leaning posts and the rails are just as conveniently got at when wanted. The standard "rail rack" of the Southern Pacific Co. is a two-bent arrangement of this kind, the posts or bents being 16 ft. apart. When level ground is available it stands 2 ft. 3 ins. high, above the ground, and 20 ft. clear of the track rail. When set on the side of an embankment it is placed lower than the bottoms of the ties and 6 ft. from the track rail. To prevent mischievous boys from shoving spare rails over embankments, without going to some exertion, the rails may be put through holes in the posts, as in Fig. 261. As examples of more permanent construction, the Lake Shore & Michigan Southern Ry. uses 6-ft. pieces of old rails for posts, set with the web facing the track, with old fish plates bolted to each side of the web and bent outward and upward to serve as brackets to hold the rails. The standard rail rest of the New York Central & Hudson River R. R. (Fig. 262) consists of two posts of old 60 or 65-lb. rails 7½ ft. long, set 4½ ft. in the ground and 18 ft. apart, with iron cross arms bolted to the bases of



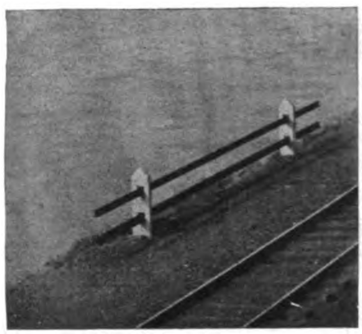


Fig. 260.—Rail Rests—Fig. 261.

the rails to serve as rests for the spare rails. The posts are painted black and around the foot of each there is a cobble paving. These rests are located at mile posts, two miles apart. For single-track lines one cross arm and two spare rails are standard; for double-track lines, two cross arms and four spare rails; and for four-track lines and large yards, three cross arms and six spare rails. Where curves are numerous it is well to have at the mile post at the middle of the section or at the mile post most convenient to the curves, a spare short rail of the length habitually used on the inside of the curves. Each spare rail should have a pair of splices bolted to it, and a few spare spikes should be cached somewhere near the rail rest.

The rules of the maintenance of way department of the Southern Pacific Co. require that in addition to the spare rails kept on hand for use on each section (six rails for each main-line section and three rails for each branch-line section), known as "section stock," each roadmaster's district shall be supplied with at least 1000 ft. of rail of fair quality, suitable for construction of temporary tracks around wrecks, washouts or slides, piled where it may be readily loaded on cars. All other rail which may be on hand is reported as "repair stock," and no section is allowed to have such material piled in more than three different places.

Bent Rails. Rails sometimes get bent and have to be straightened or else taken out of the track. A side kink in a rail may be taken out by prying with three bars against the rail—one bar being placed at or near the kink, as though to straighten it, and the other two placed against the rail a few feet on either side, so as to pry in a direction opposed to the single bar. Pry hard with the bars and at the same time strike the rail at the kink a few blows, against the side of the head and the edge of the flange, with a sledge-hammer; if it is not bent too much it can in this way usually be straightened. If this method fails, use the jim-crow at the bend and pry against the rail with a bar or two while the jim-crow is being screwed up. A roller rail bender can also be used to staighten side-kinked rails in the track. In one instance reported to the New England Roadmasters' Association, where the rails on ½ mile of track had been kinked inward through some defect in the running of a locomotive, the kinks were removed by working a roller rail bender along on the rail. Where moving rails at stub switches are bent by being thrown before the car has passed entirely over them, take one rail out, and turn it end for end, so that its spring counteracts the spring of the rail opposite. Where there is not sufficient ballast to hold it, the first spiked tie under the switch rails, nearest the head-block, will be moved over with the rails, especially if the switch rails are short, and the rail at this point will not move all the way back when the switch is thrown back to main line, thus leaving a kink in the rail at that point. To remedy a matter of this kind, throw the rails to line when the switch is set for main track and drive a stake firmly into the ground hard against the end of the first spiked tie, so that it cannot be moved when the switch is thrown .

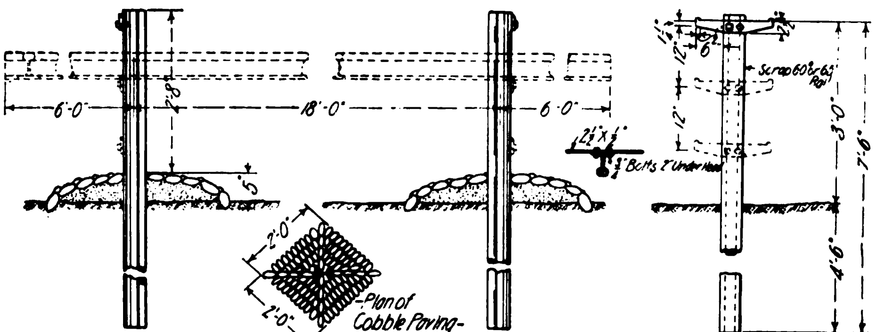

Fig. 262.—Standard Rail Rest. N. Y. C. & H. R. R. R.

On roads running through timber, rails are bent occasionally by falling trees. A rail badly surface bent cannot be straightened in the track, but should be taken out and another rail put in its place. One way to straighten such bent rails is to take them to a turnout, build a fire and heat them to a cherry red, not getting them too hot, because it is difficult with a wood fire to heat the rail very hot without heating it for several feet each side of the kink. In the angle back of the frog place two short pieces of rail across the two near rails of main track and side-track, one underneath and the other on top. The former piece will serve as a hold, and the latter as a rest, for the rail to be straightened, and the latter piece should be adjusted to come under the bend in the rail. When the rail is sufficiently heated pry downward with it between these two short pieces until the rail is straightened. About six men will be required to handle the rail, and tongs may be used to handle the hot part of the rail, if necessary. If the men know how to act together and fully understand what moves are to be made, the rail can be straightened very nicely. This method is best for straightening a kink at or near the quarter in a whole rail or long piece of rail. If the kink is near the end of the rail it can be straightened by heating the rail, laying it across a track rail for a support, placing the kink directly over the support, and striking down on the end of the rail with a heavy sledge. If the kink is at or near the middle of the rail, place the rail over the fire, supporting it at the kink by a piece of rail crosswise, the long end of the rail hanging over unsupported and the other end secured under a track rail or in some other way. When the rail becomes sufficiently heated it will bend down from the weight of the overhanging end, or at any rate by pushing down on it a little. Ordinary men who will take a little pains and use good judgment may satisfactorily straighten some pretty badly bent rails by such methods. Some will do to go back into main line and the others can be used in side-tracks. The following information regarding some work of straightening rails in a different way was furnished me by Mr. C. C. Dunn, of the Atlantic Coast Line:

"Several years ago I had considerable experience with straightening bent rails on another road. In this instance there were a great many surface-kinked rails in the track and we found that the best and cheapest way to do the work was to handle the rails with a floating gang. This gang was provided with a portable forge and a rail bender of the same pattern that is used for straightening alignment kinks. Of course a rail bender could be made for surface kinks that would work better. It does not require a very heavy forge for this work. If I remember rightly, we used a Buffalo No. 3 forge which we procured from a bridge gang. With this forge we could concentrate the heat on the exact point desired. We started with about 12 good rails to substitute for the bent rails taken from the track, and in a short time we very much improved the rails in 30 miles of track."

97. Regaging.—If rails are spiked to gage when the track is laid, the gage on tangents will seldom vary, if proper attention is given to it in tie renewals. The gage of curves, however, will spread when the ties get old, and it needs readjusting now and then. The wear of the outer rail of curves widens the gage by the amount of wear to the side of the rail head. On some roads the gage is adjusted occasionally for this widening, by moving one of the rails in a distance corresponding to the side wear, but such is not general practice, since the increase of gage by the wear is everywhere the same; and then when it comes to transposing the outer and inner rails the original gage is restored, unless the rails have spread. In regaging track which has been improperly gaged when built, pull both outside and inside spikes and plug the holes with wooden plugs which fit snugly, driving them to the bottom of the hole left by the spike. Holes should not be plugged with sand. If the change in gage is only slight the spikes may be driven in the plugged holes at one side of the plug; but if it is much, each spike should be driven near the other edge of the tie face from its old hole. It is always proper to drive a spike in an old hole where it can be done by plugging, because every additional spike hole weakens a tie at the place where the greatest pressure and bending moment come. But when a spike cannot be driven in the old hole beside a plug and reach the rail flange when the rail is in the right position, it should then be driven as far from the old hole as possible, in order to be in sound fiber. Back-spiking—that is, driving a spike at the back of a spike already driven, in order to crowd it against the rail flange—should not be practiced; a plug will do the work just as well, if the spike be pulled and the plug be driven tightly enough. If the rail has spread, having been in good gage before, simply pull the outside spikes and then plug and redrive. If the spikes are badly cut in the neck, pull them out and throw them into the scrap pile; and it may sometimes occur that by driving new spikes in the old holes, without plugging, the rail can be brought back to gage. If this can be done it is better than the practice of bending the head of the cut spike against the flange, or breaking off the head of the spike and driving another spike in a new place, to weaken the tie. In using new spikes the outside of the rail should be given the preference; that is, the new spikes should be driven on the outside of the rail, as far as they go, and the same rule applies to the best of the old spikes when such are redriven. The best time to do regaging on improperly gaged track is in the winter, when section work is slack.

It may here be explained that "spreading rails," as popularly understood, is a good deal of a bugbear. On fairly sound ties rails, if kept spiked, will not suddenly spread to dangerous extent. The spreading of rails and lateral displacement of spikes is seldom if ever caused by overwhelming pressure from the wheel flanges acting at one time. Such displacement is a gradual process, caused by lateral flexure of the rails, which increases in amplitude and intensity, of course, after the spreading of the spikes has once started, such action being most liable to begin where the track is out of line. On sharp curves without rail braces or tie plates the outer rail is quite liable to spread, but proper inspection and attention are sufficient safeguards. Many accidents charged to "spreading rails" may be traced to derailment from some other cause. Of course rails are likely to be spread after cars have been derailed.

Tie Plugs.—As already intimated, wooden spikes or tie plugs are much needed on old track, and it pays to have them made by machinery. Each section should have a supply on hand; and if they are not furnished from headquarters the crew, or part of it, should spend time enough at the tool house during wet weather to keep a good quantity ahead all the while. Straight-grained, sound oak ties, old brake beams, etc., may be cut up into blocks and the plugs split out with beetle and hand-ax. They should be kept in a barrel so that they will not be kicked around and wasted, and a few should always be carried on the hand car with the iron spikes; otherwise it will often be found necessary for one of the crew to putter around splitting slivers off fence boards or the ends of the ties, to make tie plugs. Unless the holes left in ties by pulling spikes are plugged, rain water will enter them and penetrate the surrounding fiber, the result of which is to hasten the decay of the tie under the rail seat. Tie plugs should be made of tough wood, which will stand hard driving, so that they may be made to entirely fill the hole without breaking. Pine and cedar are not suitable for this purpose, being too soft or brittle and inclined to break off before reaching the bottom of the hole, with the result that the plug will go partly down with the spike when it is driven, leaving the spike without backing at the neck. White oak and ash give satisfactory results, but second growth elm is recognized as the best material, being tough and presenting a roughened surface to the spike when the latter is driven through it. The Goldie tie plug, which is designed to fill all the hole left by pulling a spike, has a wedge point somewhat more blunt than that of a spike, with a body of the same size as the main part of the spike but with an enlarged top end to fill the oblong hole in the face of the tie made by the backward bending of the spike as the claw bar rolls back on its heel.

An interesting application of tie plugs is made on the Paris, Lyons & Mediterranean, the Northern, the Eastern and other roads in France, to increase the holding power of screw spikes and dog spikes in soft wood ties and in old ties in which decay has started around the spikes. A wooden screw of hornbeam or other hard wood, 2.08 ins. in diam. at the top and 1.38 ins. at the bottom, having a thread with a pitch of 0.59 in. and a depth of 0.197 in., is screwed into the tie in position for each spike and then sawed off flush with the tie face. There is an iron band around the screw plug to prevent splitting, and a hole in the center for the spike. The procedure with old ties is to bore out the old spike holes and tap them for the screw plugs. With new ties all of the holes for each tie are bored at one operation, by machinery, before creosoting. A series of experiments with a dynamometer showed that the increase in the holding power with these wooden plugs was 29 per cent for Baltic pine and 39 per cent for Landes pine ties, while with old ties 8 years in the track, the percentage was greater, being 80 for pine, 33 for beech, and 62 for oak. It is also found that the ties resist decay longer, as moisture does not penetrate the wood and the hard screw plugs prevent the tie plates from working into the timber. The device was invented by Mr. Albert Collet.

98. Righting Canted Rails on Curves.—The canting or tilting outward of the inside rail of curves is caused either by the elevation of the outside rail, being too much for the slow trains; or by unsound ties. The former cause is explained at length in § 44, Chap. V. Where the elevation is found to be too much it should be reduced by raising the inside rail; but neither this nor replacing part of the old ties with sound

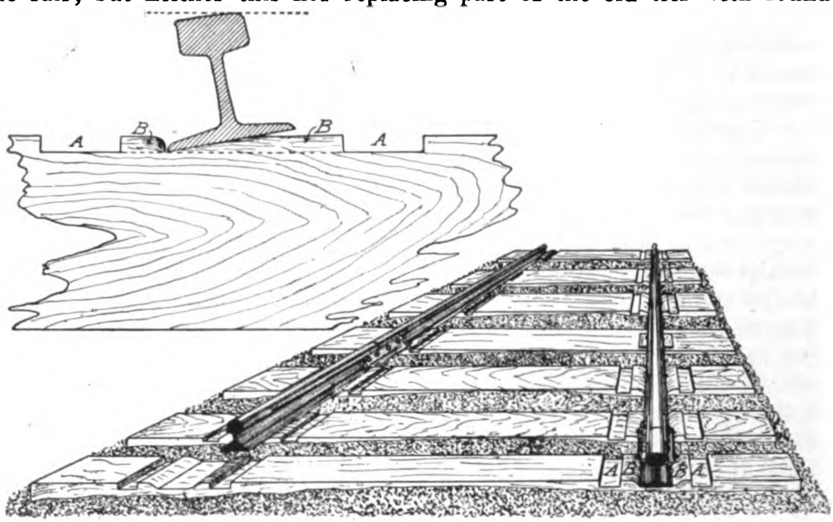

Fig. 263.—Work of Tie Spotting Machine, Pere Marquette R. R.

ones will bring the rail back to its proper position. This can be accomplished only by adzing the rail seat to a proper bearing. The way to go about it is to pull all the spikes from the rail, both outside and inside, and drive all stubs of spikes ½ or ¾ in. into the tie. Also clean away all ballast which may be on the tie face near the rail base, or near the rail base between the ties. Raise the rail about an inch and block it there and adz each tie to a bearing for the rail, parallel with the plane of the tie face, although if the ties are old it might be made to cant the least bit inward. Then let the rail back to its place and drive the spikes in the old holes. By taking not more than a rail or two at a time the work can be done without much hindrance from trains, and, being the inside rail of the curve the track can be made temporarily safe to let trains pass by tacking down hastily a few of the spikes. As the work progresses the rail will tip back to place and to proper gage.

In the work of righting tilted rails on the Pere Marquette R. R. a traveling tie spotting machine has been used to prepare the ties in a way to facilitate adzing out the rail seat. This work of preparation consists in cutting a groove into the tie face, each side of the rail and even with the base of the same, as illustrated in Fig. 263. In the upper view there is a sketch of a tilted rail. The grooves cut by the machine are lettered "*A*," and two shoulders (*B*) remain between the rail and the grooves. To prepare the seat for the rail in its righted position it is only necessary to chip away the shoulders *B*, which readily split off to the bottom line of the grooves. The construction of this machine and its method of operation are described and illustrated (Figs. 279-281) in connection with "Laying Tie Plates," the subject of § 106, of this chapter.

A sure cure for canting rails is the use of tie plates. This device cannot be too highly recommended for service under rails that show a marked tendency in this direction, especially after they have given trouble and been straightened up. Where tie plates are applied in a case of this kind they serve to fill up to some extent the depressions or notches in the tie face caused by adzing down the rail seats; and prevention of recurrence of the trouble is more especially desirable at this stage in the life of the tie, because repetition of the process of cutting into the tie by rail and adz will ruin many a tie that should see longer service.

99. Cutting Rails.—Rails are usually cut by first notching around with a track chisel and then breaking at the notch. The piece of rail to be taken off and used should be measured accurately, allowance being made for expansion, and it is usually notched squarely all the way around. As measurements are usually made along the rail head, the first cutting is made across this portion; and pains should be taken to have it started squarely across, for upon the manner in which this first cut is started depends largely the success of carrying the cut squarely the rest of the way around the rail. It is well to mark a line for this first cut, with a rule and pencil, because it is somewhat difficult to sight squarely across a rail to the blunt edge of a track chisel. After the notch or groove has been cut across the head, stand over the rail and sight squarely past the ends of this groove to the edges of the rail flange, and mark these edges with the chisel. By these marks the notch can then be extended all the way around. In notching, one should cut into the corner or fillet between head and web as much as possible. In cutting across the base the notches on the two sides of the flange, near the edge of the flange, should so nearly meet that the rail shows signs of cracking or fracture there. In short, notch all the way around the section as deeply as the chisel will cut conveniently; and chisels which have become much blunted should not be used. By continually pounding on a blunt chisel the steel is toughened at the cut and is liable to break on one side of the cut instead of in it. The rail while being notched should rest squarely across a track rail, or squarely across a short piece of rail placed on a sound tie which is solidly bedded. It is much easier to notch squarely around a rail if the support is perpendicular to, or square with, the rail, than otherwise. The cutting should be done directly over the support. This done, the rail is ready for breaking. A rail notched squarely all the way around is pretty sure to break off right; that is, if it is broken in the right manner.

About the easiest way to break a notched rail is to do it with the jim-crow, providing this device can be used. If the rail to be broken in two is a short piece the jim-crow is by all odds the best means to employ, for, unless the piece of rail has considerable weight it cannot be easily broken by striking it or by throwing it. If the jim-crow is not used, and the piece to be taken off is less than 3 ft. long, lay the rail on its side, with the notch directly over another rail for a support, and break the piece off by striking the end of the rail with a heavy hammer or sledge, or by dropping upon it a piece of rail as heavy as a man can lift over his head. To break off pieces 3 to 8 ft. long from a long piece or whole rail, raise the rail and let it drop across another rail or piece of rail, falling on its side with the notch directly over the support. In breaking off a considerable piece the rail need be raised only hip high, but to break off a short piece the rail should be lifted as high as one's head. If all the men fully understand what is to be done and step aside at the word, no one need ever get hurt; and if the notch is dropped directly over the support the rail will not be kinked. In taking off pieces longer than 8 ft. there is too much spring to break the rail by throwing. In such cases the rail to be broken should be laid on its side, parallel to a track rail, 6 to 10 ins. therefrom, having the head turned toward the track rail and supported on pieces of rail or blocks 3 or 4 ins. high placed near the ends, or at least far enough away from the notch each way to allow considerable spring in the rail. Then pry down over the rail, near the notch, with a bar, taking hold under the head of the track rail, at the same time holding a track chisel in the notch on the side of the head and striking it a heavy blow. A piece as short as 2½ or 3 ins. may be broken from the end of a rail by notching it and striking with a sledge; but it may be done with one blow, or it may take a half hour. For cutting off such short pieces the hack saw or other rail saw should be used. When it is found especially difficult to break a rail in hot weather, turn it on its side, make a little mud dam on the web, on each side of the notch, and cool the rail by pouring in cold water and allowing it to stand a few moments.

One way to break off a short end (pieces 10 ins. to 3 ft. long) from a rail is to notch it on the sides and around the base, rest it workwise on an end bearing, have the men stand upon it, hold the chisel in the notch on top of the rail flange and strike it with the hammer. In breaking rails it is not necessary to notch them across the top of the head, and some do not notch the sides of the head. Where rails are broken by dropping them on side across an anvil some make it a practice to notch only one side and across the bottom of the base. The rail is then lifted and dropped with the cut side up.

A rail may be cut or broken in two without removing it from the track, by notching it conveniently deep on the sides and top with a chisel and breaking it with the jim-crow. A good break is best assured in a case of this kind by first cutting the head clear through with a hack saw. Before applying the jim-crow pull all the spikes on one side of the cut, so that that end may be free to swing when the rail is bent. After a rail has been notched and broken there will be found a burr on the broken end, which should be trimmed off with a hand cold-chisel, so as to give a smooth bearing for the splice bars. Tools for cutting rails, such as chisels and saws, are considered in § 125, Chap. IX.

100. Expansion in Rails.—Failure to allow the proper amount of joint space when laying rails is generally the cause of considerable repair work afterward. Where too much space is allowed rails will, in extremely cold weather, pull apart at the joints, breaking either the bolts or the splices, and leave a dangerous opening, particularly if such pulling apart occurs on the outer rail of a curve. But it is more frequently the case that too little space is allowed, so that the evil effects thereof are felt mainly in hot weather. While the coefficient of expansion for steel undoubtedly holds good in all cases, yet it almost seems that no reliance can be placed upon it in summer time with rails in the vicinity of a stub switch. Here is where the bad effects of too little space for expansion are first seen. The rails will expand so tightly that the switch cannot be thrown during the middle of the day without the aid of a hammer to drive the rails over. Of course, the only remedy is to take out a piece of rail, and this is done by cutting about 3 ins. from the end of some rail back of the moving rail. Leave an opening of about ½ in. at the headshoe and take up the rest of the 3 ins. by opening out joints farther back. If the joints in the direction of the frog also are tight, the same thing must be done with the rails on that side of the headblock, or else the headblock will continually be shoved toward the moving rails. In doing this the piece of rail should be taken out somewhere beyond the frog or guard rail and the full number of holes should be drilled for the bolts of the splice. The short pieces of rail taken off should be buried in the ballast under the joint, so that they may be had to put back when cold weather comes, if needed. If the steel is pretty tight in the joints the rails will have to be shortened more than once during the summer. In driving rails apart a track chisel should be used which is rather sharp and thinly drawn out, as a blunt chisel is not good for starting the rails to move and it will also raise a burr at the ends of the rails.

The tightening of the rails on the headblock at stub switches is not, however, the only inconvenience and trouble caused by the expanding of close-jointed steel. During hot days the rails will kink into a snaky alignment, and they cannot be thrown in line until after cooling down; and then, not to stay there. On curves, frequently, and sometimes on straight line, tight rails will expand and shoot sidewise out of line several inches within a rail's length or so. This phenomenon is commonly known among trackmen as a "sun kink," and has often been the cause of a wreck. It is almost sure to occur with close-jointed rails where the ties are not well filled in between. It usually takes some time to get such kinked rails back into line, as the only remedy is to take out a piece of rail. But rather than hold a train very long at such a point it is well to throw the track out *with* the kink, temporarily, for a rail or two each side, making a longer curve, or, on tangent, a double reverse curve, over which the train may be allowed to pass slowly. When laying a shorter rail in such a place allowance should be made for proper expansion at the joints for some distance in each direction. A sun kink is sometimes started while the track is being raised for tamping or while throwing the track into line. When the rails are expanded and crowded together tightly a slight disturbance will sometimes cause the track to buckle in the manner above indicated, particularly on curves, or where there is only a small amount of filling between the ties. Filling against the ends of the ties makes track secure against expanding steel, and hence track should always be filled in that way if the quality of the ballast is such that proper drainage will not be interfered with.

101. Stretching Steel—Sometimes the proper amount of space for expansion is allowed but not evenly distributed, there being tight joints between successive rails for a distance, so that the rails will kink when the weather gets hot; and then a number of joints at which the openings are wider than necessary. If this state of things exists only in short stretches of track in a place, it may be remedied by manipulating the splice bolts to take advantage of the expansion or contraction in the rails. The most favorable opportunity to do this is when there is a considerable change in temperature between night and day, or between the middle of the day and evening or morning. The way to go about the work in summer is to start during the cool of the day and loosen the bolts at the open joints. When it gets hot the expansion of the rails will run into and toward the loosened splices, the bolts of which should then be tightened, at the same time loosening the bolts at the tight joints, so as to allow the latter to pull apart when it gets cooler. The operation should be repeated two or three times, or until the space for expansion becomes evenly distributed among all the joints. After slackening the bolts on a splice the bars should be struck a side blow with a hammer, to loosen them, and to give the rails free movement, the slot spikes should be drawn from the splices. If the work is undertaken in winter the bolts should be tightened on the open joints and loosened on the tight joints. During the night the tight joints will be pulled open. The next morning the bolts should be tightened at the joints which have pulled apart and loosened at the others. By keeping up this practice for a few times the joint openings may be readjusted to even spaces.

Where the necessary amount of space for expansion has not been allowed a piece of rail must be taken out and the space thus obtained evenly distributed among all the joints. To start with, a piece as long as the distance between the first two bolt holes may be cut from the end of a rail, the rail thus shortened to be laid in place of a whole one when the time comes to begin the work of pulling open the joints. This arrangement will permit the use of at least one of the original bolt holes in the shortened rail. After ascertaining how many joints must be opened out in order to take up the space to be gained by laying the shortened rail, the bolts should be removed from one side of the joint in each of the splices, so that the rails may be pulled apart. Thus all the splices remain on the rails, with half the bolts at each joint still in place, so that the running of trains is not endangered. Only such spikes are pulled as are found driven in the slots of the splice bars or such as will be in the way of the splice when the rail

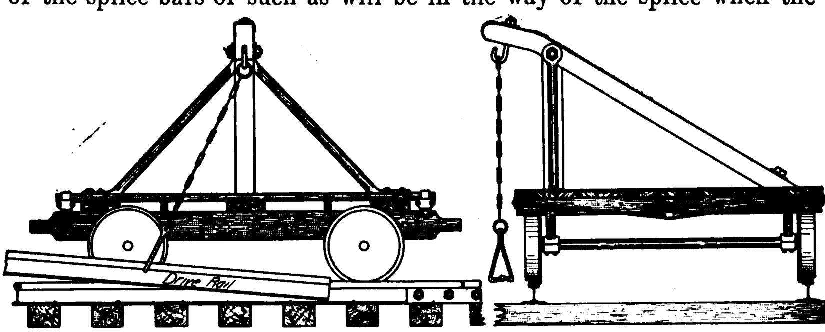

Fig. 264.—Rail-Driver Truck, Yazoo & Mississippi Valley R. R.

is moved. The shortened rail is then laid in the place of a whole one taken out, and the close-jointed rails are driven toward the opening, one at a time, and properly spaced at the joints. The work can be done rapidly, and a space longer than 6 or 7 ins. never exists between any of the rails while they are being moved. Should a train approach while there is a wide gap still undistributed, a rail or two may be quickly driven to divide the space among two or three joints. Where too much space has been allowed at the joints the latter may be closed to the proper interval by driving the rails along in the manner just described, putting in a short piece of rail or "dutchman" as often as the gap opened up behind amounts to a few inches, but not exceeding 6 ins. in length. The joints at each end of such a short piece of rail should be closed up tight and should be supported by a tie directly underneath, respacing a few ties in the vicinity, if necessary, to bring one under the dutchman. The splice should then be full bolted. The length of the dutchman is usually determined with a view to have some bolt hole in the shifted rail come right for service.

Another occasion for stretching steel arises from the creeping of rails on hilly roads, where the rails pull apart on the summits, opening up the joints, and drive together, closing the joints, in the hollows. Particularly is this true of single-track roads, where the running of trains both ways on the same track drives the rails into each hollow from both directions. In such cases it is necessary to drive the rails back from the hollows toward the summits, making a redistribution of the expansion allowance, which, if properly calculated when the track was laid, can be done without cutting rails or laying dutchmen. In such places, however, the work proceeds from the summits toward the hollows, and on a long hill the gap opened up in setting back the rails may become so long before reaching the "bunched" rails in the hollow that temporary use of a short piece of rail must sometimes be made in order to close up and let a train pass. Careful attention should be given to the proper spacing of rails in side-tracks, as well as in main track. It has frequently happened that close-jointed rails in side-tracks have expanded, pushing the frog out of its proper alignment for main track or shoving the headshoes against the moving rails at stub switches. Where such trouble occurs it is necessary to stretch the rails in the siding.

The method of driving rails when stretching steel, known as the "butting back" process, is to strike the end of the rail or the end of the attached splice bar with a piece of rail 8 or 10 ft. long. The piece of rail is handled in various ways. Where it is butted against the end of the rail that is being driven, the joint is first opened up about an inch wide with a track chisel and hammer. The striking end of the butting piece is slid along on top of the rail behind and the other end is held about hip high, so as to cause the striking end to drop into the opened joint and strike against the end of the rail to be driven. If the rail is to be moved by striking against the end of the splice bar the butting piece is either swung as a battering ram or slid forward on the ties.

The work of handling the driving rail, either when held in the hands of the men or swung with tongs, is severe physical exertion, not only in the act of striking, but also in carrying it from joint to joint as the work proceeds. On the Yazoo & Mississippi Valley R. R. a push car has been rigged up to carry the striking rail in such work. The division of this road extending from Vicksburg, Miss., to Wilson, La., 113 miles in length, is quite hilly and creeping rails are bothersome, the trackmen finding it necessary in years past to drive the rails on about half the length of the division annually. Formerly this work was done in the ordinary way, with a squad of eight or ten men handling the rail serving as the driver, and so fatiguing was the labor of carrying it from place to place that a new crew had to be put on about every six hours. The arrangement of the push car above referred to is shown in Fig. 264. In the middle of the car, at one side, there is a vertical post secured to the car decking and by side brace rods, while extending across the car there is a beam inclined upwards and framed over the top of the post, the overhanging end being provided with a hook bolt, from which hangs a chain and grapple a few inches clear of the side of the car. In closing up an interval between two rails the truck, with the drive rail hanging at the side, is run to a proper position behind the joint splice to be driven, and the driver is then swung and guided to strike the splice. The number of men required to handle the driver in this way is only three, but two men can do it quite handily. Aside from the saving of labor in lifting and carrying the rail the truck is also utilized for carrying the tools needed in the work, and short pieces of rail or switch points used in closing up openings when it is desired to let a train pass. As the framework is light the truck is easily set off the track after the driver rail has been released from the grapple.

102. Adjusting Bolts.—The importance of keeping track bolts properly tightened is not always recognized. It seems to never occur to some foremen that loose bolts may be largely responsible for most of the low joints on their sections. No matter how much tamping is done, track cannot be maintained in good surface easily if the bolts are allowed to get loose and stay in that condition very long at a time. The strength of splice bars is effective only when the bolts hold them tightly in position; in fact, so far as efficiency of the splice is considered, leaving safety out of the question, the nuts might as well be entirely off the bolts as to be at all loose. And then, if track bolts are allowed to remain loose for any considerable length of time the threads of the bolts become so much worn or battered that they are no longer fit for service. Where day track-walkers are employed they should be kept busy at tightening or adjusting bolts when not actually engaged in patrolling the track. If this work is not done by track-walkers, one day each month should be devoted to it by the section crew. In winter time, when work is not pressing, much attention might be given to tightening bolts, and in wet weather, in other seasons, the time can be put in at such work to good advantage. The splices should all be kept fully bolted with good bolts and the bolts should be tightened evenly. The effect of one bolt much tighter than the rest is to loosen the two adjacent ones.

Although it may not generally be thought so, bolts in splices may be got too tight, so that evil effects may result from overtightening as well as from loose bolts. Bolts may be turned on so tightly that the rails will kink or the track buckle before expansion can take place at the joints. In view of this fact some trackmen take the precaution, when raising track on curves during very hot days, to slacken the bolts on a few splices before lifting the rail, in case the appearance of things seems to require it. Experiments conducted by Mr. P. H. Dudley on testing machines showed that a force of 46 tons was required to start the ends of 80-lb. rails spliced with 40-in. six-bolt angle bars, and a force of 23 tons to slip one end of the same rails spliced with 22-in. four-bolt angle bars. To slip 95-lb. rails in 20-in. four-bolt angle bars required a force of 30 tons, and after the angle bars had been "sledged in" and tightened again the force required to slip the rail in the splice was 58 tons. These records prove that track bolts turned on hard resist rail expansion and contraction with great force. To cite one instance where due recognition is taken of this fact, it is the practice on the French Eastern Ry. to lubricate the splice bars, in order to facilitate the shifting of the rail ends under temperature changes. It should be taken into consideration that splice bars, when tightly adjusted, are wedged in between the head and flange of the rail very securely, and that all there is required is to keep them to a snug fit. In order to do this it is not necessary to screw on the bolts until they are at the point of snapping in two. A splice may be adjusted very tightly and still allow the rails to expand through it. Each rail should be so held by the splices at its ends that it may expand and contract in its place; but where the bolts on some splices are too tight several rails may expand as one rail, and either kink themselves into a snaky alignment or shove rails less tightly spliced; hence the importance of adjusting bolts to a uniform tightness on all the splices. The reason why some joints pull farther apart than others is because the bolts on the splices are not so tightly adjusted as on the others. To remedy a situation of this kind the bolts may be slackened on the open joints in the morning, and then during the heat of the day, when the rails have closed in, all should be adjusted to an even tension. Where good spring nut locks are used it is not necessary to adjust the bolts as tightly as otherwise. When tightening a loose bolt on a splice one should inspect carefully to see whether any of the others have been slackened, and if such is the case each should be readjusted to take its proper share of the work.

Foremen should make a thorough study of this matter and learn for themselves, from observation and experiment, the proper adjustment for track bolts, and then see to it that all the men do the work right and uniformly alike. A man can pull on an ordinary 18-in. wrench with enough force to break a ⅞-in. track bolt. The practice of lengthening out wrench handles with a piece of pipe, 2 ft. or so long, is an indication of either ignorance or laziness, or both. A wrench with so long a handle cannot be manipulated as dextrously as one with a handle of ordinary length. That part of the operation of tightening a nut which requires the most time is in screwing it to take up slack and to bring the bolt to a snug bearing; the number of pulls at the wrench requiring the laying out of strength are comparatively few. A section crew trained to know when track bolts are properly tightened, have learned an important matter in track maintenance.

While bolts are being adjusted, cracked splice bars should be replaced with sound ones. While a cracked splice may answer for holding the ends of the rails in line it is of no more account in supporting the joint than a broken one. The broken or cracked splices should not be thrown into the scrap pile. The pieces make good temporary rail braces, which come handy in shimming, or they serve quite well for two-bolt splices for joints in unimportant spur tracks or sidings—that is, if the bolt holes come right for the holes in the ends of the rails.

103. Creeping Rails.—There are two longitudinal movements, or tendencies to movement, in rails: one, a molecular movement of expansion or contraction in the metal, the other a progressive shifting of the rails bodily, commonly known as "creeping" or "running." The former is caused by change of temperature and its effects, however severe, are local—that is, the damage resulting from expansion or contraction of rails will always be found in the near vicinity of improperly spaced joints, and movement takes place in the direction of least resistance. With steam roads this movement is practically irresistible. The tendency to movement by creeping is caused by the running of trains, and is always in one direction for the same direction of the moving train. Where this movement takes place it usually extends over comparatively long stretches of track. The tendency is sometimes held in check and usually may, to some extent, at least, be prevented. There are some peculiar things related of creeping steel, some of which would apparently defy satisfactory explanation on existing theories for the cause. It is now pretty generally conceded, however, that the principal cause is the wave motion in the rail set up by moving trains. There is usually a slight upward and then downward movement of the rail and ties just preceding a moving locomotive or train, owing to the flexibility of the rail, but the whole ground also springs for quite a depth underneath the track and for some distance each side, so that there results a wave motion in the rail of much greater amplitude than at first appears. Those who are interested in the subject of track depression may find some account of extensive experiments in this direction in § 181, Chap. XI.

Starting with the fact that there is a wave motion in the rail, it may be explained that if the rail was continuous this wave would be propagated along it simply as an undulating motion and there would be no onward movement in the rail any more than there could be in the ground. But by laying the rail in sections of 30 ft., or other length, the propagation of the undulating motion is more or less arrested at every joint (completely, where the splice is loose) and each section of the rail is permitted to sprawl ahead. Hence the running or creeping of rails takes place successively by sections, one section at a time; or, at most, by a few sections acting together as one; and this is why steel may creep and not close the joints, as many have undoubtedly observed. So, while the ground and the ties undulate continuously, and return again to the position in space occupied before the train arrived, the rail undulates intermittently by sections and does not return unless provision be made to compel it to do so; that is, unless each rail is made to hold fast to the ties and ground it will remain shoved ahead by a very small amount at each passage of a train.

The reason the rail is shoved ahead when it loses the undulating motion is this: When a heavy load rolls along the track the ground and the rails with it give downward. This giving downward with the ground is a displacement, and earth is moved outward in all directions and compressed; but after the load passes, the earth, by virtue of the elastic force due to its compression, moves back to its former position, the old level of the roadbed is restored, and its motion has been simply undulating or oscillating. Now, if the rail was continuous, as the load rolled forward it would stretch out the rail behind and crowd it together in front, compressing the particles slightly, thus setting up behind an elastic force of tension, and in front, an elastic force of compression, in the rail, both of which would act to restore the disturbed portion to its former place after the load had passed; then the rail would undulate with the ground. But with a rail made up of spliced sections the undulations cannot be fully propagated unless the splices hold the joints securely enough to resist the stresses from the undulations as firmly as the solid part of the rail; otherwise the rail will shove through the splice ahead, into the open joint, and pull through the splice behind, and there will be no elastic force to return it to its former position relatively to the ground. Hence the ground and the ties, which are embedded in the ground, undulate backward after the load has passed, but the rail remains shoved ahead relatively to them, unless provision be made to carry it back. Although such forward movement can take place only by almost imperceptible stages, it takes place, nevertheless, wherever the rail is not so held to the ties as to be carried back with the undulations in the ground and ties; and the space at the joint is just what permits this creeping, for it could not take place except by sections. If it was possible to tighten splices so as to hold against creeping they would be too tight to allow the rails to expand easily, and much evil would result. The two movements do not take place in the same way; for creeping occurs only under the trains, while with rise in temperature every section of rail along the whole line expands at the same time.

Three important facts should be noted in connection with creeping rails: the creeping is most rapid during hot weather, it is greater on double than on single track, and it runs with the trains. In hot weather the rails must expand; and some splices may be bolted tightly enough to cause the expanding rail to flex or bend. If there is but little filling between the ties or the spikes be not driven snugly up to the rail flange the rail may kink laterally and throw itself out of line. But if there is filling at the tie ends, or the spikes have not been kept driven down to the flange of the rail, or if the ties are sawed four-square, so as to be easily lifted through the ballast, or if there are low joints, the rail may spring upwards or camber more readily than it can be forced through the splices at either end. Many have doubtless noticed this; and how in some hot days the cambering of the rails at the centers gave the appearance of low joints, for the time being. Now a locomotive running over these cambered rails will depress them and such depression must drive the two ends of the rail further apart, of course, the friction of the splices not being sufficient to hold the rails back. But the load rolling on from one end will cause the rail to slip through the splice in the forward direction, as carpet is ruffled when the foot is shoved over it; because no matter how loose the splice behind, the weight of the rolling load tends to hold that end of the rail firmly and to drive ahead the other end.

But there is another reason why rails should be expected to creep faster in hot than in cool weather. When the rails are heated up the tendency to expand sets up considerable compressive stress in the metal before properly bolted splices will permit the rail to give at the joints. When there is no train running this compressive stress or force might be considered as producing an equal effect toward expansion in both directions and all the rails might be considered as being frequently stressed up to the point of forcing the splices. As the train advances, however, the wave in the rail preceding it should increase the stress in the rail just ahead of the train, and the jarring effect of the advancing load on the molecular structure of the metal would be expected to cause the rail to suddenly expand and slip through the splice. As has just been shown, this expansion will be in the forward direction, or away from the point where the rail is held down firmly under the train. Now when the rail is in tensile stress, as in cool weather, any disturbing cause, such as the jar of a train running over the track, will affect the creep of the rail in the same manner; that is, the rail will be forced to suddenly contract and pull away from the point where it is held firmly under the train; but the tendency will be to creep less, because the wave in the rail running ahead of the train will operate to relieve the rail, just ahead of the train, of some of its stress. It seems likely that the jarring of the rail by moving trains, while the rail is in a state of stress, may have no small influence in the creeping of the rail at all times, for the rail is in stress, either of compression or tension, at any time when the temperature is rising or falling—that is, if the splice bolts are kept properly tightened. Most trackmen have probably seen a rail on a very warm day suddenly expand to fill the joint opening upon loosening the bolts at a tightly spliced joint, the sudden increase in length being accompanied usually by a loud report, showing that the rail had been subjected to heavy stress. In very cold weather rails will contract with equal suddenness upon being freed from the gripe of a tightly bolted splice. However much, change of temperature, as a primal cause, may have to do with rail creeping, it is certain that except for the running of trains the rails would expand and contract in place; and as every effect due to the running of trains is to cause the rails to move forward, the tendency of rails to creep is always forward, or in the direction of the movement of the train which causes it, and never backward. Another reason why rails should creep more rapidly in summer than in winter is that when the ground is frozen it is less yielding and there should be less wave motion in the track.

On double-track roads the tendency for each track to creep is in one direction only. On single track, if there be no predominating influences favoring one direction, the tendency to creep in one direction is balanced by that from the other, and movement, if at all, is slight and not nearly so much as on double track. It has been observed, however, that on single track, with traffic one way much heavier than the other, the rails creep with the heavier traffic; also that on single track the rails creep habitually down grade, owing no doubt to the faster speeds in that direction and, on heavy grades, in some degree perhaps to the continuous application of brakes and the back action of double-header engines. The same explanation would also account for the greater creeping down, than up, the grade on double track. On single track where the trains habitually take a running start for a grade, the rails for some distance above the foot of the grade have been observed to creep up grade, due, of course, to the excessive speed of trains going in that direction.

Rails usually creep most on embankments, especially newly-made ones, and little or least on solid, hard ground not raised above the surrounding level. Track laid over swampy or boggy land creeps worst of all, and on some trestles it is not far behind, especially where there is a drawbridge to break the continuity of the rails. The outer rails of double track, on a fill, creep more than the inner rails, because the support for the former is less firm. The records of track inspection apparatus which measures rail deflection, show that almost invariably the rails on the outside of double track are subject to greater average deflection per mile than the inner rails. In tunnels rails creep none or scarcely at all, unless pushed by the rails outside, thus showing that the creeping is least where the foundation is firmest and wave motion least; the nearly constant temperature may also have its effect. M. Couard, a French authority on maintenance of way questions, states that in the Credo tunnel, between Lyons and Geneva, no creeping whatever was discoverable, and on a 2½ per cent grade in the Sauvages tunnel the maximum amount of creeping was only 4 ins. during 9 years of service. On curves where the inside rail receives the heavier load, on account of a too great elevation of the outside rail, the inside rail creeps faster than the outside rail. On straight double track which is out of level the lower rail will creep the faster. The relative amount of creeping of the two rails may also be affected by side pressure against the cars from prevailing winds, which operate to throw a disproportion of the weight to the lee side.

It is of frequent report that the outer rail of curves creeps faster than the inner rail or that one rail (on either curve or straight line) creeps while the rail on the opposite side of the track creeps little or not at all; and some claim to have seen the two rails creep in opposite directions—in fact there seems to be a great variety of ways in which rails will creep. I believe, however, that there are five essential conditions which govern all cases of creeping rails and that a knowledge of the conditions prevailing in any case will enable one to explain all the attending phenomena. I would say that the manner in which rails will creep, and the amount, depend upon: (1) the character of the ground or foundation for the track; (2) the direction in which the train loads are the heavier, if any; (3) the proportion of weight distributed on the two rails; (4) the speed of the trains; and (5) the manner in which the ties are spiked. On a curve the 3rd condition may depend upon the 4th, as, for instance, high speed, where the elevation is too little, will throw the greater portion of the weight on the outer rail, whereas if the elevation of the outer rail be too great for the slow-speed trains the preponderance of weight will fall upon the inner rail; and the rail which receives the more weight, other conditions being equal, will creep the faster. Where there is no relative advance of either rail it is quite likely that the effects produced by heavy, slow-speed freight trains and fast passenger trains are compensating. I have never seen a case where the two rails of a piece of track have crept in opposite directions, but have found explanation for cases of the kind reported. In every instance of the kind which has been brought to my notice there has been a curve at, or in proximity to, the place where the creeping in both directions took place, and there was a marked difference of either speed or tonnage in the trains passing in the two directions. The creeping of rails due to the setting of brakes may have some influence on grades, where no doubt the retarded wheel has a tendency to skid the rail under itself; but here, as in the vicinity of stations, its effect, at most, can be only local. The slipping effect of wheels on curves may also exert some influence on the relative amount of creeping of the two rails, but it is probable that the matters of speed and superelevation, which determine the distribution of the weight between the rails, are of more consequence.

Some of the German engineers who have theorized a great deal on the subject of rail creeping claim that the unequal movement of the two rails is due to the unsymmetrical working of the locomotives. Such action is supposed to result from the phase difference of rotation of the two sides of the locomotive consequent upon the condition that the crank on one side leads that on the other side by a quarter turn, causing side oscillation and greater intensity of pressure on the rail which is on the side opposite from that on which the crank has the lead. Thus, if the leading crank be on the right side the deviating tendency of the locomotive will be toward the left, and the excess pressure resulting from such one-sided action will be on the left rail. These people tell us that on electrically operated roads, where the driving force is not reciprocating, there is no difference in the rate of creeping of the two rails.

Anti-Creeping Contrivances.—It now remains to discuss how the creeping of rails can be prevented or retarded. In the first place, the laying of the rail in sections with open space between the sections being the primary cause of the creeping of rails, the keeping of the splices to a snug fit may lessen the creeping, although it is clear that they cannot be bolted tightly enough to entirely prevent creeping. Again, the creeping may be greatly augmented by having the splices too tightly bolted to allow the rails to expand and contract freely. The bolts should, therefore, be kept turned on to a snug bearing at all times, but not too tight, especially in hot weather. The principal method employed to prevent rails from creeping, or to retard the creeping, is to slot-spike the splice bars; and to get additional anchorage a "dummy" splice is sometimes bolted to the middle of each rail and slot-spiked. Where the tendency to creep is not great, slot-spiking at the joints will hold the rail in check, but where this tendency is strong there may be seen examples numerous enough where, for mile after mile, every joint tie has been shoved bodily by the creeping rails, crowding out the ballast or splitting open the ties, the latter effect occurring principally on bridges. It would seem that in such cases it had indeed been better if no splices had been slot-spiked, and the rails allowed to run unopposed; for then it would only have been necessary to redrive the spikes which the splices had pulled away from, or the spikes which the splices had run against. It is doubtful whether any advantage to be had from spiking in slots at the joints can offset the damage which arises when joint ties are shoved off their tamped and pressure-compacted beds onto the less firm filling material between the ties. Such displacement of the ties weakens the support for the joint and leads to settlement, and much labor is required to shift the ties or square them with the track and tamp them. One roadmaster who for a number of years has kept careful account of track repairs on a double-track road maintained in first-class condition, on gravel ballast, puts the average expense of this item at $14.88 per mile of single track per year. This amount does not, however, cover the cost of raising and tamping low joints, with the shoulder and quarter ties that become low in consequence of the shoving of the slot-spiked joint ties by the creeping rails. The slot-spiking of splice bars is therefore not always a satisfactory means of resisting rail creeping, for in very extensive practice it seems clear that any advantage gained in resistance to rail creeping is compensated by a considerable expense entailed in the work of tamping low joints and in respacing joint and shoulder ties; while in some instances recourse is taken to the laborious process of driving back the rails. Nevertheless, the majority of maintenance-of-way officials seem to regard the method of slot spiking at the joints as of at least some value in resisting rail creeping, even if it does not entirely prevent it.

It is my opinion that where the creeping force is irresistible the joint ties should not be slot-spiked. The principle of so anchoring each individual rail to the ties that it will be self sustaining is the right one, but if the method of anchoring is not effective the fact of having the correct principle in view does not help matters any. No method should be followed which results in derangement of the spacing and bearing of the joint ties. Where the creeping is so bad that it becomes necessary to respace the ties at and in the vicinity of the joints every year I would recommend some other method of anchoring than that of slot-spiking the splice bars. As the weakest part of the rail is at the joint, it seems like putting too many duties on the joint ties to slot-spike them when they cannot be maintained in position. Anchorage at intermediate portions of the rail is usually effected by dummy splices or "check plates" at the centers, and sometimes also at the quarters. The first cost of these devices and the cost of the labor of putting them on is something of an item, to be sure, but if the rail creeps the damage from the dislodgment of center or quarter ties is not nearly so much as that which results from a similar dislodgment of the joint ties; and then, owing to the greater tendency to deflection at the joint than at intermediate parts of the rail, the filling material about the joint ties is more or less shaken up and loosened, so that, as a rule, the ties at the center, quarter or other intermediate points are more firmly embedded in the ballast filling, and therefore better able to resist creeping of the rails. Dummy splices may be had cheaply by cutting up old angle bars, retaining a bolt hole in each piece and slotting the horizontal leg of the piece. Where such practice of anchoring the rails becomes standard all new rails should be ordered drilled at the proper points by the manufacturer. The flange of the rail should never be notched or slotted for the purpose of setting spikes to resist creeping, or for any other purpose. The practice of setting spikes against the ends of splice bars, as is sometimes done in lieu of slot-spiking, should not be followed, as in this position the spikes are extremely difficult to draw.

Resistance to creeping may be much increased by placing blocks between the ties ahead of the anchor plates. For this purpose the sound parts of old ties may be cut into proper lengths (10 to 13 ins.) and split into quarters. By using blocks, one anchor plate at the center of each rail may be sufficient to prevent creeping. The use of long ties is also recommended in cases, particularly on soft or swampy roadbed. To resist creeping under such conditions, a committee reporting to the Canadian Roadmasters' Association recommended ties 10 to 12 ft. long, 7 to 8 ins. thick, spaced 8 ins. apart in the clear, on cinder ballast 18 ins. deep, blocking four ties each side of each joint with pieces of 4x4-in. scantling and using long angle bars at the joints slot-spiked to the ties. One member representing the Canadian Pacific Ry. reported good results under such conditions from having used ties 12 ft. long and 8 ins. thick, on cinder ballast, spiking through the slots of long angle bars at the joints.

Perhaps the most remarkable experience with rail creeping on record has occurred on the Canadian Pacific Ry., where it crosses the Barclay muskeg, about 217 miles east of Winnipeg. Some of the facts regarding the creeping at this point and the method of prevention employed there and elsewhere were given to the Railway and Shipping World, in May, 1900, by Mr. W. Whyte, assistant to the president, Canadian Pacific Ry., as follows: "When the track at this point was laid with 56-lb. steel it used to move under every train, rendering it necessary to keep a watchman on duty there day and night with short pieces of rails to meet the expansion and contraction. I myself, in 1887, saw the track creep while a train was passing over it, 2 ft. 4 ins. In addition to my own personal observations, measurements have been taken of the distance the track crept under a moving train, and these show that a movement occurred in the track of from 2 to 37 ins., depending on the temperature, weight of engine and train, and softness of bottom. To stop this creeping, the length of the ties was increased from 8 ft. to 12 ft., and a slot was cut in the base of the rail over each tie, the slots being staggered, that is the slot over one tie would be on the inside of the rail and over the next tie on the outside of the rail. When the track was laid with 72-lb. steel, 44-in. angle bars were used and the steel was laid square joints, so that the ties would not slew with the creeping. The rails were not notched as above set forth, but angle bars were used on the center of every second rail and spiked to the ties. This is the practice we have been following on muskegs where track creeps. This has had to be done at Oxdrift and Telford with our 73-lb. steel and 26-in. angle bars, which have spike holes punched through them, and which give far better service than the 44-in. angle bar with the slotted holes, as the shoulder was continually wearing off on the latter, rendering the bar useless for holding the rails, and by slipping past the spikes, destroyed the gage of the track. By this means we have been able to stop creeping track, but the joint ties still churn on the muskeg."

A method planned on a principle similar to that of blocking the ties ahead of the slot spiking is to tie the ties together. Such a method has been adopted on the Hungarian State Ry., the arrangement consisting of two long flat plates corresponding to a rail length, crossed and screw-spiked to the ties, inside the rails. In this manner all the ties for a rail length are interconnected or framed together to act as one against rail creeping, the splice bars being slot-spiked to the ties. Where the tendency to creeping is strong this arrangement is repeated for four to ten rail lengths in a place, according to the force to be resisted.

It is important that the means of anchorage on both rails should engage the same tie at each point of application. On square-jointed track this practice follows as a matter of course, because the joints and corresponding points of the rails for both sides stand opposite. The plan of anchoring both rails to the same ties is much more effective than that of anchoring to separate ties, because the resistance of a tie to being pushed bodily through the ballast filling (that is, both ends together) is several times the resistance of one end to being slewed. To follow this plan on broken-jointed track slot-spiked at the splice bars, it is necessary to anchor the center of each rail to the joint ties of the rail opposite; but if it is desired not to slot-spike the splice bars on track so laid, then the anti-creeping devices must be applied at the quarters, the first quarter of each rail on one side standing opposite the third quarter of the rail opposite. The slot-spiking of joint ties on broken-jointed track without placing an anti-creeping device in the center of the rail on the opposite side of the track is usually the cause of a large amount of work necessary to maintain the joint ties in position squarely across the track, and to rectify the gage which is tightened by the slewing of the ties. The recurrence of this distortion of the track and ties is so general and frequent on some roads that the work of replacement cannot be kept up by the ordinary section forces, and this accounts for the fact that it is so frequently neglected for many months at a time.

Of the several forms of anchor plates the most common is a metal clip of some kind bolted to the web of the rail and projecting far enough beyond the rail flange to be notched or punched for a spike. A contrivance which has been used on the Boston & Albany R. R. for a long time, called a "check plate," consists essentially in a tie plate having one end doubled over the rail flange and curved to fit up against the web, to which it is bolted, on the outside of the rail. The doubled edge of the plate is slotted for a spike and at the inside edge of the rail flange the plate is punched for two spikes. The track is broken-jointed and this device is applied to the rail center, opposite each joint. Use has also been made of a special plate to lie under the rail and extend over the next tie beyond the joint tie or ahead of the check plate. As applied at the joint, it is punched on one end to receive the spikes driven through the slots in the splice bars and at the other end for spiking to the tie over which it extends. As applied at the check plate, one end edge simply abuts against the check plate and the other end is punched for spiking to the tie beyond the check plate. Wooden blocks between the ties for two or three spaces ahead of the anchor plate have also been used on this road with good results. The Bonzano anti-creeper consists of a twisted strap, about $\frac{5}{8}$x$2\frac{1}{4}$ ins. in section, of sufficient length to be spiked to two ties with one tie intervening. The middle of the strap is bolted to the rail web and the tail ends are spiked to the tops of the ties through punched holes.

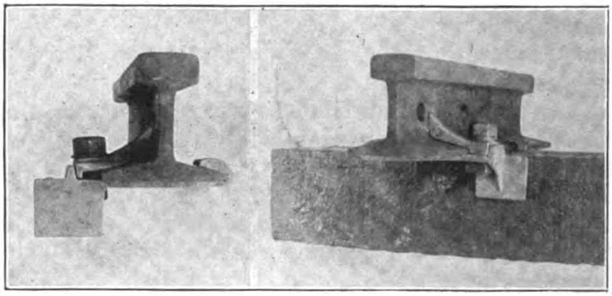

Fig. 265.—Laas Anti-Creeper, C., M. & St. P. Ry.

The application of the foregoing devices to the rail is a matter of considerable expense, as the rail must be drilled for bolting; and then the drilling of the rail fixes the point for the application of the anti-creeper, affording but little or no leeway for respacing the ties in the vicinity of this hole when tie renewals are being made. Mr. E. Laas, while roadmaster with the Chicago, Milwaukee & St. Paul Ry., designed and put into service an anti-creeper which can be applied to the rail at any point, except at the joint splice, without drilling the rail. It is a malleable iron skew clamp with a depending lug, or tail piece, bolted to the flange of the rail, as shown in Fig. 265. There is a plate hooked over the rail flange and formed into the depending lug, about $2\frac{1}{2}$ ins. deep, on the outside of the rail, which engages the side of a tie. This plate is bolted to a dog clamped to the top side of the rail flange and extending to the web. The oblique position of the clamp gives it a gripe on the rail which is sufficient to prevent the slipping of the rail through the clamp. As the device can be applied to any part of the rail, except at the joint, it may always be placed to engage a sound and well bedded tie, and as it is not spiked to the tie, no injury is done to the same, as is sometimes the case where the crowding of the creeping rail against the spike will split open the tie. Since it is not advisable to slot a splice bar at or near the middle, no measure is usually taken in general practice to anchor the rail to supported joint ties. In the case of long splices slot-spiked to the two shoulder ties, the creeping of the rail will "bunch" the ties together, shoving the shoulder tie against the center tie and carrying the joint off the latter. To prevent such derangement of the tie spacing under long splices, Mr. Laas designed and put to service another anti-creeping device which is bolted to the splice under the head of one of the middle bolts in position to engage the side of the center tie, as shown in Fig. 266. It consists of a malleable iron clip or lug hanging some 2½ or 3 ins. below the base of the rail, with a shoulder under the rail to prevent the device from swinging upward when the movement of the rail forces it against the side of the tie.

The application of measures to prevent or resist rail creeping on bridges or trestles having open floors is usually restricted to the track on the grade, no stop devices being permitted on the structure. The rail, if not held back on the grade, is then free to creep over the bridge unopposed. Nevertheless, slot-spiking of rail splices on bridge ties in connection with anti-creeping measures on the grade, is sometimes practiced with reported satisfaction. In such cases blocks are placed between the ties to catch the slot spikes wherever the timber guard spacing does not permit the tie to come under the slots in the splices. One of the roads on which slot-spiking of splice bars on bridge ties is required is the Southern Pacific lines west of El Paso. The instructions regarding anti-creeping measures to be taken

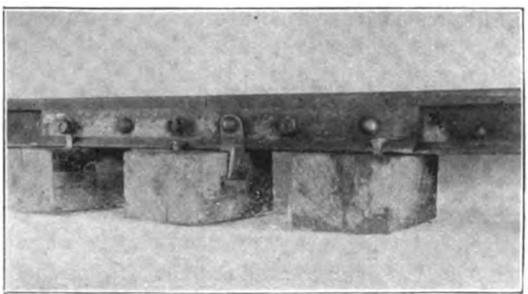

Fig. 266.—Laas Anti-Creeper for Supported Joint Ties.

on the bridge approaches are as follows: "Where rail shows so strong a tendency to run as to shift the ties along the roadbed, on each side of the structure, this tendency will be prevented by bolting the joint ties together for as many joints as may be necessary to stop this movement." The standard distance between joint ties is 8½ ins., and to preserve this interval old cast iron spool stringer separators, adding a few old cast washers to make up the 8½ ins., are used between the joint ties, directly under each rail, and the ties are bolted together with old ¾-in. bridge bolts 27 ins. long. Where the tendency to creep is unusually strong a pair of angle bars is bolted to the center of each rail, opposite the joint on the other side (broken-jointed track), and slot spiked, thus securing an anchorage every 15 ft. As a general proposition the practice of slot-spiking on bridge ties is not safe unless the creeping of the rails can be entirely prevented. In one case where bridge ties were securely fastened to the stringers and the splices slot-spiked, the creeping of the rails pushed the bents of a pile trestle a foot out of plumb, and in another instance a 154-ft. bridge span was shoved endwise 3 ins. in one season.

On long bridges or near the ends of the same expansion or slip joints are sometimes used to permit the rails on the bridge to expand or creep without hindrance, or to prevent the rails on the grade from shoving those on the bridge. In some instances these expansion joints consist of rails halved together for a distance of 12 to 24 ins. at the ends and firmly secured to a base plate, and in other instances they consist of switch points and stock rails, as in Fig. 211, already described in connection with drawbridge joints (§ 80, Chap. VI). A most remarkable example of the application of the latter type of expansion joint, when taken in connection with the attending conditions, is at the Eads steel arch bridge over the Mississippi river at St. Louis. The east approach to the bridge is a steel viaduct 2500 ft. long, on a grade of 80 ft. per mile, and on the bridge proper, which is 1600 ft. long, there is a rise of 5 ft. at the center. The line across the bridge is a double track, and the rails creep in the direction of the traffic, up the approach grade and across the bridge on the west-bound track, and in the reverse direction on the other track, with a force sufficient to fracture splice bars and shear ⅞-in. bolts. The rate of creeping on the bridge is about 16 ft. per month for each track, and on the viaduct about 37 ft. per month for the west-bound track and 44 ft. per month for the east-bound track, although the actual amount of creeping varies with the traffic. In former years a gang of five trackmen were employed by day and a gang of three at night to remove and replace pieces of rail to adjust for the creeping, but eventually expansion joints, locally known as "creeping plates," were put in. Of these there are eight—one in each track at each end of the bridge and at the east end of the viaduct, and one in each track to protect a crossover on the viaduct near the point where it joins the bridge proper. Figure 267 is a picture of the so-called "creeping plate" on the west-bound track at the west end of the bridge, the direction of the traffic and of the creeping being toward the observer. The set of disconnected switch points (A) is rigidly bolted to the guard rails (B), to a 2-in. flangeway, and both are anchored to steel plates (1 in. thick and 6 ins. wide) on the ties. The main rails (C), called the "sliding rails," are secured to these heavy tie plates by clips which engage the top of the flange but leave the rail free to creep, and do not interfere with the fish plates on the joints as they creep over the plates. As the creeping proceeds, say on the west-bound track over the bridge, rails are coupled on and gradually drawn through the creeping adjuster at the east end while rails are being pushed out of the adjustment device at the west end. As often as rails are released at the west end they are carried and started in at the tail of the procession on the other track. In this manner the rails are continually traveling in a circuit without interrupting the traffic.

Many practical students of rail creeping regard loose or improperly arranged spikes as the conditions most largely conducive to such movements, and claim that timely attention to these details will avert the trouble. Thus, it is frequently reported that the practice of holding up the ties and driving down the spikes to a snug bearing on the rail flange, once or twice each year, has stopped rail creeping, without the use of special anti-creepers, and that in cases where slot-spiking of the splice bars had failed. In order to increase the anchoring effect of the spikes in their hold upon the rails, there is a method of spiking known as "cross binding," or so staggering the spikes that they clutch the rail whenever there is a tendency to creep. This arrangement is to have the outside spikes on each rail lead the inside spikes in the direction in which the rails tend to creep. Referring to Fig. 268, the spikes A and E on tie X lead the inside spikes D and F, the arrow points denoting the direction of the creeping tendency. It will be apparent that if the rails tend to creep, the spikes A and D will clutch the rail and the tie will resist the creeping movement. The least movement of the end of the tie X with the rail R causes the spikes A and D to make tighter contact with the rail and the spikes E and F to lose contact. On the other hand, and to show contrast, any movement of the end of the tie Z with the rail R, swings spike B outward from the rail and spike C inward from it, causing them to lose contact, and, consequently, the tie does not resist the rail. So, then, if the rails R and R' creep or tend to creep in the direction of the arrows, either R will be clutched by the spikes A and D, or R' by E and F, depending upon which end of the tie is the easier started; while any tendency in the rails to move in the opposite direction will be opposed either by spikes B and C clutching R, or H and G clutching R'. Here is no doubt an explanation for the fact that one rail sometimes creeps while the rail opposite creeps little or none—the spikes in the vicinity happen to be so driven that they clutch the rail on one side of the track only. On double track, or on down grade on single track, or where for any reason the tendency is for the rails to creep in only one direction, the spikes in all the ties should be driven alike, and so as to cross bind the rails for that direction only; as, for instance, the spikes in tie X, for the direction indicated by the arrows; in which case, presumably, half the ties will clutch or cross bind each rail. At any rate, as some of the ties under each rail will clutch and resist it when the spikes are driven

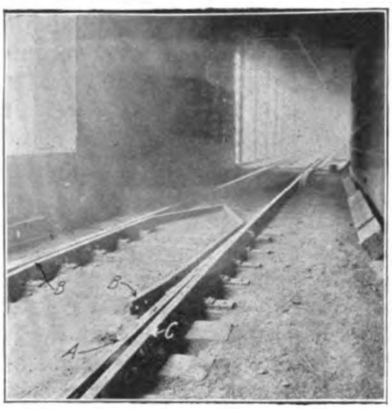

Fig. 267.—Creeping Adjuster at Eads Bridge.

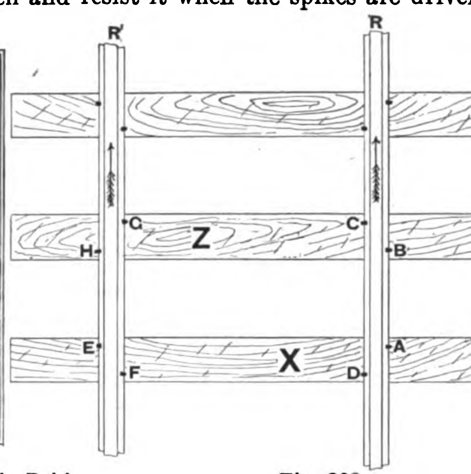

Fig. 268.

cross binding, while others will clutch and resist the other rail, be they divided half and half or not, they certainly strongly oppose creeping, and if the rail does move they tend to carry it back to its place after the impelling force ceases to act. This system of spiking, in connection with slot-spiking, has been known to stop rails from creeping where slot-spiking every angle bar has failed. Where the system is pursued on broken-jointed track an exception should be made with the position of spikes on the end of a tie which is opposite to a slot-spiked splice bar. In that case the end of the tie which is slot-spiked must necessarily move with the creeping of the rail, and if at the other end of the tie the outside spike is leading the inside one, the least swinging movement or slewing of the tie will cause these spikes to lose contact with the rail. If, however, their regular position be transposed, they will lock to the rail and resist the creeping tendency. By way of illustration, suppose the spikes D and A are driven in the slots of splice bars in that position, then the spikes E and F on the opposite end of the tie should be transposed, or set with spike F leading, so that any movement of the rail R causing the tie to slew in the direction of the arrow, will lock these spikes to the other rail—in the position shown they would lose contact under such a movement.

If the cross binding of the spikes is not done when the track is laid, it should be attended to in tie renewals, and every spring the section men should go over the track and drive down the spikes, so that the heads have a snug bearing on the flange of the rail, holding the ties up to the rail with a bar, wherever necessary. It is hardly possible to entirely stop the creeping of rails in every case, but if proper attention is paid to the matter it can, in most instances, be so resisted that it will cause but little trouble. Heavy rails, being stiffer than those of lighter section, are subject to less undulatory movement and consequently creep, or tend to creep, less. The laying of 100-lb. rails in track over swampy ground, where creeping was troublesome, has been known to stop the creeping entirely. As already explained, low joints, or rough track, in hot weather especially, facilitate creeping, and if the track has insufficient ballast filling between the ties the efficiency of anchor plates, slot-spiked splice bars or other anti-creeping arrangement is impaired.

104. Shoveling Snow.—As soon as snow begins falling the foreman should equip men with brooms and shovels and start them going to and fro over the switches, to keep the points clear of snow. If the switches are widely separated or are located in groups some distance apart, it may be necessary to give some attention to the detailing of the men, so as to cover the work most effectively and avoid loss of time which might occur from walking over long distances. A pretty good practice is to scatter a few handfuls of rock salt around the switch points, guard rails, frogs, and switch rods to keep the snow melted as fast as it falls. It is not so well to place salt around road crossings or wherever it will be retained, because several years' use of it under such conditions will corrode the rails badly. The bad effects of salt on joints, bearings or moving parts may be neutralized or prevented by the application of oil as soon as the snow is melted. Some make it a practice to take a brush and smear the rails with a coating of black oil and kerosene mixed, as it prevents the snow from adhering to the rails and causes metal parts to shed water quickly when the snow melts. All guard rails, frogs, highway crossings, point switches, signal and interlocking connections, and the angular spaces about frogs and switches should be kept clear of packed snow and ice.

Soon after snow stops falling the men should turn their attention to the flangeways at the road and street crossings, and the gage side of the rails, all along the track, should be flanged out, not as a matter of safety but to make room for the wheel flanges, so that freshly fallen or drifted snow may be crowded out of the way and not become a hindrance to the adhesion of the drivers. Such work should not be delayed with the expectation that thawing weather will remove the snow before another storm occurs, for fresh snow on top of old snow that is packed down forms a serious obstruction to traction almost as soon as it begins falling. Where a train flanger is not to be used or where the snow has thawed and frozen into ice, this work must be done by hand, picking being necessary in the latter case. If there are grades on the section it is well to flange out the track on the grades first, giving early attention also to stretches of track within starting distance of the stations. Figure 269 shows a snow flanger made to be pushed by hand on one rail at a time. The mold board is of sheet steel ⅛-in. thick and 3 ft. long, set at an angle of 45 deg. with the rail. The frame is carried on two 4½-in. double-flanged wheels set 12 ins. centers, and the hight of the pushing handle is adjustable by means of the link shown. At one time the Pennsylvania R. R. and Lines West of Pittsburg had 200 of these machines distributed among the section men, but since flangers attached to locomotives have been adopted these machines have gone largely out of service. The use of this flanger is said to have been quite satisfactory, as a hand device, being much more efficient than hand shoveling. Three men with one of these machines would ordinarily flange six miles of single track, in good shape, in a day, working in snow up to 8 or 10 ins. depth if it happened to be that deep. For heavy work, as in hard-packed snow, assistance should be rendered by extra help, pulling on a rope attachment.

Snow should be removed from side-tracks as soon as it stops falling. Trains may keep the main track clear, but a freight train attempting to enter a side-track where the snow lies at full depth is liable to be stalled. When deep snow falls it is also necessary to shovel out the turntable pits. Scoop shovels are best for handling light snow. Switch stands also must be looked after attentively, as a freezing sleet will sometimes freeze switch stands so solidly that they must be thawed out before they can be thrown. This can be done by burning a piece of oily waste on a stick or shovel and holding it under the frozen bearing. The Elliot double latch "Snow Cap" switch stand (Fig. 123) is designed to protect the bearing of the main shaft in the top table from sleet and snow and thus prevent the occurrence of trouble of this kind. To keep ground switch stands, especially those with gear movement, from clogging up or being covered up with snow it is to

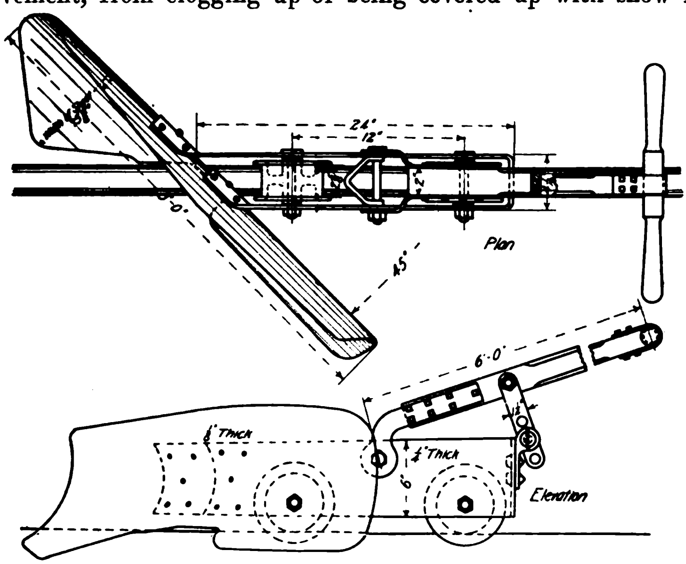

Fig. 269.—Hand Snow Flanger, Pennsylvania R. R.

some extent the practice to cover the stand with a gunny sack or piece of old carpet, while snow is falling. In order to have tools conveniently at hand for clearing switches of snow, use is made on a number of roads of a "shovel post" or "broom post" set a few feet beyond the end of the head-block. It has a peg on which is hung an old shovel or a broom, for use when the switch points are snowed under or packed about with snow. Such an arrangement is especially convenient at outlying switches, where close attendance is not liable to be had. In this way the tools are available at all times to the track-walker or the trainmen, and at times when snow is falling fast they are much needed. On the Union Pacific R. R. this post consists of a piece of old boiler tube stuck into the ground. Near the top of the tube, which stands about 3 ft. out of the ground, there are hooks for hanging the switch lamp during daytime, or a shovel, and a splint broom, with its handle stuck down the tube, is kept on hand for sweeping snow.

During winter, at such private crossings as will not be used, the planks each side each rail should be taken up, so as to reduce the work of cleaning flangeways, and also to avoid trouble liable to arise at such crossings through the planks being loosened or crowded out by snow packed in by the wheel flanges. Taking up the plank at such times also removes obstructions to snow flangers. When snow is to be "bucked" and there are cuts filled with snow, it is sometimes the practice to have the trackmen shovel out sections of about a rail's length in a place, 10 ft. wide, skipping a rail's length between sections. When such work is under way a lookout should be posted at some point above the cut where he can see both ways along the track, so as to give warning to the men shoveling in the cut in case a train approaches. Foremen should take no risk in sending men into a cut; it is dangerous unless there is a way for the men to get out easily and quickly. At each end of the cut it is usual to shovel the snow away until a depth of at least 3 ft. of snow is reached, so as to hold down the nose of the plow at the entrance, in case the snow should pack hard and freeze. When a snow plow is run over the track the section men should follow after it and remove heaps of snow from the highway crossings, from turnouts and other places. Cuts are sometimes widened out by shoveling the snow onto flat cars and hauling it away.

105. Oil-Coated Ballast.—Discomfort to passengers from dust stirred up by fast trains is an important consideration from a traffic point of view, and particularly with railway companies which depend largely upon summer resort or pleasure travel. On not a few roads which handle a large passenger traffic a means of preventing this annoyance is in practice. The remedy consists in the application to the surface of the roadbed and track of a heavy oil of low cost, the oil, penetrating for some inches below the surface, having the effect of laying the dust present and of collecting what may afterwards settle or be blown upon it. The principle upon which the effectiveness is claimed is that the oil sinks into the ballast and prevents dust from flying by holding it down. Its action differs from that of water, in that water prevents dust by making mud, and after it evaporates the dust is as bad as before; while the oil evaporates but very slowly, so that spraying is required but once a season. This method of laying dust is the invention of Mr. J. H. Nichol, assistant engineer with the West Jersey & Seashore division of the Pennsylvania R. R., where the treatment was first inaugurated by him in the spring of 1897. The earliest roads to make ex-

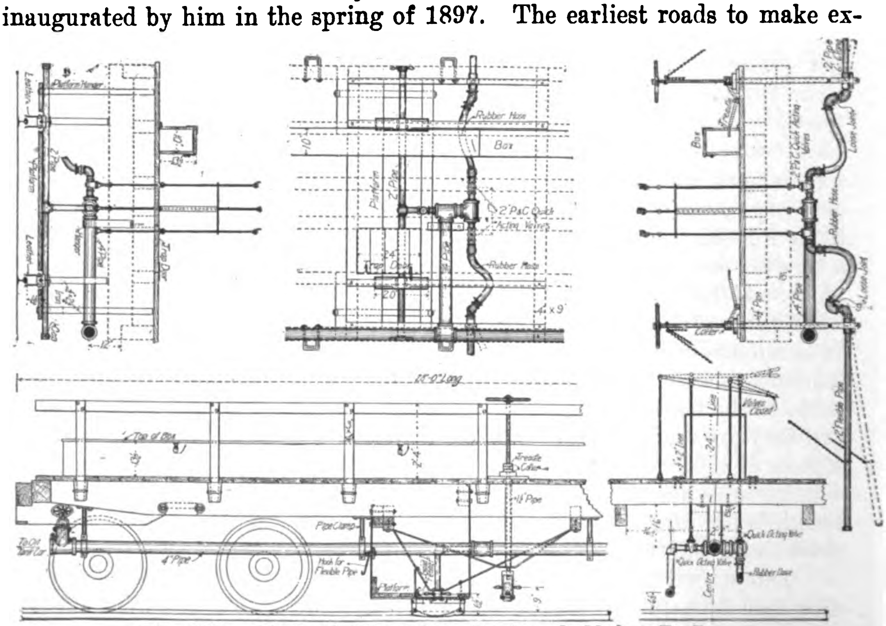

Fig. 270.—Oil Sprinkling Car, Boston & Maine R. R.

tensive use of the treatment, in addition to the above named, were the Philadelphia, Baltimore & Washington and seacoast lines of the Pennsylvania R. R., the Long Island R. R., the Boston & Maine, the Boston & Albany, the New York, New Haven & Hartford and the Delaware & Hudson.

The oil used is a by-product of petroleum distillation, the grade giving best satisfaction having a specific gravity of about 0.887. It is known by the trade name of "roadbed oil," and the cost, in different years and in different localities, has been 2 to 3½ cents per gallon. It is high test, and under the conditions in which it is used it is practically noncombustible. On this point it is said that fewer ties are burned on oiled track than on track or roadbed not so treated. The sprinkling apparatus is arranged on and under an ordinary flat car. One of the cars used on the Boston & Maine R. R. is illustrated by Fig. 270 and the details of the equipment are briefly as follows: A 28-ft. flat car is used and a 4-in. supply pipe is hung 12 ins. below the side sill, on one side of the car, and provided with couplings at either end for connecting with an oil-tank car. Connection with the oil-tank car is had by 4-in. hose, 24 ft. long. At the middle of the car a branch pipe of the same size leads crosswise the car to a "T," where connections are made with a 2-in. stationary distribution pipe 8 ft. long, resting upon hangers, crosswise the track, 6½ ins. above top of rail, for sprinkling oil in the track; and to flexible rubber hose connections with 2-in. pipe 6½ ft. long swung from either side of the car, for sprinkling the roadbed beyond the ends of the ties. Special hose connections may also be provided with hand sprayers, for sprinkling parts of the roadbed beyond the reach of the fixed pipes. The flow of oil escapes from the distribution pipes through slit openings 3 ins. long and 1/16 in. wide, in the bottom of the pipe, the openings being spaced ¾ in. apart. The ends of the pipes are capped, as shown. The adjustment of the swing sections is effected by chain and hand wheel, so that the pipe may be held to conform to the slope of the earthwork, be it in a cut or on a fill. These side sections are yielding, so as not to be broken or torn loose by meeting with an obstruction. Alongside the distributing pipe which hangs underneath the car there is a wooden platform suspended from hanger irons, access to which is had by a trap door through the floor of the car. On this platform, while the car is in service, a man is stationed with an implement to open oil passages that become clogged. Hanging from the under platform, each side each rail, there are leather flaps serving as guards to keep the rail clear of oil. The flow of oil into the distributing pipes is controlled by three 2-in. quick-acting valves operated by levers above the decking of the car. Running the length of the car there is a box 13½ ins. high by 10 ins. wide except for 5 ft. of its length at one end, where it is 3 ft. wide. This box is used for stowing the 24-ft. hose, together with other parts of the equipment when not in use. In operation the car is pushed ahead of the locomotive.

The oil is applied to the surface of the track, to the shoulders at the ends of the ties, and for a distance over the slope in cuts and on fills. In warm weather the oil is so thin that it flows sufficiently well by gravity, but steam or air pressure for the blast can be taken from the locomotive, if need be. The sprinkling train is operated by four men, including engineer and fireman, and covers 3½ to 4 miles per hour, while working. Tank cars are previously distributed at sidings along the line, to be picked up as oil is required. On first application 2000 to 2500 gals. of oil per mile of single track are required, and the penetration into the ballast is from 1 to 4 ins. During succeeding seasons less oil is required. The penetration deepens with each application, being found 8 ins. deep, or reaching below the bottoms of the ties, in some cases. At this depth no dry ballast is thrown up in process of tamping or in tie renewals, and therefore no special application is required after such disturbance of the ballast. The general practice is to delay the oiling treatment until after the tie renewals have been completed for the season, which makes it an inducement to push this work along promptly, in order to get the ballast filling into settled condition early. It is also desirable to have the track in fair surface before the oil is applied; the filling should be carefully dressed, the track and shoulders cleared of vegetation and the ditches cleaned. Where the ballast is worked over to a considerable extent later on, as in surfacing, local applications are sometimes made with a hand sprinkler. On fine sand ballast the oil does not penetrate deeply—usually only 1 or 1½ ins.—and has a caking effect; that is, it forms a thin crust over the surface.

As a means of preventing the raising of dust the oil treatment of roadbed is conceded to be very efficient. Where clouds of dust had formerly followed in the wake of trains no dust is lifted after the application of the oil. It is most needed on gravel and cinder ballast and on seashore lines built on sandy roadbed or on track ballasted with sand. Aside from its value as a preventive of dust there are other claims. A direct benefit derived from the laying of dust is a reduction of wear to journals, locomotive parts and all exposed moving machinery on the trains, and particularly a decrease in the number of hot boxes. It is thought that drainage is assisted materially, since rain water falling on treated track is collected in small puddles and runs off over the slopes or into the ditches alongside, where otherwise the ballast would absorb the water. It is said that the soaking of rain into treated ballast which has been disturbed in repair work will float the oil to the surface, thus renewing the coating. This water-proofing quality of the treatment should afford valuable protection during thawing and freezing weather, when the heaving of track depends upon the amount of moisture retained in the ballast and roadbed. The growth of vegetation in the ballast is retarded and the oil, which is very penetrating, is thought to be of some value as a preservative of the ties, being water-repelling at all events. It is the testimony of experience that considerable oil follows the spikes and soaks into the surrounding wood fiber for a distance of about an inch, causing the spikes to work up more readily than is the case on untreated roadbed; but no trouble of a serious character is reported to have been observed from this cause.

Aside from its use on roadbed continuously, the process is applied quite extensively at dusty highway crossings, through dusty yards and through towns, on rock-ballasted roads where the use of a dust layer is not needed except at such places as the ballast is liable to be excessively dirty from outside conditions. Occasional sprinklings at road crossings are made by hand. Of further interest on this subject it may be stated that in California considerable use is made of the oiling process to lay the dust on the public highways, including county roads. On the French State Railways creosote residue has been used experimentally to lay dust on track.

106. Laying Tie Plates.—The increasing use of tie plates, consequent upon increased weight of rolling stock and the use of a larger proportion of soft wood ties, has prominently shown the importance of careful work in setting the plates. Failure to prepare an even bearing for tie plates results in buckled plates, and careless work in embedding the plates gives uneven gage. Experience has demonstrated that the full benefit of tie plates cannot be realized unless attention is paid to the proper setting of the plates. The expense for the labor of setting tie plates is also a matter not to be overlooked. The cost of applying a single tie plate is no doubt regarded as a trifling matter, yet when multiplied several hundred thousand times, or several million times, which measures the scale on which some of the larger railway systems have invested in tie plates, it becomes a subject of no inconsiderable importance. To the various questions pertaining to the subject a good deal of study has been given, in consequence of which several methods of doing the work and numerous special tools have been devised and put into service.

The work of tie-plating track is necessarily divided on two general lines, namely, that of plating ties before they are laid in the track, which applies to track construction and to tie renewals; and the plating of ties already in the track. In the former case the work is comparatively simple, as access to the rail seats on the tie is unobstructed, and the force necessary to embed the flanges or claws of the plate into the tie can be conveniently applied. The usual method of procedure is to take the ties from the piles, before they are distributed, and drive the plates to a proper seat with some striking instrument, which may be a heavy sledge hammer, a beetle or wooden maul, a paver's rammer, an oak tie bored and fitted with two hammer handles at right angles, or a piece of rail with cross-bar handles. To protect the tie plate from bending or other injury by hammer blows, and to distribute the force of the blow, it should be covered with a thick metal plate or driving block. The tie plate should be set to center over the bottom face of the tie, and should be driven far enough to cause its under side to take a firm bearing on the tie. If the plate is not centered on the tie the latter is liable to cant, and unequal bearing will result. If the top face of the tie is winding one of the seats should be adzed to the plane of the other. At the Las Vegas (N. Mex.) tie preserving plant of the Atchison, Topeka & Santa Fe Ry. the ties are run through a spotting machine, which levels off seats for tie plates or for the bases of the rails, wherever any unevenness exists. Tie plates should be set squarely on the ties. If there is any difference in the margin outside the spike holes on the two ends of the plate, the latter should be set to bring the wider margin outside the rail. Before setting tie plates which are punched for rails of different widths of base, a clear understanding should be had concerning the end of the plate which corresponds to the gage side of the rail; otherwise, mistakes are liable to happen which may make it necessary to move the plates when relaying with rails of the changed section. Drawings are usually supplied by the engineering department explaining the manner in which such plates should be laid, and for convenience of the trackmen the shape of one of the holes punched for the gage end of the plate is made to indicate the section or weight of the rail for which it is intended. In cases where unusual difficulty is experienced in maintaining rails to gage on curves, it is sometimes the practice to dap the ties for tie plates, to give the outer rail an inward cant. On the Burlington, Cedar Rapids & Northern Ry. such practice is general for both rails, and on tangents as well, the ties being adzed so as to set the plate to cant the rail slightly inward, causing a bracing effect which counteracts any tendency of the rail to tilt outward. Such practice is, however, unusual in this country. Regarding the time of application, it is the custom with some roads to embed the plates in the ties during winter, so as to get the work out of the way before the tie renewing season opens.

In setting tie plates it is desirable to have some form of tool for quickly locating the position of the plates on the ties, so as to facilitate speed in laying the plates and insure that the plates will be laid in the exact position for the rails properly gaged. For such work there are various styles of gaging tools in service. A common way of proceeding is to set the first plate to a mark on the line side, and then gage the second plate from the first as already driven, using a gage rod having lugs to fit the spike holes. On the

Burlington, Cedar Rapids & Northern Ry. a gage is used in setting the line plate, instead of drawing a mark across the tie face some fixed distance from the end. This gage consists of a strip of boiler iron with a rectangular opening cut in it to hold the plate while it is being driven, the end of the piece of boiler plate being bent down to hook over the end of the tie. On the Boston & Maine R. R. use is made of a double-ended gage working somewhat on this principle, for holding both tie plates simultaneously the exact distance apart to seat the rails at gage. The gage, which was designed by Roadmaster Louville Curtis, is made of wought iron and has a rectangular opening at either end just large enough to receive the tie plate and hold it in position while it is being driven into the tie. Figure 271 shows the dimensions. The center piece is 2½ ins. wide, and ¾ in. thick, and the gaging

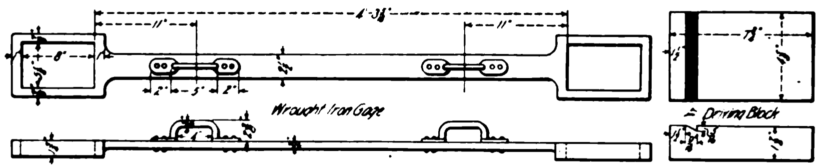

Fig. 271.—Curtis Gage for Setting Tie Plates, B. & M. R. R.

ends are 1¾ ins. thick, being made heavy, so they will not break in case they are struck by a spike hammer. In advance of the work of setting the plates the ties are carefully inspected, and if necessary are prepared for receiving the plates in proper position. If the tie is more than one inch longer than the standard length it is sawed off to the right length. The center of the tie is marked, and if there is any wind in the face the seats for the tie plates are adzed to a plane surface. The tool for testing ties for warped face is a "leveler," consisting of a stick of suitable length with small rectangular frames set in the same plane and nailed fast at the two ends. The tie plates are driven to a seat by means of a driving block and sledge. The driving block, shown also in the figure, is a soft steel plate 7¾ ins long, 4⅝ ins. wide and 1⅛ ins. thick, grooved to fit over the shoulder of Goldie tie plates. The manipulation of the tool is simple, all that is necessary being to place the center of the gage over the center mark on the tie and set the plates into the gage openings. It can be made for setting tie plates of any pattern and is

Fig. 271 A.—Tie Plate Setting on Boston Elevated Ry—Fig. 271 B.

Fig. 271 C—Gaging Tie Plates on a Curve, Boston Elevated Ry.

not patented. The tie plates used on the Boston Elevated Ry. were set with gages of this design.

The work of laying tie plates on an elevated structure or on a bridge floor must be more carefully attended to than when applying them to ties on a graded roadbed. On the earth roadbed the track can be thrown into alignment after the rails are laid, but on a bridge floor it is, of course, necessary to bring the rails to correct alignment before the spikes are driven, and this requires very careful work in bedding the plates. The ties used on the Boston Elevated Ry. were of hard pine, and the plates were all set and embedded before the rails were laid. The tie plate used was of the Goldie claw pattern with a shoulder, making it necessary to embed the plate exactly to position, so as to bring the shoulders of all the plates in line. Figure 271A shows two rows of these plates on tangent, seated in advance of laying the rails. For laying plates on the curves use was made of a tool having an opening for a tie plate on one end and an upward bend and hook on the other, as shown in Fig. 271C. After the running rail and guard rail were laid on the inside of the curve the hook end was held in engagement with the service side of the guard rail by means of a stick, so that the rectangular opening at the other end of the gage would bring the tie plate exactly to position for the rail. Figure 271B shows tie plates set in position for a switch lead, both on the curve and on the straight lead, between the frog and the heels of the point rails.

The Kiley tie plate gage, devised by Mr. John Kiley, foreman of the Salamanca (N. Y.) yard of the Erie R. R., and used satisfactorily in laying a great many tie plates on that road, has a hook arm which gages the position of the plates from the end of the tie. This gage is shown by sketch in Fig. 272. The essential parts are a fixed head (*A*), a connecting bar or pipe and an adjustable head (*B*) secured to the cross bar by means of a thumb-screw. Attached to the head *A* there is the hook arm *D*. Each head piece of the gage is stamped out of a single piece of sheet steel. The head *A* has a rectangular space in which to place the tie plate, and out of the vertical portion there are cut two lugs (*C*), which are bent over so as to leave two upright projections (E), the purpose of which is explained in connection with the use of the gage in applying plates to ties already in the track. The portion of the plate between the lugs C is bent over backward and shaped in tubular form to receive one end of the connecting rod, which is firmly riveted thereto. The adjustable head B is formed by bending a plate at right angles and bending over the edges to form a lapped tube to receive the thumb-screw and engage with the connecting rod, which is graduated to indicate the gage of the heads. This head also has a rectangular space for setting the tie plate. In using the gage on new ties the head B is adjusted to the proper gage distance and the surface plates of the two heads are brought into the same plane. The tool is then laid on with the hook caught over the end of the tie, and if the face of the tie is warped or twisted the rail seats are adzed to conform to the surface plates. One of the tie plates is then placed in the rectangular space in the gage head, when the

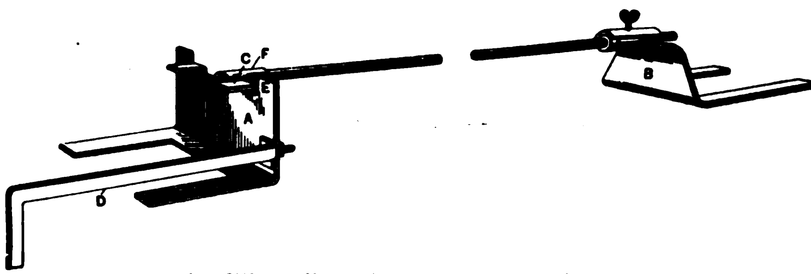

Fig. 272.—Kiley Tie Plate Gage, Erie R. R.

gage is removed and the plate is embedded with a wooden beetle, or other driving tool. The gage is then placed back on the tie to give the position for the second plate with relation to the plate previously set, when the second plate is embedded. If desired, however, the person manipulating the gage may pass rapidly from tie to tie, marking the position of each tie plate with a pencil or scratch-awl, so that a number of men may be engaged at embedding the tie plates at the same time. The tool may be used across the lead rails of a turnout without interference from rails which come between the heads of the gage, as the connecting rod is high enough to clear them.

The tool that is perhaps most widely used for gaging tie plates is the Ware "surfacer" and gage, designed by Mr. Henry Ware, roadmaster with the Buffalo, Rochester & Pittsburg Ry. As illustrated in Fig. 273, it consists essentially of a rod or piece of pipe joining the heads of two flat metal plates called "surfacers," the rod being fixed to one of the heads and adjust-

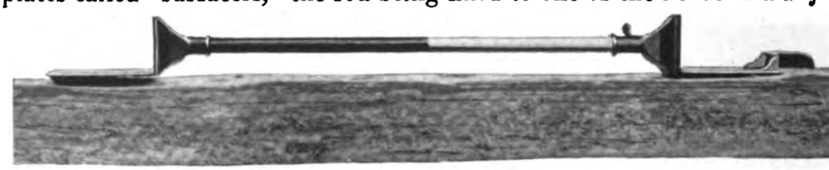

Fig. 273.—Ware Tie Plate Gage (Testing Rail Seat Level).

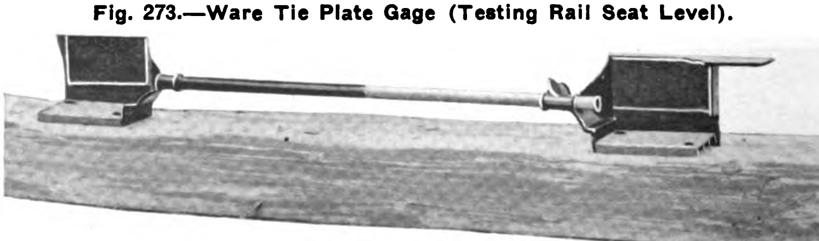

Fig. 274.—Ware Gage (Locating the Tie Plates).

able with the other by means of a thumb-screw. To apply the tool to new ties used either in track-laying or in tie renewals, the heads are adjusted by the graduation of the rod to the proper distance apart to correspond with the gage of the track and the dimensions of the tie plates to be used. The surfacers are brought accurately into the same plane and set tightly therein by the thumb screw. Where hewn ties are used it is necessary to inspect the upper face to see that the seats for the rails are in the same plane. This inspection is made with the tool, and if the seats are out of true they are adzed to the proper level to meet the surfacers, as applied in Fig. 273. The tool is then turned partly over, as in Fig. 274, and the plates are placed on the tie to proper gage and settled to place with a beetle or other tool. In practice it is customary to first embed one of the plates and then put the tool back on the tie and place the second plate accurately to conform to its required position with relation to the plate first embedded. After the plates are set the tool can be applied, as in Fig. 273, to test the surface level of the tie plates.

Fig. 275.—Machine for Plating Ties, S. F. & S. J. V. Ry.

The foregoing methods and tools for setting tie plates by hand are quite generally applied, but in plating ties for new track construction on a large scale power machinery has been used for the purpose, notably in the building of the San Francisco & San Joaquin Valley Ry., when more than one million ties were plated. The ties used were redwood, with 5x8-in. Servis tie plates, and the work was so extensive and so rapidly pushed that some means for cheaply and quickly applying the plates before the ties were distributed on the roadbed was desirable. The machine used consisted of two presses, as shown in Fig. 275, with rollers to assist in the movement of the ties into and out of the presses; and of a 15-h. p. boiler to furnish steam to operate the presses. The general scheme of the operation of the machine is obvious from the illustration. The tie is shoved over a series of rollers, on horses, until it enters the presses, where it is held in proper position by a stopping device which appears at the right hand. The plate for each end of the tie is inverted and placed upon the plunger of the steam cylinder, which works from underneath. The plate comes between two rollers and is low enough to be out of the way as the tie is shoved to place. Between the presses there are two pairs of clamps which are opened up (they appear in the closed position in the illustration) before the tie is shoved in, and attached to these clamps there are side levers for moving the tie into line and centering it over the plates before the pressure is applied. The position of the two presses is adjusted for properly gaging the plates and the pressure is applied to the two plungers simultaneously, lifting the tie vertically against the tops of the presses and forcing the plates into the tie. After the plates have been pressed home the tie is dropped down into its original position and pulled out at the end opposite from that at which it entered the presses, the stopping device being dropped by the lever and link arrangement shown. The presses are adjustable to the extent that they will allow ties of varying thickness and width to be used.

The operation of the machine required at least seven men—two to shove the ties into position, two to place the plates, one to apply the power and two to remove the tie after the plates had been forced into place. When first received the machine was used on a car. This car being started at one end of a long pile of ties worked slowly through the same, the ties then passing either to a pile on the other side of the car or directly to cars for shipment to the front. While handling ties in this way the capacity of the machine was about 3000 ties plated in ten hours. Continuous working, night and day, was sometimes necessary when track-laying was progressing rapidly. The cost of handling the plant was slightly over one cent per tie, and as nearly all the ties went to the front as fast as they were plated, this figure included the cost of loading. The actual cost for plating and loading 149,836 ties during the months of March, April and May was $1717.67, or 1.146 cents per tie. This was made up of labor 1.056 cents, fuel .075 cent and the balance, or .015 cent, was chargeable to repairs, oil, etc. The fuel was coal at $6 per ton of 2000 lbs. The number of men employed during this part of the work was one pressman, one foreman and 15 laborers. After plating ties in this way for a number of months the machine was removed from the car and placed on a platform in the material yard. All ties received here came from barges and were delivered directly to the machine, in slings, by a derrick. They were passed through the press and then placed on cars for piling in the yard or sending to the front, as was necessary. A 30-h. p. boiler was used, furnishing steam for the derrick as well as the press. When ties were shipped directly to the front, the cost per tie from barge to car came as low as 0.6 cent.

It was found that the plates remained in place during shipment to the front, and that during the distribution of the ties for track-laying but very few fell out. When this occurred a man, whose business it was to look after the tie plates, replaced them in the grooves which had been originally made. When the rails were strung out, the plates which came on joint ties were changed and the joint plates, which had a different punching, were substituted by the same man. The plates as they left the machine were spaced so that they were exactly in place for gage and line and, except for the joint plates, required no changing of position when placed in the track. The redwood ties used on the Pacific coast are what are known as "split ties," and there is a slight tendency for the grain to be in wind. It was thought at first that on this account it would be necessary to spot them, and such was done for awhile, but later on when it became necessary to rush the machine this practice was abandoned, and the results afterwards were so satisfactory that the spotting was not again resumed. It was found that the powerful work of the presses left the top surfaces of the plates practically in the same plane. Subsequently the same machine was used in plating ties for the construction of the San Pedro, Los Angeles & Salt Lake R. R.

On the Southern Pacific road tie plates on bridge ties have in some instances been driven to seat with a pile driver, before the ties were laid. The ties were placed under the 3000-lb. hammer, the plates set and the hammer dropped 2 to 3 ft. Use has also been made of a hand machine with a lever and cam arrangement for pressing the plates into the ties. Figure 275A shows a machine of this kind used on the Pacific Electric Ry., Los Angeles, Cal. It consists of two cams or eccentrics worked by levers, mounted on a large stick of timber. At the end of each lever there is a cast iron eccentric working loose on a shaft held by straps fastened to the sides of the timber foundation. Extending under both eccentrics there is a gage bar, on the under side of which there are two cast plates, each of which has two square lugs. These lugs fit into the spike holes in the tie plates, and the cast plates are at such a distance apart that tie plates fitted on the lugs stand to the proper gage for the rails. In order to lift the gage bar from the tie when the eccentric is thrown up it is attached to the latter by means

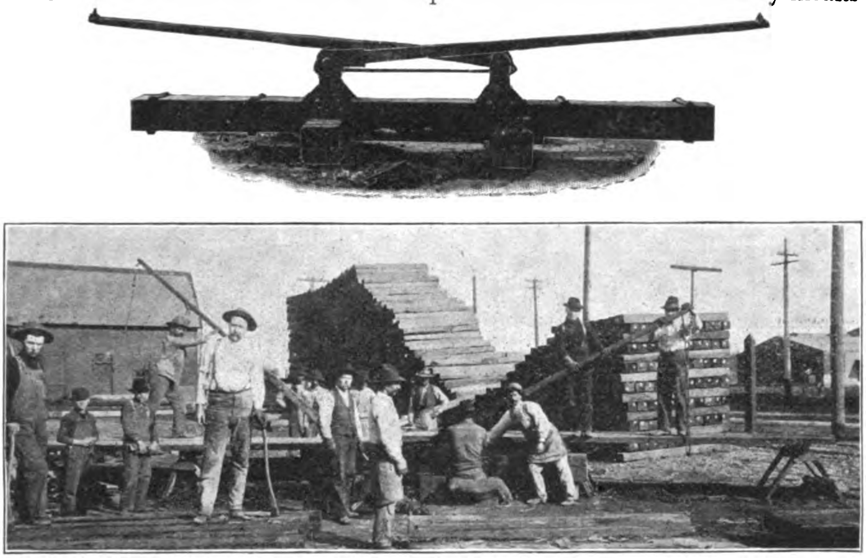

Fig. 275A—Lever Tie-Plating Machine, Pacific Electric Ry.

of a light chain. On either side of the two levers there are pipe rollers for entering and removing the ties, the roller nearest each eccentric being placed to act as a gage for the tie. In operating the machine, the ties are first adzed, to properly seat the plates, in case such is necessary, and then the ties are pushed over the rollers and under the eccentrics, one by one. The tie is pushed to butt against the gage roller, and a man at either end places a tie plate to fit the lugs on the gage bar, holding it in place with a small flat bar of iron. As the tie plate enters the tie, when the lever men throw over the levers, this bar is withdrawn. The levers are thrown entirely over toward the other end of the machine—that is, nearly 180 deg.—and the plates are pressed home. As fast as the plates are seated the ties are pulled out from the end of the machine opposite from that in which they entered and are carried to the plated tie pile. One machine with a crew of 16 men will plate 1000 ties in from eight to ten hours, according to the uniformity of the ties in respect to dimensions, wind in the faces, etc., at a cost of about 3 cents per tie.

Tie-Plating Old Track.—In applying tie plates to ties already in the track the first thing to do is to adz an even bearing for the plates on the rail-cut ties. Disregard of this important requirement usually results in

Fig. 276.—Laying Tie Plates by Method of Throwing Out Rail.

buckling of the plates. At one time a special tie plate of Goldie claw pattern was made for use on tangents, to be applied without adzing rail-cut ties. The length of this plate was approximately the width of the rail base, and there were no spike holes. Other advantages in contemplation were that it could be used with rails of any width of base sufficient to cover the plate; that it could not buckle or get out of shape under any conditions of service; that it would be cheaper than longer plates and that it would fully protect the tie from wear under the rail, which is the only place where wear takes place. Notwithstanding these expectations, the plate did not come into extensive service. Other matters requiring attention in setting plates on ties in the track are to plug the holes from which spikes have been drawn, and to drive the spikes perpendicularly through the plate, so as not to bind against the plate and prevent it from settling down to a firm and even bearing. In order to drive all of the spikes to take a firm bearing on the rail it is necessary to hold up some of the ties with a bar.

Methods of embedding tie plates on ties already in the track are quite numerous. Apparently the easiest, but in the end the most unsatisfactory, method is to draw the spikes, apply the plates loosely to the ties, redrive the spikes as far as they will go and then wait for the traffic to settle the plates into the timber before completing the job by driving the spikes to final depth. In some cases it takes considerable time for the plates to become seated, and meanwhile gravel, cinders or other dirt will get under the plate and cause it to take an uneven bearing. In view of this delayed action of the plates a plan that has been put into practice is to lay the plates only on every other tie or every third tie at one time and permit the trains to press them into the timber. In this way the weight of the traffic is concentrated on fewer plates and they are forced into the timber sooner than is the case where it is attempted to embed all the plates at the same time. The practice of embedding tie plates by train pressure has been styled the "automatic" method or the "lazy man's way," but it is the quickest way to get the plates into the track and has been very extensively employed. Until the plates become seated the aspect of things is displeasing, to say the least: the rail fastenings are in a slovenly, if not uncertain, condition, and the rails are liable to settle out of gage, particularly on curves and wherever the track is out of surface. It is needless to say that this method is not highly recommended.

The next general method which might be considered is that of setting the plates under the rail in place and pounding them down in some manner with a sledge hammer. By this method the track is not obstructed and the work can proceed without much regard to the trains. The spikes are pulled on a few ties at a time, and started on a few ties still further ahead, the rail is lifted high enough to slip the plates under, and the latter are driven down to place one at a time. The best plan is to place only one plate at a time, as then the full weight of the rail can bear upon it and be of material assistance to the driving force. The driving is frequently done with a sledge hammer and set, or with hammer and a thick plate or follower placed on the tie plate to protect it from being injured by the blow. In some instances two hammers are used, striking over diagonally opposite corners of the plate simultaneously. Sledges weighing 12 to 16 lbs. are best for this work, the preference being with the heavier weight. A heavy sledge is also convenient for knocking around ties that are out of square with the track. On the Norfolk & Western Ry. it has been the practice to embed one end of the plate at a time in the following manner: The rail is lifted and the ties properly adzed and the tie plates slipped under the rail. One end of the tie plate is then put down by means of a sledge or other driving tool, and then a wedge is slipped between that end of the tie plate and the rail base to hold it down while the other end is being driven. With the tie plate thus secured the other end is driven to a proper bearing. The "hammer-blow" action on the ends of the plate is not, however, always satisfactory, as tie plates have frequently been cracked or broken up by improper driving with sledge hammers and plates. The introduction of the "straddler" for driving tie plates with hammers has not been successful, as a tool of sufficient strength to endure the service was usually found to be so heavy as to absorb too much of the blow.

Another method of embedding tie plates, which is in considerable use in applying longitudinal flange plates to soft wood ties, is that of "plowing" them in. This is done by lifting the rail high enough to admit the end of the tie plate underneath it, and then to let the weight come upon the plate and drive it through with a spike hammer, the flanges plowing their way through the grain of the wood. The plate is driven from the gage side of the rail. With some trackmen it is the practice to start the plate by driving it under the rail without lifting the latter. This is done by placing a spike under the outer end of the plate and pounding down the end next the rail flange until it will make entrance under the rail when struck endwise. The objection to "plowing in" tie plates is that furrows are made in the tie face outside the tie plate, into which rain water will collect to start early decay, in the bruised fiber, and from which the water finds an easy entrance under the plate. In the early days of tie plates mention was sometimes made of the method of burning the plates into the ties. A fire would be built and the plates heated just hot enough to burn their way to a snug fit on the tie when pressed by the weight of the rail. Some professed to think that the charring of the wood under the plate had a preserving effect on the fiber, but for some reason or other the method has not survived.

It is easy to see that when tie plates are embedded with the rail in position, the latter is a serious obstruction to the work. It would seem, therefore, that matters should be much facilitated by having the rail entirely out of the way while the plates are being settled into the ties, and such is a method extensively followed. It obstructs the track, of course, and necessitates sending out flagmen, but in working a gang of considerable size it affords opportunity for the best speed. The spikes are pulled from a stretch of rail on one side of the track and the rail is thrown out of position far enough to leave the upper surface of the ties entirely clear for whatever adzing may be necessary and for the embedment of the plates, as shown in Fig. 276. The plates are set by gage and driven into the ties with a beetle or other striking tool. The use of the Ware gage is shown in this figure. After the ties have been adzed the surfacers are set to proper gage for placing the plates. In this application of the tool the fixed surfacer is made to abut against the web of the opposite rail, as shown. Each plate is located by placing it in the angle formed by the end of the adjustable surfacer and a projecting arm which shows clearly in Figs. 273 and 274. After all the plates have been embedded the rail is thrown inward and spiked to place. When using the Kiley tie-plate gage (Fig. 272) in work of this kind the hook is removed from the gage and the adjustable head *B* is loosened and turned half way around on the bar, or so that it stands upside down. With the rail on one side of the track moved out of its seat and the ties adzed off to give proper bearing for the plates, the gage head *A* is placed upon the top of the opposite rail, resting upon the lugs *C* and held in position by the clips *E*, which bear against the gage side of the rail. The other head of the gage is then brought down upon the tie right side up and the tie plate is placed in the rectangular space in the proper position for embedment. The gage used by Roadmaster J. W. McManama, of the

Fig. 277.—Tie Plate Driver, M. C. R. R.

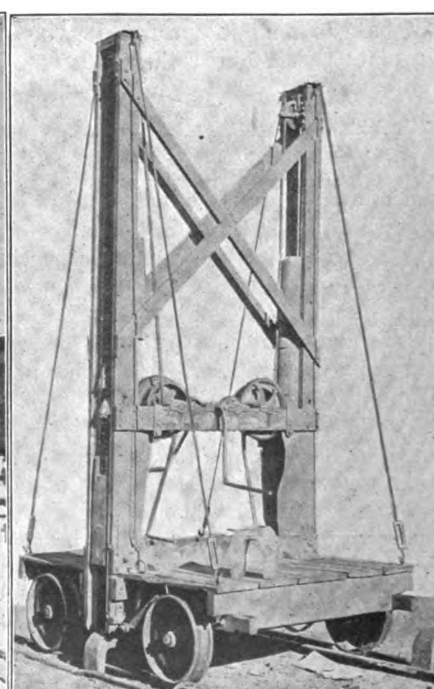

Fig. 278.—Tie Plate Driver, S. P. Co.

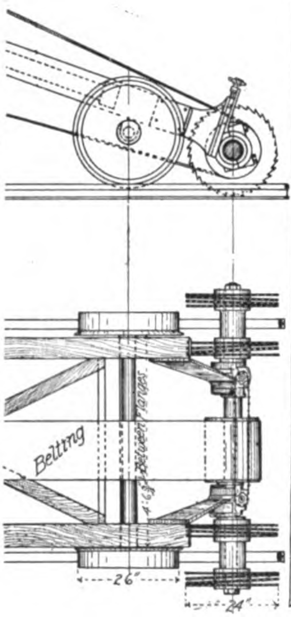
Boston & Maine R. R., for locating the exact position of tie plates with one of the rails moved out, consists of a piece of rail about 2½ ft. long riveted to the single end of a Huntington track gage, the forked end being retained for use against the rail opposite the one moved out of its seat.

For the most economical and most expeditious work of applying plates in this way, it has been found advisable to get as many spikes drawn as safety will allow, plug all spike holes and do all adzing possible before disturbing the rails. Then, when there is sufficient time between trains to permit such a move to be undertaken, all of the men are put to work with claw bars to draw the remaining spikes and move the rails out on the ends of the ties, as before described. The men are then organized three in a gang, one man to carry the gage and place the plates in the square; the other two men with wooden beetles to settle the plates into the ties. The first blow, as least, is given by a man standing at right angles with the longitudinal ribs of the tie plate, if such plates are being used; this in order to cause the plate to settle more accurately than would otherwise be the case. When a sufficient number of plates have been embedded to allow the rails to be moved back into position, one of the embedding gangs is turned back to move the rails in onto the plates and spike them; thus keeping the different parts of the work going at the same time, so that should an unexpected train arrive there would be but little delay in making the track passable.

In placing tie plates upon new switch ties the two plates for the main-track rails are applied before the ties are placed in the track, and the plates for the turnout rails are temporarily withheld until the main-track rails have been fully spiked and thrown into proper alignment, the turnout rails meanwhile being temporarily held by a sufficient number of spikes to permit the safe passage of trains. The plates are then applied to the turnout rails in the same manner as already described for applying plates to ties in track. Considerable use is made of long tie plates, which extend under both main and turnout lead rails, where they lie close together, plates as long as 24 ins. being sometimes used in such places and under frogs. In such plates it is usual to punch only two holes at the mill, these being near one end of the plate. When laying the plates they are first put under the lead rails, as aligned for their final position, to mark the position of the spikes, and then they are removed and punched by hand tools.

Machines for Tie-Plating Track.—With sufficient force to drive it, a follower made to straddle the rail and rest upon the projecting ends of the tie plate is a pretty satisfactory tool for embedding plates in the track. Such a tool is known as a "straddler," and on some roads machines built on the principle of a pile driver, on a small scale, are used to administer the driving force. One of these has been in service on the Michigan Central R. R., having been devised by Roadmaster M. Sullivan. This machine consists of a light pair of leads hinged to sills placed upon an ordinary push car and pivoted to swing to working position over either rail. The machine is shown in Fig. 277, and although the photograph was taken when the weather conditions were not especially favorable for laying tie plates, yet all the essential equipment is seen in position to do execution. The straddler is a forked piece of steel weighing 24 lbs. The hammer consists of a cast iron weight with a wide and thick wrought iron strap shrunk around it to fit the grooves in the leads and provide a striking face on the bottom. The weight of the hammer is 100 lbs. It is lifted by a small rope running over a pulley at the top of the leads and thence to another pulley at the foot of the leads, between the sills. In lifting the hammer the rope is pulled by a man standing directly in the rear, or in the position occupied by the man who appears in the picture. The plates are applied by pulling the spikes from a short stretch of rail both sides the track, lifting the rail and placing the plates in position and then following with the driver, which is swung alternately from side to side, into position over each plate, as the car advances. The machine is handled and worked by two men. When it is desired to remove it from the track, the leads are made to fall backwards on the hinges by disconnecting the braces which secure them in the upright position. The driver and push car are then lifted off the track separately.

A machine tie plate driver used on the Southern Pacific road is of heavier construction, consisting of a strongly built push car with driver leads erected permanently at both sides, as shown in Fig. 278. These leads are braced together, and upon a strut uniting the two there are two winches, one for each hammer. The hammer in this case is much heavier than that of the Michigan Central driver, and must weigh several hundred pounds. The straddler is also much heavier, as would be surmised from the view, one being seen over each rail and another appearing on the front end of the car; it weighs probably about 100 lbs. The method of driving is obvious from



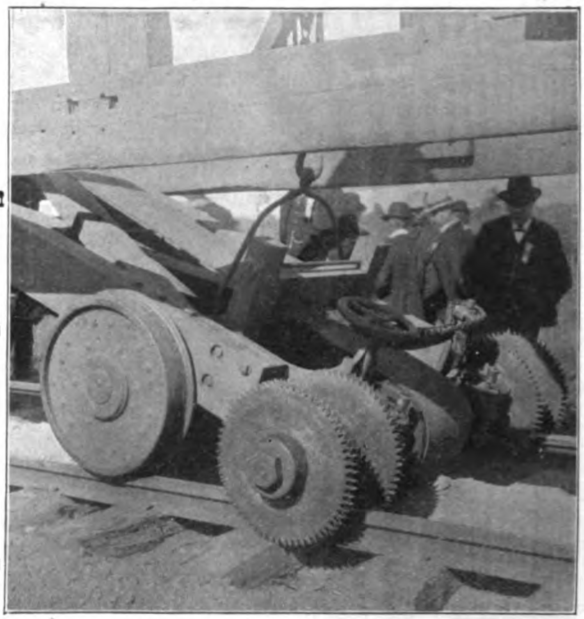


Fig. 279.—Wabble Saws of Brown Tie Spotting Machine—Fig. 280.

the picture. The plates are placed in position under the rail and the car advances, driving both plates on the same tie simultaneously. The hammer is raised by the winch and tripped by a foot lever operating a clutch which throws the winch out of gear. Each straddler used with this machine, when out of service, is lifted clear of the rail by a steel strap hanging from the side of the car, at points just over the wheels, and running under the bend of the straddler. As the car of which the photograph was taken was not in service at the time, being out of repair, this strap does not show on the side toward the observer, but it may be seen hanging down from the opposite side of the car, just ahead of the wheel. When it is desired to move the car ahead this strap is pulled up far enough to lift the straddler clear of the rail, and is then hitched to a peg. After the straddler is lowered to the service position, and while it is being used, the strap hangs loosely under the bend of the straddler. This machine was designed by the late J. T. Mahl, engineer of maintenance of way of the Atlantic division of the road, where several of the machines have been in service.

Reference has already been made to the practice of running ties through a "spotting" machine before they are laid in the track, to cut the rail seats parallel with the axis of the tie, and in the same plane, so as to afford an even bearing on the tie for the rails or for tie plates. An idea along this line has been worked out and put to practice to facilitate the cutting and evening of rail seats on ties as they lie in the track. The machine was conceived of and designed by Mr. George M. Brown, when chief engineer of the Flint & Pere Marquette R. R., which has since become part of the Pere Marquette R. R. system. The need of such a machine was suggested by a consideration of the following well-known facts: When rails become tilted or canted on curves the only remedy is to draw the spikes, adz the rail seats to a proper bearing and return the rail to a righted position. In placing tie plates on ties already in the track, a seat should be adzed for the plate wherever the tie has been cut into by the rail; otherwise, or if the plate is seated so that the ends are higher than the center, it will buckle. Again, when relaying rails with a new rail having a wider base

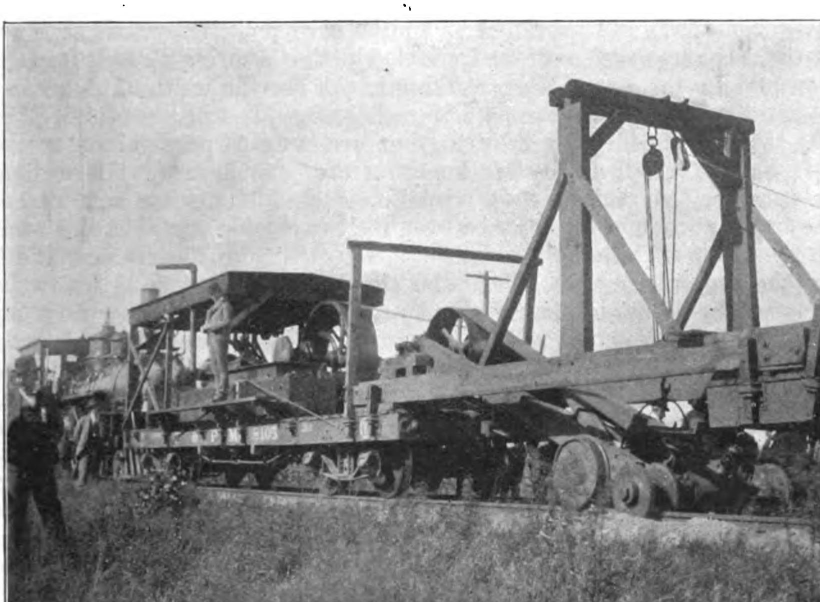

Fig. 281.—Brown Tie Spotting Machine, Pere Marquette R. R.

than the old one, a widened seat must be adzed for the new rail on every rail-cut tie. In such work the ties are usually covered with more or less sand and grit, so that the tools soon become dulled; and in any case, unless the men are expert with the use of the adz or are closely watched, the work will result in a saucer-shaped seat for the rail or tie plate, as the case may be.

The working portion of the machine consists in a number of circular saws, running in groups upon a common shaft, which is journaled in an arbor suspended crosswise the track and held in position to cut grooves each side each rail. The purpose is to cut a groove near to, and level with, the base of the rail, so that the trackmen will have a gage to work to when adzing the tie to an even seat for the rail or tie plate. Figures 279 and 280 show the lower end of the arbor and the saws, and Fig. 263 shows the work done by the same. To explain the source and transmission of the power, Fig. 281 shows a locomotive and train of two flat cars, the car next the engine mounting a stationary engine having a 12x20-in. cylinder and a

60-in. fly wheel, steam being taken from the locomotive through a hose connection. This engine drives a jack shaft on the head end of the car, from which a belt is run to the shaft bearing the saws, which is journaled at the end of an arbor swinging about the jack shaft. This arbor is supported at the track end by a pair of 26-in. wheels journaled about 30 ins. in rear of the shaft carrying the saws. Supported in this manner the arbor frame holds the saws in a fixed position relatively to the level of the rail and assures a uniform depth of cutting by the saws. When not at work or when passing switches, frogs, crossings, etc., the frame is swung upward from the track by block and tackle suspended from a bent supported upon beams extending between the two flat cars, which beams also maintain the proper interval between the cars. The tackle is operated by a winch on the head flat car. The saws are run at a speed of about 1500 revolutions per minute. Figure 280 is a near view showing the saws lowered into position for work.

In preparing for the work the ballast is removed to a depth of 2 or 3 ins. below the tops of the ties, in line with the grooves to be cut, and when in operation the train is moved forward (in the direction in which the locomotive is headed) at a speed of 4 or 5 miles per hour. The wheels supporting the arbor are gaged to fit the track closely, thus securing a steady forward movement for the saws. When working in oak ties the width of groove cut is 1⅛ ins. and three saws are used in each group. It will be noticed (Fig. 279) that the outside saws in each group are hung perpendicularly on the shaft, but the intermediate saws, known as the "wabble saws," take a diagonal position, so that in each revolution each intermediate saw sweeps over a wide portion of the space between the two outside saws. In this manner the group of saws cuts a groove corresponding to the extreme width over the two outside saws. For cedar ties the groove cut is 2¾ ins. wide. The saws are adjustable to cut a groove of any desired width and at any desired distance from the rail. The vertical adjustment of the shaft bearing the saws is effected by means of a screw, in iron brackets carrying the journals in guides, on either side, the two screws being operated together by means of sprocket wheels and chain. The saws when new are 24 ins. in diameter, but from wear and filing they gradually become smaller, the vertical adjustment of the shaft taking care of the diminishing diameter. The saws are also adjustable endwise on the shaft, so that the ties may be grooved in position convenient for the class of work on hand, whether it be renewing rails, changing gage, righting tilted rails or laying tie plates. If part of the ties are already laid with plates, as is frequently the case in old track where tie plates are gradually applied in connection with tie renewals, the saws are set far enough apart to miss the plates. An example of this kind is illustrated in the lower engraving in Fig. 263.

On the road where it was invented this machine has been very useful, as has been proven by the variety of work to which it has been put besides that of spotting ties for seating tie plates. In 1898 the Flint & Pere Marquette R. R. changed the gage of 92 miles of narrow-gage (3 ft.) track, and this machine was put to work cutting the seats for the rails, which were moved outward to the standard gage of 4 ft. 8½ ins. For this work six saws were arranged in a group on either end of the shaft and set to cut a seat 8 ins. wide. The inner edges of the grooves cut were 4 ft. 2¾ ins. apart, or in proper position for the rails to be moved to standard gage. With this preparation the stretch of 92 miles of narrow-gage track was changed to standard gage in one day, with a force averaging three men per mile. On some sections the work was completed in 12 hours and on others in 15 hours, on the day referred to. The actual length of track worked over that year was 110 miles, the remaining 18 miles of narrow-gage track being changed the following year. In one of the subsequent years the machine was used in cutting over 100 miles of standard-gage track in preparation for renewing rails.

Cost of Laying Tie Plates.—The cost of laying tie plates by hand on ties out of track averages about ½ cent each, and on ties in the track it ranges from ½ cent to 2 cents each, according to the kind of timber, the amount of adzing to be done, the extent of interference from trains, and, perhaps most of all, to the thoroughness with which the work is done; under ordinary conditions 1¼ to 1½ cents per plate is a fair estimate for good work. A maintenance of way officer who has paid much attention to tie plate laying for a number of years, requiring thorough work in all details, and who has kept careful records, gives 1.55 cents per plate as the average cost of the work of six different foremen, working 8 to 12 men in a gang, including flagmen. This figure includes time lost in going to and returning from work on hand car, the price for labor being $1.25 per day. The tie plates were of the Servis pattern, laid on oak ties, by the method of pulling the spikes and moving the rail out of its seat, using a Ware gage to set the plates, and beetles to drive them. The train movements were such that the track was opened each day for putting in plates an average of 4.43 times, and the average length of time the track was open in each instance was 39½ minutes. The actual cost of embedding the plates, not including any work incident thereto, was 0.14 cent per plate, which illustrates how largely the incidental items in thorough work of this kind figure in the total cost.

In order to carefully supervise the work of laying tie plates and be able to form correct estimates of the cost, or to draw comparisons of results under stated conditions, it is necessary to have itemized reports from the foremen in charge of the work. An example of such accounting, as made to the office of Mr. Henry Ware, roadmaster with the Buffalo, Rochester & Pittsburg Ry., appears below, together with certain explanations from that gentleman regarding his methods of work and records, which I think are interesting to publish. Mr. Ware states:

"My practice in putting tie plates on ties in the track is to 'double up' section gangs to assist the foreman on whose section the plates are to be put in, and the foreman in charge makes a daily report to me of work done, on a form for that purpose, a sample of which I submit herewith:

John Doe, Foreman.

"As a rule I do not make a record of such reports, for it would require more clerical work than my office could devote to it. The distribution of labor at the end of each month covers it sufficiently for all practical purposes. My object in requiring such report is that I may know each day what the men are doing when I am not over the road to see them, and thereby keep in touch with what is going on. The knowledge that I am interested in each day's work acts, I believe, as an incentive to industry. As will be noticed on the form, I require foremen to report whenever they have been obliged to flag a train, giving the reason, and the length of time the train is held. A record is made of this report in my office. The object of this report is two-fold: first, that I may know if any unnecessary flagging is done; and second, to check up any exaggerated statement that may be made by the transportation department."

107. Bank Edging.—Deficiencies of construction, the washing effect of rains and the wasting effect of grubbing vegetation frequently leave the shoulders of roadbed on embankments too narrow or too much worn down to properly retain the ballast. In order to economically maintain the track surface it then becomes necessary to widen out the top of the embankment to full roadbed width or bring it up to sub-grade by replenishing the sunken

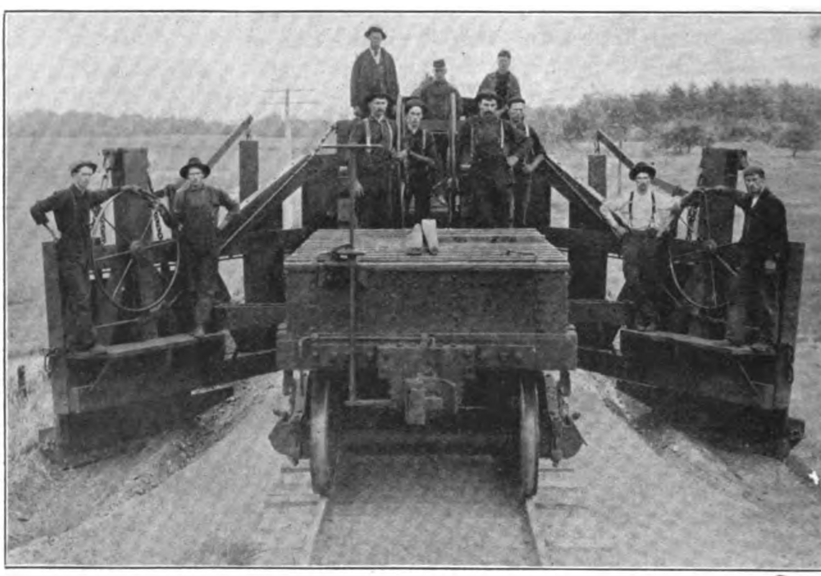

Fig. 282.—Track Shouldering Car, Boston & Maine R. R.

shoulders, especially if the ballast is to be renewed or the track raised to a higher grade line. Such work is known among trackmen as "bank edging." The filling material necessary for this purpose may be obtained and deposited in various ways, one good plan being to so dispose of the earth that is removed from time to time in ditching cuts. On some roads, even on high embankments, such work is done with teams and scrapers, and in cases it is moved from the side of the right of way in wheelbarrows, but in perhaps the majority of cases the material is loaded with a steam shovel and hauled out by work trains. The work of leveling down the material that is dumped or plowed from cars and left in heaps along the track is an item of considerable expense, if done by hand, and in many cases where extensive operations of this kind have been undertaken machines have been designed for the purpose. Bank-leveling or earth-spreading machinery operated as an attachment to the side of a car is now commonly in service, both for shouldering embankments and plowing out filling material in grading for a second track. The principal difference in the construction of the machines for these two classes of work is in the sweeping distance or reach of the side wings or plows, although in some instances the adjustment of these parts is made sufficiently flexible to answer both purposes. The machines described in the present connection were designed primarily as shouldering cars. Other machines sometimes used for shouldering service receive mention in connection with "Constructing Double Track" (§ 112, Chap. VIII).

A track shouldering car that has been used satisfactorily on the Boston & Maine R. R. is shown in Fig. 282, as it appears in operation. It consists of a specially constructed 70,000 lbs. capacity flat car 34 ft. long, fitted with side wings carrying interchangeable knives. The width of the car over side sills is 6 ft. 4 ins. The wings, which are constructed of heavy timbers strongly framed together, are hinged to upright posts fixed to the side sills, at either side of the car, and securely braced both crosswise the car and longitudinally. The position of the wings, which can be extended or contracted, is controlled by sliding struts guided within a boxed way suspended from the middle portion of the car, and forced in or out by the large hand wheels and chains appearing in the center of the picture. The cutter knives, carried at the bottoms of the wings, each consisting of a ¾-in. x16-in. steel plate reinforced by a 4x4-in. angle and 3x6-in. channel, may be raised or lowered by racks and pinions operated by the hand wheels shown. Two men are required to adjust the cutter on each wing. At either end of the car are ballast boxes, in which scrap iron is placed to hold the car down to its work. Minor improvements made since the photograph was taken include a derrick, similar to the davits on a vessel, for handling the cutters from the wings to the deck of the car and vice versa, and an additional strut placed against the end of each wing when it is spread out to maximum distance.

This machine has been used both for shouldering down widened embankments and for leveling material to sub-grade for a parallel track. By extending the wings to their full sweep and attaching a special cutter for leveling purposes, material can be plowed out to a width of 12 ft. from the rail and to any desired depth not exceeding 18 ins. In shouldering work all surplus material can be removed from one or both sides of the track and cut to lines parallel with the rail, whether on straight or curved track, thus working the roadbed down to a uniform section of any desired shape. The machine can also be used for ditching. The force required to operate it properly consists of a train crew, a foreman and four men. As an example of what the machine can accomplish in comparison with hand labor, it is stated that the car in four days trimmed up a 30-mile section of track, the work on which if done by hand would have cost, as determined by actual trial, $75 per mile. The expense of the shouldering car outfit for the four days was $114.20, to which should be added $378, the wages of 70 men employed in leveling back material which the car could not reach, and clearing up material in cuts that the car could not dispose of. In one instance the car moved 500 cu. yds. of filling material, leveling it 6 ins below top of ties and 10 ft. from rail, over a distance of 1000 ft., in 25 minutes.

The Gulf, Colorado & Santa Fe and the Atchison, Topeka & Santa Fe roads have spreader and shouldering cars of a pattern shown in Fig. 283, built for spreading material plowed from flat cars to raise embankments in grade reduction, and to prepare the shoulders of embankments to receive the ballast. The design was worked out by Mr. E. McCann, supervisor of bridges and buildings for the Atchison, Topeka & Santa Fe Ry. The machine consists of spreader wings fitted to an ordinary flat car and provided with overhead hoisting apparatus. The wings are of ordinary heavy ($4\frac{1}{2}$-in.) plank construction, faced with boiler plate and hinged to the car at the floor line by means of heavy struts ironed off and well braced longitudinally with angle irons. Each wing is divided into two sections, the rear section extending from the ends of the ties outward, and the forward section from the rail to the ends of the ties and overlapping the rear section. The intention of the forward section is, of course, to clear away material from the rail and uncover the ties, while the rear section cuts to a depth even with the bottoms of the ties, or below if desired. The spread of the

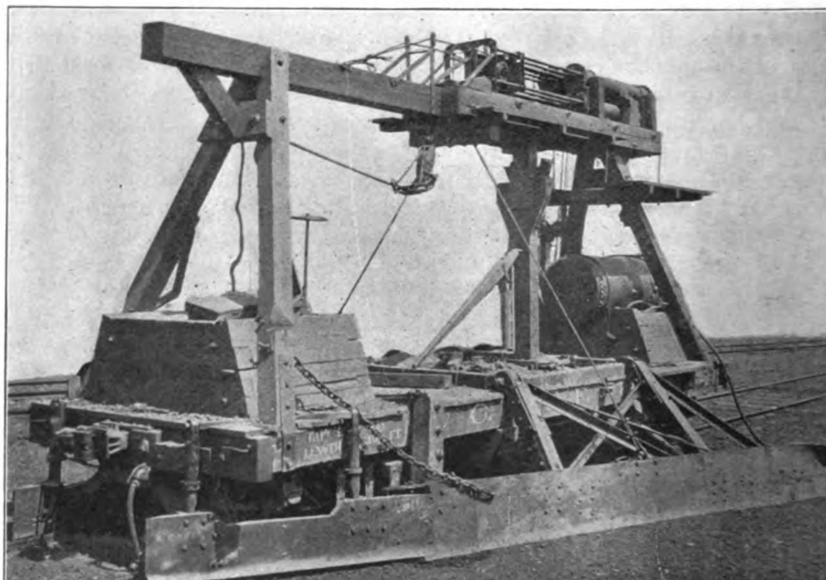

Fig. 283.—Track Shouldering and Spreader Car, G., C. & S. F. Ry.

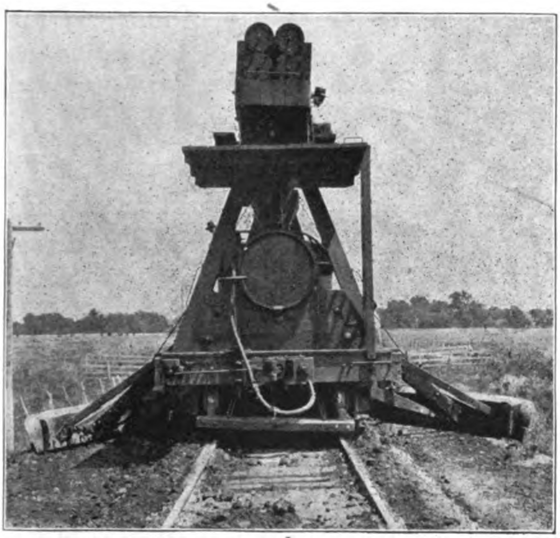
wings is 13 ft. 8 ins. on each side of the center of the track. The front section is hinged to a heavy bar extending diagonally across the corner of the car, and a piece of stout chain is attached to the rear section to prevent dislodgment of the same in case a hinge should break. The side pressure against the front section is received by a hinged strut, which abuts against a stop block bolted to the under side of the end sill of the car. The side thrust against the rear section of the wing is received by struts abutting against heavy timbers extending across the car, underneath the sills. In constructing these cars a heavy timber box was placed at either end, with the idea that ballast might be needed to hold the car to the track while in service. In practice, however, it has been found that ballast loading is not needed, and the boxes are used as a place for storing chains, templet plates, tools, etc. The construction of the wings, leaning as they do from a vertical position, and sprung at the lower edge, and backed by struts hinged from above, is such as to give them a downward draft when plowing through material, the action being similar to that of a plow point. This draft assists in holding the car down to its work. The apparatus for hoisting the wings consists of four 8-in. air cylinders mounted upon a longitudinal beam that is supported upon an A-frame at each end of the car, at a hight sufficient to clear the wings in their raised position. These cylinders operate pistons which have a travel of about 5 ft., and the piston rods are fitted to a cross head to which are attached two pulleys, around each of which is doubled a wire cable for hoisting the wing on one side of the car. The pistons thus pull the end of the cable a distance equal to twice the travel of the piston. The weight of all the apparatus which is attached to the naked flat car is 22,600 lbs., of which 10,400 lbs. are carried by the forward truck, and 12,200 lbs. on the rear truck.

The wings are operated by one man, who stands at the end of the car, next to the air storage reservoir, where he handles the air cocks of the hoisting cylinders and where he can push the leveler arms over the dead center when lowering them to position. The air for operating the hoisting cylinders is taken from the brake system of the train. The cable for lifting the wing on each side is attached to the rear section, which lifts the forward



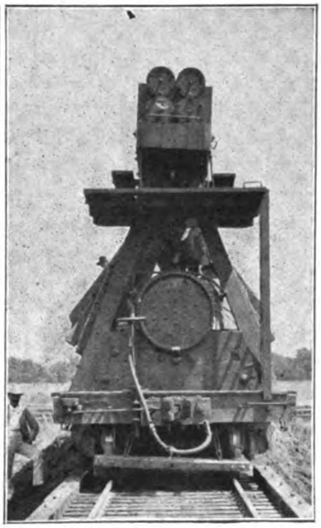


Fig. 284.—G., C. & S. F. Shouldering and Spreader Car—Fig. 285.

section, which comes to rest in a notch in the corner of one of the posts of the A-frame. In lifting the wings they are revolved past the center and thus rest in stable equilibrium. In lowering the wings to position they are shoved over the center by means of a lever shown, and dropped to working position by gravity, being controlled in their fall by admitting air to the cylinders, to act as a cushion. The wings can be raised to clear bridge floors, cattle guards, etc., in a very few seconds, and let down again into working position without requiring the train to stop. As a precaution against any failure of the air supply a rope tackle is carried on the framework for hoisting the wings in case of necessity. The air contained in the storage reservoir (capacity $57\frac{1}{2}$ cu. ft.) is sufficient for four applications. The pipes which feed the top cylinders are only $\frac{1}{2}$ in. in diameter, so that the flow of air is not sufficiently rapid to do damage to the machinery in case an inexperienced operator should open the cocks too suddenly. The wings when free from dirt are lifted without admitting full reservoir pressure, the cylinders being designed with a capacity sufficient to lift the wings when plowing through dirt the full depth, and when the train is in motion. There is an automatic valve to prevent the reservoir from being emptied in case the train should pull apart and break the hose connection. An end view of the machine with wings raised to clear is shown in Fig. 285, and Fig. 284 is an end view of the machine at work. For trimming the edge of the bank to form a shoulder a boiler-plate templet is attached at the outer part of the wing. This attachment is adjustable and can be set to trim the edges of banks 16 to 20 ft. in width.

Some minor improvements have been introduced on machines of later design which do not appear in these views. To prevent the end of the front section of the wing from scraping against the rail, and to carry it safely over rail braces and joint splices, a wheel has been placed at the front end to run on the rail and hold the wing to a proper clearance. On the cars of later design there are two hoisting cylinders (instead of four) each 14 ins. in diam. and 6½ ft. long, with a piston travel of 6 ft., and in putting the wings into service they are pushed outward past the vertical position by two 7-in. air cylinders—one for each wing.

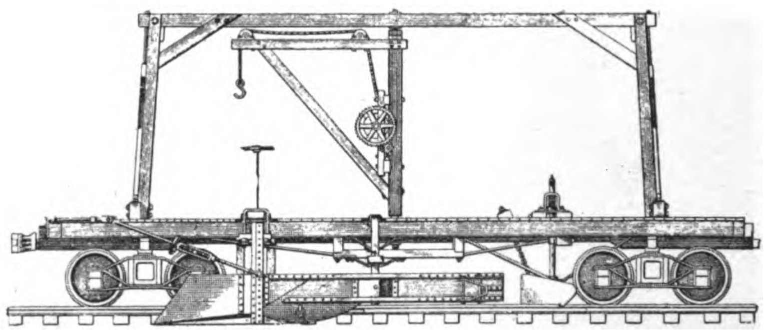

Fig. 285 A.—Side Elevation of Scott Ballasting Car, G., C. & S. F. Ry.

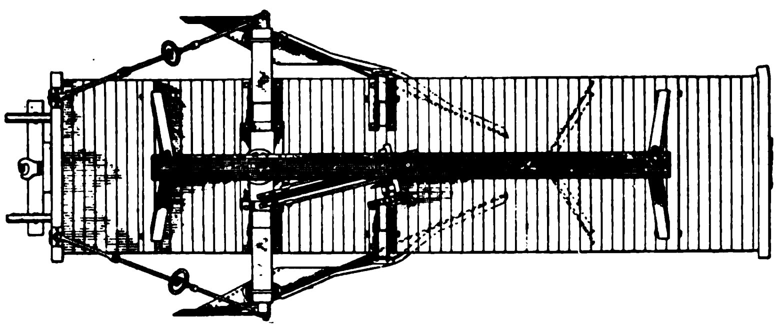

Fig. 285 B.—Plan of Scott Ballasting Car, G., C. & S. F. Ry.

In actual service this car has spread earth at the rate of 17,000 cu. yds. per hour, all the operations of the car being handled by one man. In one instance the car, starting from a standstill, dropped the wings and spread 176 car-loads of earth, carrying from 20 to 30 yds. to the car, in 13 minutes. Either one or both sides of the car may be used as desired. The stability of the car when spreading from one side only is sufficient for heavy work. In numerous instances two engines have been used to pull the car when it was spreading on only one side. So long as there is sufficient tractive force the car will plow its way through heavy gumbo or rock without difficulty. In leveling down rock large stones weighing from one to two tons have been handled without trouble.

A machine designed by Mr. W. R. Scott, while superintendent of the Northern division of the G., C. & S. F. Ry., is used to pull material inward to fill the center of the track. In one instance it was used in spreading the top material where a long trestle was filled in, taking dirt that was plowed from cars to the side of the track and filling in between the stringers, as high as the tops of the ties, thus dispensing with all hand shoveling. Besides filling in between the stringers it left the shoulder in proper shape. Another purpose of the machine is to handle ballast from the shoulder to the center of track that is to be raised for ballasting, thus dispensing with hand labor to this extent and with center-dump cars. The machine consists essentially of two winged plows hinged at the side sills of an ordinary flat car, with a crane for hoisting the plows to clear road crossings, wing fences at cattle guards, etc. Figure 285A is a general elevation view showing the position of the wing plows as set for service, and Fig. 285B is a plan view showing the position of the wings relatively to the track. The spread of the wings is controlled by chains winding upon a vertical shaft, with a brake wheel, and also by adjustable stay rods. The wings converge without meeting, and in rear of them there is a center plow for clearing the rails. The plows are made adjustable to varying widths and depths, so that if a large quantity of ballast has been unloaded they can be spread far enough to take in the extreme width. If it is desirable to make two lifts of the track in ballasting, the plows can be dropped low enough to bring the ballast up after one raise has been made. The ballast is left in exactly the same shape as though dumped from a regular center-dumping car and then plowed level with the rail and spread out over the ends of the ties. There is no danger of the machine clogging, as all surplus material is carried to the shoulder at the ends of the ties. It can be handled in this way at a speed of five or six miles per hour, and it has been used with equal satisfaction in gravel, crushed stone and slag ballast.

A side leveler and shouldering machine that has been used on the Kansas City Southern Ry. is built on a flat car, with wings of heavy plank hinged to upright posts framed over the side sills. The wings, which have a spread of 16 ft. on either side of the center of the track, are raised or lowered by compressed air supplied by the air-brake system, and when opened for duty each is backed by two brace struts. The swinging ends of the wings are supported by chains run to the tops of the posts to which they are hinged. The car is ballasted with three round wooden tanks, each holding 1800 gals. of water, which may be utilized to feed the locomotive in case the supply in the tender runs short, thus saving time which might be lost in making special trips to water stations. The total weight of the car with the tanks full of water is 48 tons. The wings proper extend from the ends of the ties outward. The tops of the ties are cleared by a flanger attachment held to its work by springs which permit it to yield when meeting the end of a high tie or other obstruction. The rounding of the shoulder over the top of the slope is accomplished by an adjustable plate attachment which drops below the bottom edge of the wing proper. On the Intercolonial Ry. the wings of a snow plow have been fitted with adjustable steel blades, to adapt it to the purpose of a shouldering car.

CHAPTER VIII.

DOUBLE-TRACKING.

108. General Considerations.—The report of the Interstate Commerce Commission for the year ending June 30, 1902, puts the aggregate length of railway line in the United States at 202,472 miles. This total mileage was made up of 188,751 miles of single-track road, 12,517 miles of double-track road, 309 miles of three-track road and 895 miles of four-track road (there being 13,721 miles of second track, 1204 miles of third track and 895 miles of fourth track), so that 93.2 per cent of all railway line was single track. In 1890 this percentage was 94.8, the average decrease being about one tenth of one per cent each year. Any general treatment of track therefore applies principally to single track. So much of the work of construction and maintenance considered in the foregoing chapters has the same application to double that it has to single, track, and so many variations of methods specially applicable to double track have been pointed out, that but little additional need be said with special reference to double track. There have not been opportunities, however, to go into certain details of double-track construction and operation, and these may perhaps be best treated in a separate chapter.

109. Advantages, Etc.—The advantages to be had with double track, over single track, are many, not a few of which must be apparent from the standpoint of the trackman, as well as from that of men engaged in the transportation department. Of course the advantage most likely to be considered is that of profit, and usually the question which must determine the advisability of double-tracking a road, or any part of it, is whether the additional traffic which can be had by increasing the capacity and facilities of the road, will increase the receipts sufficiently to warrant the expense of additional construction and maintenance; or, perhaps, indeed, whether the traffic already at hand could not actually be handled on double track with increased economy sufficient to compensate for such additional outlay. It is no doubt true that as the traffic on a road increases, the point where the same traffic can be handled more economically on double, than on single, track will be reached before the single track becomes crowded to the full extent of its physical possibilities. The chief consideration which settles this principle is the obvious fact that the trains can be moved with greater convenience, dispatch and safety, and hence with increased economy, on the double track. The element of increased safety obtains, for the most part, from the fact that on double track less dependence is necessarily placed on human reliability and foresight. Nevertheless, with double track it is possible to eliminate from the track itself many features properly considered elements of danger in train operation. A discussion of the question "Limit of Capacity of Single Track" is published as § 207, Supplementary Notes.

On double track there is but little passing of trains which use the same track, and hence sidings or passing tracks can to a large extent be dispensed with, so that danger inhering with frogs and switches is far less. This is true, not necessarily because the dispensing with so many sidings makes frogs and switches less numerous, because for every siding taken out there will usually be put in a crossover, which double track operation requires at most stations; but such crossovers can be laid with frogs and split switches trailing to the prevailing movement of the trains, so that the danger arising from such appliances when used on single track is removed. Likewise, double track naturally favors making the switches for all, or nearly all, spur tracks, trailing switches; whereas, in making a round trip with a train over a single-track road or division, every switch on the line becomes a facing switch to that train once during the trip. Also, on double track the total number of switches is divided between two tracks, so that a train in going over the road in one direction does not pass over all the switches and frogs on main track, as it necessarily must on single track.

110. Comparative Cost of Construction and Maintenance.—The first cost for rails, ties, fastenings and ballast for double track is twice that for single track, but the same ratio does not hold true in other particulars—it favors always the double track. Thus, for instance, in earthwork with slopes 1½ to 1, a roadway 18 ft. wide, in cuts or fills of 10 ft. depth, may be widened out to 31 ft. (the corresponding width of roadbed for double tracks at 13 ft. centers) by the handling of only about 40 per cent more material, the proportion of additional material growing less as the depth of cut or fill increases. The same ratio will hold true for the increased cost of masonry for bridge abutments for double-track, as compared with single-track, structures. In most regions cuts and fills of the above dimensions are only ordinary with roads handling a traffic so large that they can afford to double their tracks. And besides, the cost for filling or excavating per yard of material for an additional track should be less than that for a single track, after the single track is once in operation, owing to the increased facilities for hauling, handling by machinery, etc. Taken all around, therefore, the cost for earthwork for a second track should usually not exceed 50 per cent of that for a single track on the same location. As regards cost of construction of a second track, it ought to be considerably less than the cost of the first one, since the materials can be distributed much more cheaply; moreover, better opportunities are offered for the company to build its own track, and not only save the profit which ordinarily goes to contractors, but to build it as it should be built—which contractors not always do.

In the matter of repairs or maintenance expense, approximately twice as much will be required for tie renewals for the two tracks as for one. Where trains run frequently rails lose but very little from rust, so that the cost of renewing rails for double track will not much exceed the cost of renewing the rails for the same length of single track carrying the same traffic. There is also much work, such as ditching, mowing grass and weeds, cutting brush, policing, repairing and renewing fence, track-walking, bank-edging, maintaining snow fence, protecting banks, and other work which requires the same time for single as for double, track; in fact, the cost of mowing and cutting brush on double track is sometimes less than it would be on single track for the same width of right of way, owing to the narrower width outside the slopes at cuts and fills. Regarding lining and surfacing, the cost for two tracks will not be twice that for one, because each track undergoes only half the service which one track would in carrying all the traffic. Unlike the matter of rail wear, however, the work of maintaining two tracks in line and surface is more than that of maintaining one track to carry all the traffic, for the impairment resulting from weather conditions, such as rain and frost, may reasonably be supposed greater on double track than on the same length of single track, not only because of the greater extent of track structure and roadbed, but also because double track is not usually as well drained at sub-grade as is single track. Data bearing on this point would seem to indicate that the cost of raising and tamping double track to hold it in surface is 40 to 70 per cent greater than the cost of performing like labor on the same length of single track to carry the same traffic tonnage. In another respect, however, double track is favorable to lower cost of surfacing than it might otherwise be, as there is less interruption to the work, for the same number of train movements, and the trains are more likely to run on the regular schedule, so that track work can be laid out to better satisfaction. Consider, as an instance, the case of two freight trains, each consisting of three or four sections, scheduled to pass at a certain point on single track. If one or two of them should be just enough behind time to cause the meeting point to be changed from the regular one, trains might become so strung out as to seriously hamper the work of several section crews for the large part of a half day—not to speak of the worry over the work which such an interruption sometimes brings upon the ambitious foreman, often resulting in irritation and eruption between him and his crew—etc., etc. As experienced trackmen know, this matter of delayed trains cuts considerable of a figure in the progress of track work. It is not at all a question of time lost while workmen stand aside for trains to pass, but the uncertainty regarding the time the trains will be along, which often catch the work when it is partly done, requiring it to be performed the second time or, in many instances, causing delay as a matter of precaution, in starting out with the work. Taking all matters into consideration, it is a reasonable estimate that the cost of keeping up two tracks on the same roadbed to carry a stated amount of traffic does not exceed that necessary to maintain one track to carry the same traffic, by more than 45 to 55 per cent. As the result of a careful study of this question, using average cost data covering the various items of the labor and material accounts of track maintenance, I find the ratio of the expense of maintaining single track to that of maintaining double track carrying an equivalent tonnage, to be 1 to 1.52. In this calculation interest charges were not taken into account.

111. Preparation for Double Track.—In this country, where so much of industrial development has depended upon the railroads, the history of roads which operate two or more tracks has been in nearly every case the building at first of one track, with such limits on grades and curvature as the outlay—which the apparent traffic of the more immediate future seemed to justify—would permit. As commerce and travel to and from the districts tapped by the roads have increased, the roads have usually reduced the grades (where the same have been of an undulating nature), eased or taken out curvature in places, and gradually brought the line into better condition; after which double-tracking has been accomplished as increased traffic, competition and other matters have demanded. Good examples of such development are the New York Central & Hudson River and the Pennsylvania roads. The New York Central has on its main line four tracks—two for passenger and two for freight trains. The Pennsylvania road also has four tracks on its main line.

Wherever there is the least likelihood that double track will ever be needed, the plans for it should be constantly in the view of the management from the time the road starts, even though nothing toward it can be done at first. Such matters as looking out for plenty of room while obtaining right of way in the vicinity of locations where expansion seems probable, or such locations as seem liable to be changed eventually, are well worth consideration, and it can usually be had without additional expenditure if negotiated for before the road is built. Sidings built from time to time should, as far as practicable, be laid out to conform to the main line roadway in grades, and at standard distance from it, where the location is good; otherwise they should be located with a view to bettering the location of main line should it seem likely that at any time in the future it will form part of a second main track. In this connection, too, even without having double track in view at all, it is good engineering, when laying out a siding or spur, if it can be accomplished without too much inconvenience in other ways, or without too much cost, to locate it at some point where the curvature of the main line needs improvement. By building a piece of track on the new location and throwing the main line to connect with it at both ends, the old piece may be used for the side-track, simply by putting in a switch—and changing the rails, if it is desired to make use of an inferior quality of rails for side-tracks. The matter of lap sidings as favorable to the subsequent building of double track, is touched upon in a previous chapter. By giving the proper amount of attention to such things during the progress of constructing and developing the road, double-tracking becomes an easy matter, comparatively, when it has finally to be done, and at the same time improvements on the general alignment of the old line can gradually be brought about. It is frequently the practice when putting in permanent bridge piers and abutments to make them of such dimensions that they may answer later for double-track structures. The cost for additional masonry required is comparatively slight in work of any considerable hight. In the matter of superstructure, however, Wellington points out that a double-track bridge weighs 90 per cent more than a single-track bridge designed for a corresponding loading, and he concludes, therefore, that it is not good policy to arrange for a third truss unless double track is certain to be built within a year or two.

Double-tracking is usually begun on that part or parts of the road where the local traffic is most congested, other considerations not interfering, and extended by sections at a time until finally it reaches the whole length. Thus parts of a road may for years be double and other parts single, track. The meeting of the second track with the first is designated "end of double track," at which point proper signals are maintained and a switchman is stationed to look after switching the trains. The switch at end of double track should be a point switch, placed preferably on straight line, where approaching trainmen can see the signals clearly for a good distance from either direction. The frog should be of large number, thus giving a lead of easy curvature, and making it possible to run trains through it at fair speed. No. 12 frogs, corresponding to a lead curve of 4 deg., are sometimes used at such places, and No. 14 to No. 18 frogs quite commonly, while in a few instances frogs as high as No. 24 have been used. To cite an example of the use of a frog of the number last named, there was for some years at the end of double track on the Cleveland & Pittsburg division of the Pennsylvania Lines West, at Bedford, O., a No. 24 rigid frog 30 ft. long, 19 ft. from point to heel, constructed in the ordinary manner. It was used with a 30-ft. split switch, having a spread of 7 ins. at the heel, and with 30-ft. guard rails, in a turnout of practically 1 deg. curvature (theoretical radius being 5472 ft.). The frog had to be renewed about once each year, and is said to have given excellent satisfaction.

112. Constructing Double Track.—The work of excavating and filling for a second track can usually be done most economically with steam shovel and work train. The shovel or excavator is used to widen the cuts and the material is hauled to widen the fills. Unless the cut, in any case, is long or deep it is not worth while to lay a turnout to get the shovel off the main line. The way this is usually done is to remove the ballast from between the ties and then cut the track and throw it over to connect with an isolated track running into the face of the cut; run in the shovel and its tender, throw the track back to place and couple up. With a work-train crew the change can be made in a short time. The piece of isolated track should be started right to make joints with the piece of main track thrown over. It is not necessary, however, to throw the main track ties at all, but to simply pull the spikes from a rail each side of the track, cut the rails loose at one end and throw the free ends over slightly on the ties so as to lead from the main line. Beginning with these rails, a temporary turnout may be laid to be continued as the isolated track, blocking under the off rail as far as the near rail remains on the old ties, running a tie under the off rail and main-track rail occasionally to hold the former to gage with its mate, which is spiked on the old ties. Instead of using a frog, the main-track rail may be taken up where the turnout rail crosses that side of the track. The tender car or tank for the shovel may be supplied with water by hose from the locomotive tender or from a water car standing on main track. The work train must, in any case, stand on main track while loading; and, as far as possible, it should be arranged to unload while on the way to a passing track to clear for regular trains or upon the return therefrom. If, however, the work in the cut will require the use of the shovel for a considerable length of time, as in a deep bank, it will pay to lay a turnout for switching water and fuel cars to the shovel. In the case of a long cut the track behind the shovel may, after some progress has been made, be used by the work train

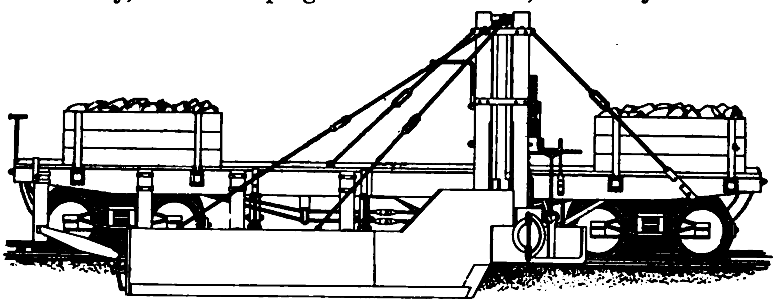

Fig. 286.—Jordan Spreader Car, Michigan Central R. R.

to let the regular trains pass. The shovel should work its own way through the cut. It should have a derrick of such length that it can stand clear of main track, reach far enough into the bank to cut the required width of roadway, and still reach the cars on main track. After the work at the cut has been completed the shovel may be taken onto main track in the same manner that it was taken off, and then proceed to the next cut.

In transporting material from long cuts to adjacent fills, surface-hauling tram roads with dump-cars are sometimes employed, the system being applicable to either grade reduction or to double-tracking. In the work of reducing grades on the main line of the St. Louis, Iron Mountain & Southern Ry., it was found necessary in some cases to transport material from a summit where the cut was made, for a distance of a mile or more, to the point where the material was deposited in the fill. Instead of using a steam shovel and work train a surface tram road was laid on each side of the main line, using a mine hoisting engine driving an endless cable, which hauled the train of dump cars from the cut to the fill, and vice versa.

In filling for a second track close by the main track the material is most cheaply unloaded by side-dump cars or by plowing it off the cars with an unloader. The usual arrangement is then to work the material over with teams, using side-hill or railroad plows, with reversible mold-board for furrowing either way. A small force of men is required to keep main track cleared and to trim the slope. On roads where considerable double-tracking is to be done, a spreader or grading car is frequently used for plowing the material off the shoulder. One of the earliest cars of this kind was used on the Michigan Central R. R., where four of these machines were built on plans devised by Roadmaster O. F. Jordan. The car is narrower than common, being only 6 ft. 11 ins. wide over the side sills. On each side of the car, and braced together across the car, are erected two 8x9-in. posts with an 8x10½-in. post sliding between them, the latter being raised or lowered by racks and gears (Fig. 286). The sliding post carries a wing or side leveler which is 22½ ft. long, made of heavy plank and faced with boiler plate. The bottom or scraping edge of the wing is reinforced with an iron strip ¾ in. thick. At a point just beyond the ends of the ties the wing has a downward offset of 22 ins. The vertical limits within reach of the scraping edge of the wing are 22 ins. below top of rail and 10 ins. above the same. The wing is braced to the side of the car by three struts, of which there are two sets of different lengths for holding the wings at different angles. With the wing set at the extreme angle it sweeps 15 ft. 4 ins. from the side of the car, although one car of this pattern built for the Michigan Central R. R. is 40 ft. long and has wings that sweep 20 ft. from the side of the car. The machine is operated by two men, who can raise or lower the wings at will. The manipulation of the car in spreading earth is about as follows: The spreader car is coupled in just ahead of the way car, and while the earth is being unloaded two of the train men extend one or both of the wings, as the case may require, and lower them to the desired level. As soon as the earth has been unloaded from the cars the engineer is signaled ahead and the material is spread uniformily as far out as the wing is set. The car is held down to its work by weighting it heavily with rock, in ballast boxes at either end.

Aside from the work of spreading earth dumped as filling material in double-tracking, building side-tracks, or widening embankments, the car can be used for a variety of purposes. One use to which it readily adapts itself is the spreading of ballast on new grade. After the roadbed has been prepared the required amount of ballast is unloaded on the grade, before the track is laid, and then it is spread with the car in the same manner as when spreading earth. After the track is laid ballast is again unloaded by the side of the new track and spread over the same with the wing resting on top of the rails of the new track. The car can also be used for removing snow piled up at the side of a track or between tracks, as in yards. This is done by extending the wing to reach over the outer rail of the parallel track, and then the wing is lowered to slide upon the rails. The train may then be moved at good speed, the car at the same time throwing the snow from between the tracks to a distance corresponding to the sweep of the wing. In removing snow from yard tracks the material is thrown from track to track successively until entirely outside of the yard. For sloping the shoulders at the side of the track a special sloping blade is substituted for the wing and attached to the upright post, and handled in the same manner as when spreading earth or removing snow. For ditching, one of the wings is removed and a scraper and earth carrier is attached to the upright post and handled in the same manner as when spreading earth. In ditching, the car will work both ways, delivering the earth at either end of the cut. When the car is not in use the wings are raised and folded against the sides, when the car can be coupled into any regular freight train and transported to desired points. Cars of the same design have been used also on the Southern Pacific, Illinois Central, Grand Trunk Western and other roads.

The Duluth & Iron Range R. R. has a spreader car designed on the same general lines as the Jordan but different in some details. The wings or side levelers are hinged to 9x9½-in. oak posts sliding between upright guide posts attached to the side of the car, and are raised and lowered by means of gearing operated by hand cranks, as with the Jordan design, but to avoid building a narrow car, so that when the wings are folded against the side of the car they come within the clearing limits, this requirement is provided for by cutting away the side sill and setting the hinge post and guide posts in flush with the side of the car. Then, in order to strengthen the floor, which is necessarily weakened by cutting the side sill, a 6x8-in. beam is laid longitudinally on the deck on each side of the car, just in rear of the hinged post, and bolted down through a sill with long bolts. Another feature of the mechanism which is a little different from cars of this class as designed on other roads is an inward extension of the wing past the hinge post. As the leveling wing is usually designed, the inner end is hinged to the car, but in this case the wing is hinged at an intermediate point and the inner end extends to the rail, being jogged off at the ends of the ties. The brace arm which supports the wing against the side of the car when earth pressure is encountered consists of a steel crane attached to the car at one end and to the wing at the other end, by means of coupling pins. The coupling head at the side of the car permits of vertical adjustment.

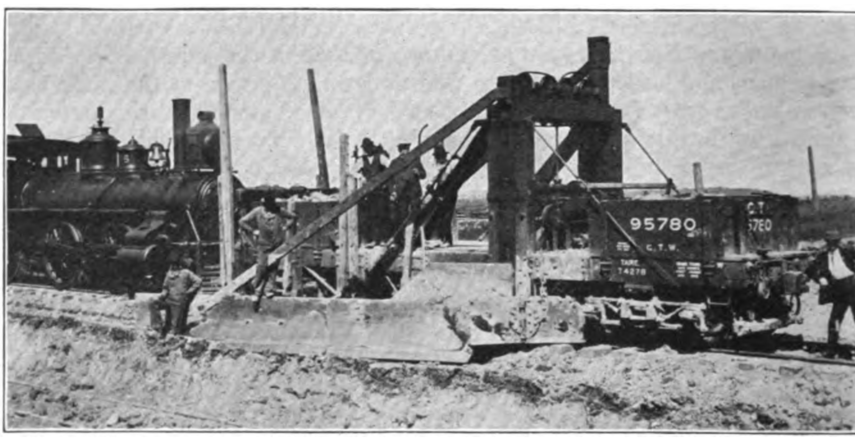

Fig. 286 A.—Jordan Spreader Car Adjustable by Compressed Air, G. T. W. Ry.

For spreading earth in double-tracking the Grand Trunk Western Ry. several cars were built on the Jordan style with wings adjusted by compressed air. As shown in Fig. 286A, these cars have a spreader wing on each side hinged to a vertical post sliding between two guide posts, as in the hand machines. The wing is held to its work by means of struts hinged to the side of the car and abutted against the wing. To adjust the wing for spreading to different widths there are sets of struts of different lengths When the wings are not in service the struts are folded up to a vertical position as shown in the picture. To hold the end of the wing down to its work there is a strut running from its outer end to the top of the hinge post, as shown. This strut consists of two plates, 6 ins. wide, with a piece of timber sandwiched between. To adjust the wing for depth of spreading, the hinge post is raised by means of a wire rope passed over pulleys at the top of a frame transverse to the car, and then attached to the piston rod of an air cylinder 16 ins. in diam. and 3 ft. 2¾ ins. long, standing vertically at the middle of the car. The wing is lifted by means of the air cylinder and cable and is lowered by its own weight. As in this work it is necessary to spread material on only one side of the track at a time, the air-lifting mechanism is fitted up to operate only one wing at a time. When it is desired to change operations to the other side of the track, the piston rod is detached from one cable and attached to the other. For clearing material from the ends of the ties there is a small auxiliary wing on each side, the hight of which is adjustable by means of a cable attached to the piston rod of an ordinary freight car brake cylinder anchored to the floor of the car in a horizontal position. The air for operating these wings is compressed on the car by means of an ordinary locomotive pump taking steam from the locomotive by hose connection. Air pressure is stored in a reservoir 24 ins. in diam. and 7 ft. long, placed crosswise the car.

In cutting down grades and straightening curved track on the Baltimore & Ohio Southwestern R. R. extensive use has been made of a spreader car built on plans covered by the Boutet patent, as many as seven of these cars having been in service at one time, spreading out material unloaded at the side of the track. This car (Fig. 287) measures 37 ft. over end sills and 9 ft. over side sills. The wings are hinged at three places on heavy underframing hung beneath the sills. These wings are each 21 ft. 2 ins. long and the spread of each extends to a point 13 ft. from the center of the track. The wing is formed of heavy planking faced with old boiler plate, and the planking is backed by heavy braced struts extending out at right angles to the side of the car. The side sills are cut away at a point 4 ft. 8 ins. back of each bolster, forming recesses into which the wings can be folded up in a vertical position when not in use, as shown in Fig. 288. When folded in this manner the wings stand against the intermediate sills, and the width over the folded parts becomes less than over the side sills, thus affording adequate protection to the wings in transit. The wings are folded by means of rope tackle attached to the top of a heavy post or mast stayed to the car

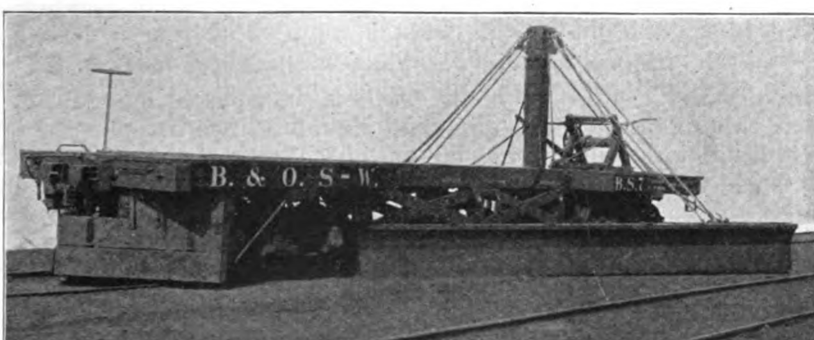

Fig. 287—Boutet Spreader Car, B. & O. S. W. R. R. (Ready for Service).

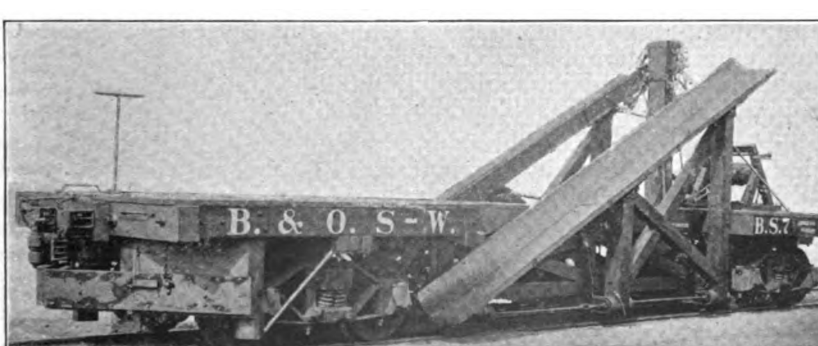

Fig. 288—Boutet Spreader Car, B. & O. S. W. R. R. (Wings Folded for Transit).

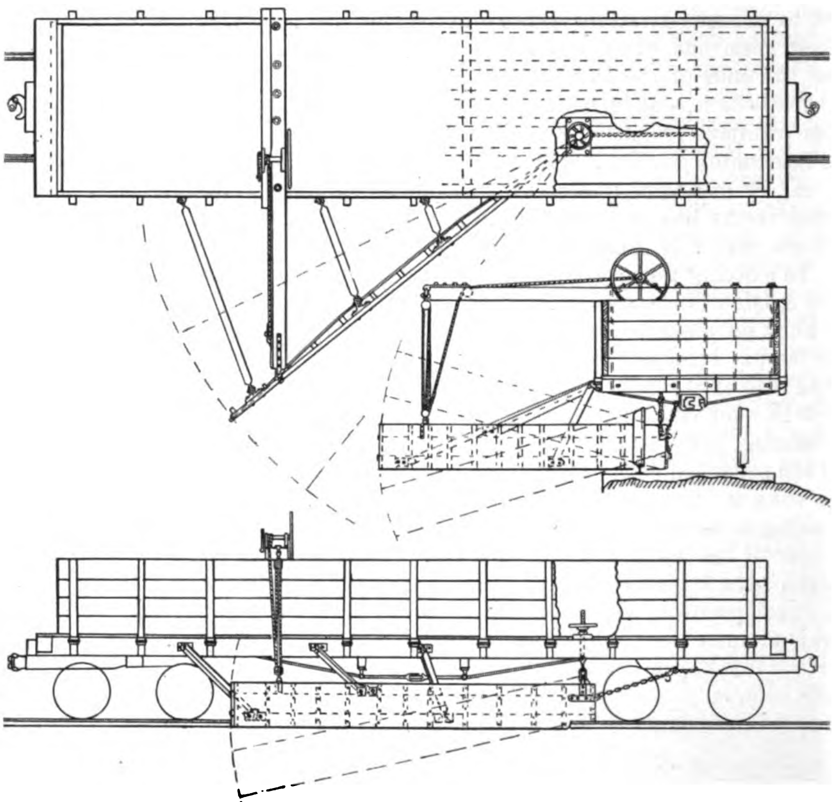

Fig. 289.—Donovan Spreader Car, Yazoo & Mississippi Valley R. R.

by brace rods. The hauling of the tackle is accomplished by means of a winch, back of the post, and to prevent the wings from dropping too low where the shoulder falls away at the side of the track, a stay chain of suitable length is run from the top of the mast to the outer end of each wing. The forward end of the car is provided with a pilot, which is used to spread any dirt that may chance to lie between the rails. The lower part of this pilot is made of a 12-in. plank, hung on hinges in such a manner that it reaches within 1 in. of the rail when the car is in use, but can be folded up out of the way while the car is being transported, as shown in Fig. 288.

An earth-leveling contrivance that has been successfully used on the Yazoo & Mississippi Valley R. R. takes the form of an attachment placed upon an ordinary coal car or gondola car at slight expense, without altering the construction of the car in any respect, the car being in special service only for the time being. The arrangement of the parts was designed by Mr. M. J. Donovan, of Vicksburg, Miss. There is a trussed wing swung from a point underneath the car and held in place by braces attached to the side sill (Fig. 289). This side wing or scraper is 28 ft. long and 24 ins. high. The depth to which the side scraper will level the material is regulated by block and tackle attached to the end of a 10x12-in. x18-ft. timber placed crosswise the car and held by long 1-in. bolts reaching through the sills of the car floor. On this beam there is a windlass for hauling on the tackle, so as to raise or lower the outer end of the scraper. The front end of the scraper is attached to a chain fastened over the car body bolster and it is adjusted in hight by a screw worked by a hand wheel, as shown. In operation the car is drawn over the track by a locomotive or coupled on behind the ballast cars and pulled along with them, thus spreading the material just unloaded. The reach of the scraper is 18 or 20 ft. from the cen-

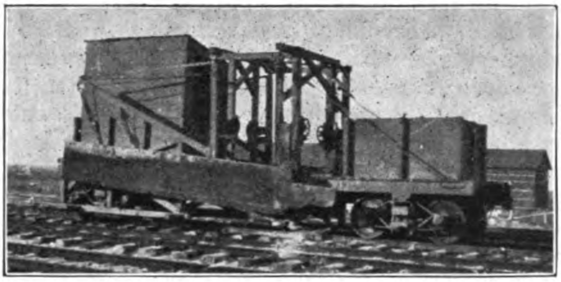

Fig. 290.—Ballast Spreader Car, Chicago Clearing Yard.

ter of the track, according to the hight at which it works. This car has leveled to a distance of 16 ft. from the center of the track, 20 car-loads of earth, extending along the track a distance of 800 ft., in 15 minutes. The wing is notched to fit over the rail, so as to flange the track and clear the material from the ends of the ties. For leveling down gravel unloaded between the tracks of the Chicago Clearing Yard for ballasting purposes, a car with winged scrapers arranged as in Fig. 290 was used. This machine consisted of a flat car loaded down with boxes of ballast at either end, with wings of heavy planking hinged to a beam adjustable vertically. The wings were supported at the back by struts, when in service, and at the middle of the car there was a timber framing, with a derrick at each side to adjust the leveling wing to its work.

In the foregoing descriptions of spreader and bank shouldering cars in service one recognizes two general types; namely, those with which the wings fold against the side of the car on vertical hinges, and those with which the wings fold upward on horizontal hinges. With the former type the wings may be adjusted for hight, but a little time is required to place the brace struts when putting the car into service and to take them down when folding the wings. With the latter type the wings are quickly handled, but they cannot be adjusted for hight.

As explained hitherto, spreader cars, as usually built, have been employed to level off material even with the sub-grade of the old track. The

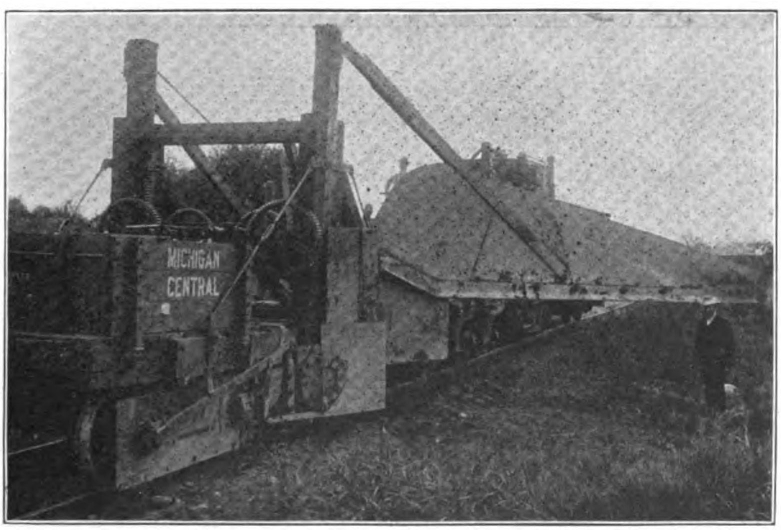

Fig. 290 A.—Torrey High-Bank Spreader Car, Mich. Cent. R. R.

Michigan Central R. R., however, has built and used cars which pile the material up into a bank at the side of the track and then strike it off at a level considerably higher than top of the rail. This type of car, known as a "high-bank spreader and leveler," was designed by the late A. Torrey, chief engineer. The purpose of the machine is to take material which is plowed off the cars to make roadbed for a second track, where the grade is to be raised, and heap it up into a bank, and then level it off on the elevated grade line. The machine was constructed by modifying the design of the wing on one side of a Jordan spreader car. The wing for the high-bank spreader is attached to the same lifting post at a higher point and arranged for such flexibility of adjustment that the earth can be spread on any level from a point 12 ins. below the bottom of the ties to a point 4 ft. 9 ins. above top of rail. The construction of the high wing is illustrated in Fig. 290A, where it is shown in position for spreading earth horizontally at a level about 3 ft. above top of rail. The wing is formed of plank, faced on both sides with

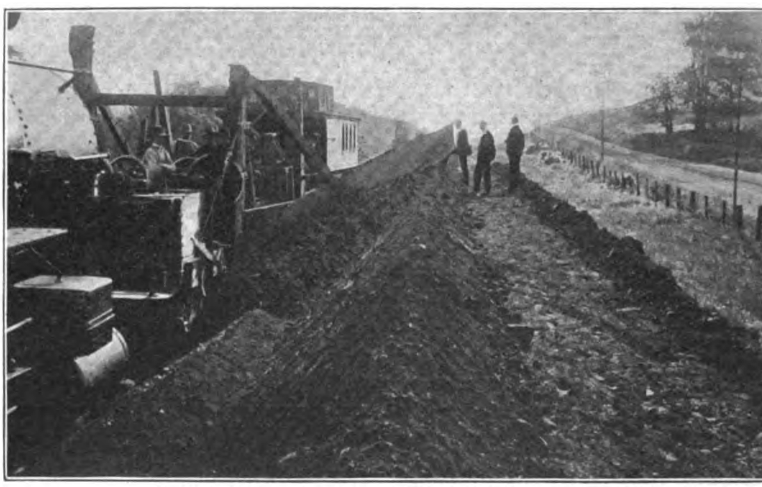

Fig. 290 B.—Torrey High-Bank Spreader Car Elevating Material.

Fig. 290 C.—Torrey High-Bank Spreader Car Levelling Material.

boiler plate, and is attached at the inner end to a heavy plate hinged to the lifting post. To facilitate the adjustment of this high-bank wing to varying inclinations the wing is pivoted to the end of a diagonal brace arm, which may be attached by means of a pin at any of the numerous holes which appear in the illustration. When it is desired to tilt the end of the wing upward for plowing dirt to a level higher than the track, the inner end is depressed and made fast to the hinged plate by a pin connection.

A view of the machine in operation, plowing dirt up to a level about 4½ ft. higher than the track, is shown in Fig. 290B. The material was first plowed from flat cars by a Lidgerwood unloader and train plow, and then the high-bank leveler was pulled along with the wing set to plow the material to the top of the bank already in process of formation, as shown. The next step consists in setting the wing horizontally to spread the elevated material across the bank. This operation is shown in Fig. 290C. Figure 290D is a side view of the same embankment. The men seen standing in the picture give the reader an idea of relative elevations.

Fig. 290 D.—Completed Work Done with Torrey High-Bank Spreader Car.

The advantages derived in the use of this machine are quite important. Referring to Fig. 290D, it will be seen that the new second track can, if desired, be laid 6 or 7 ft. higher than the sub-grade of the old track. Otherwise, to get the new track up to this level it would be necessary to first construct it and then raise it by stages and place the material underneath with shovels. Where this machine is used the new bank is first graded to the higher level, the new track is laid thereon and surfaced and put in shape for the traffic. The old track is then lifted and blocked up on old ties and the material is dumped and plowed over with a spreader car to fill the space underneath. The machines have worked successfully in both sand and heavy clay material, and there has been no trouble in keeping them on the track. When the machine is in service it is operated to plow up each train-load of material immediately after it is unloaded.

In filling for second track against an old slope it is a good plan to bench or step the slope by plowing furrows, to prevent the new fill from sliding. Time should be allowed fills made for second track to settle well before laying the track, because where such is not done it is difficult to keep the track in good surface for some time after the regular trains begin to use it.

Tracks lying close together should be at the same level, and they should also be everywhere a standard distance apart. The most convenient, and certainly the clearest, basis for measurement between the two tracks is between centers, and such affords the most logical data for engineering calculations. The employment of a certain distance between rails to express the distance between the two tracks is rather indefinite and unsatisfactory, for the width of head in rails of different sections varies. A standard distance between centers does not, however, preclude the use of a gage between rails in lining the new track with reference to the old. Where the two tracks are parallel, and on the same roadbed, side by side, and the old track is in good surface and alignment, there is no need for setting either center or rail grade stakes for the new track. Twelve feet between track centers gives sufficient clearance between trains, and on some roads, including, among others, the Boston & Maine, the New York Central & Hudson River, and the Baltimore & Ohio, this is the standard distance; 13 ft. is, however, a more common standard distance; and on a few roads (mostly in the prairie states) 14, and even 15, ft. is standard. Fourteen feet gives room for a ditch between the tracks, and some roads ballasted with dirt are provided with such a ditch. The distance between centers of double track is generally and preferably made a convenient measurement, like an even foot or half foot. It adds to the appearance of things

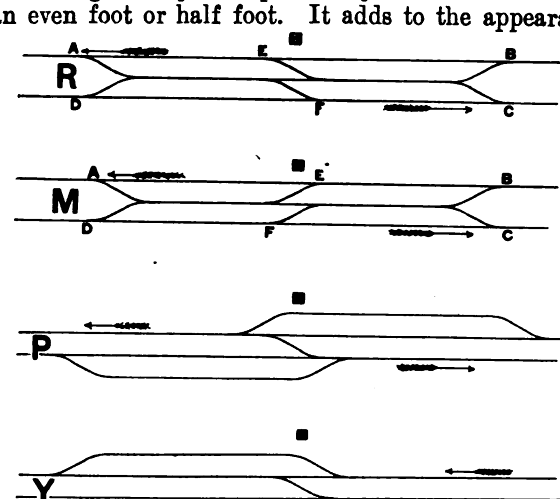

Fig. 291.—Double-Track Passing Sidings.

to fill in full between tracks with ballast, and where gravel is used for ballast this can be done. It also makes good footing for flagmen to alight upon when dropping from moving trains, and affords a supply of ballast for use, as it may be needed, when track is raised and surfaced.

113. Danger to Workmen.—There is one aspect of double-track operation which is not so pleasant to contemplate, knowing, as all do, the freedom with which pedestrians habitually use the track almost everywhere in this country. It is very seldom that any one is struck by a train while walking along a single-track road, because when a train approaches one will get off the track and stay off until after the train has passed. On double track, however, nine people out of ten, if walking along one of the tracks, will, at the approach and passing of a train, step over and walk along the other track. The result of such negligence is a frightful loss of life. During the interval between some little time before an approaching train arrives and for some little time after it has passed, the noise from it will generally drown the sound of any other train which may be approaching, or even whistling; so people who are occupying one track while a train is passing on the other, if not watching, are in much danger of being struck by another train if it should come at this time, especially where the latter is on the outer track of a curve. Many track hands have been killed in this way. It should be a rule strictly enforced that, *under no circumstances will any employee be allowed to work, walk or remain on one of the main* *tracks while a train is passing on an adjacent track.* Disregard of this rule, so obviously essential to safety, was the responsible cause of the wrecking of a passenger train with a track jack, on the Old Colony R. R., at Quincy, Mass., on Aug. 19, 1890. In this wreck 23 people were killed, and since, in the popular misunderstanding, the fault has always been charged to the failure of the track jack to trip, it is well enough that the facts should be stated. The jack was being used on a curve while a train was passing on an adjacent track. In this situation the passenger train, running fast, got so close to the men before they knew of its approach that they were compelled to jump for their lives. The man in charge of the jack (who, by the way, had worked on the track only a few days), was so frightened that he jumped without even attempting to remove the jack. The locomotive was derailed to the outside of the curve and the cars crashed into it. The wreck was therefore due to no ordinary combination of circumstances.

On double track the trackmen should also be on guard against the movement of trains in the reverse direction, which is sometimes necessary when one of the tracks is blocked by a wreck or other obstruction. The fact that such movements are usually of seldom occurrence is one of the elements of danger. On double track the danger at grade highway crossings also is imminent, for so many people will attempt to cross, or drive a team across, just as soon as a train has passed, without taking due care to look for another train moving on the other track. Wherever the public is in the habit of walking on the track a good way to stop it is to scatter good-sized lumps of broken furnace slag over the track and on the shoulders and between the tracks, for some distance in each direction from highway crossings. Such material at least spoils the roadbed for a bicycle path.

114. Sidings for Double Track.—Sidings for double track can best accommodate both tracks if arranged between the two, as then a single siding may serve the traffic in both directions. When changing from single to double track where lap sidings have been in use, such sidings can be made the main tracks of the double line and the old main line between them be used for a siding or passing track. Figure 291 shows two ways (*R* and *M*) of arranging a middle passing track for simultaneously side-tracking trains headed in opposite directions. In arrangement *R* the trains pull in at *B* and *D* and out at *E* and *F*, at the same time, without interference; and while standing, the locomotives of the two trains are together and at the telegraph office or signal tower—a desirable method of handling trains; and the switches opposite the tower are trailing switches. By arrangement *M* trains pull in at *E* and *F* and out at *A* and *C* at the same time, without interference, and, while standing, the cabooses are together and at the tower or telegraph office. By arrangement *R* the switches at *E* and *F*, being under the observation of the telegraph operator or leverman, give him opportunity to know that the switches have been closed after the trains have left the siding; whereas by arrangement *M* he would not necessarily know this unless the distant switches at *A* and *C* were operated from his tower or under control from that point. In *M*, the switches opposite the tower are facing switches. In case more than one train moving in each direction is to be accommodated the siding is simply made of length to correspond. The great convenience in locating the siding between the tracks is that in case of a rush of freight business the whole siding capacity for both tracks may be used by trains running in either direction without having to use or move across the other main track; but in order to effect this arrangement in *M* the facing switches *B* and *D* are required, which is an objectionable feature, and for which reason they are sometimes omitted. Arrangement *R* is therefore the preferable one, because the capacity of the whole siding is available to trains from either direction without introducing an extra facing switch.

In order to have a middle siding on straight line one or both main tracks must be curved reversely at each end of the siding, for which and for other reasons passing tracks are often located outside the main tracks, as shown by arrangements *Y* and *P*. The difference in the arrangement of the two determines simply whether trains shall pull in at the tower or pull out at the tower, the relative advantages being the same as were just explained for middle sidings. The arrangement with a middle siding occupies less room in width of right of way than that of outside sidings, but it does not permit of connection with branch side-tracks independent of main line, as do outside sidings. Outside sidings also afford a basis for the construction of third and fourth tracks, in case the development of the road proceeds that far. It is to be noted that when the switches opposite the tower are operated from the tower, arrangements *R* and *P* permit trains to pull out of the siding without stopping to close the switch, and arrangements *M* and *Y* permit trains to pull into the siding without first stopping to open the switch, either arrangement operating to facilitate train movements.

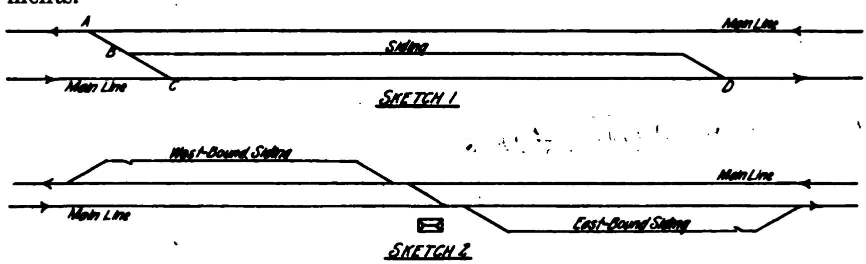

Fig. 292.—Double-Track Passing Sidings.

The safest but least expeditious arrangement of double-track passing sidings is to lay spur tracks leading from trailing switches, by which arrangement, of course, the trains must back into the siding, as when using a crossover, which is habitually laid trailing to the train movements. An arrangement for laying a double middle siding with all switches trailing is shown as Sketch 1, Fig. 292, *AC* being a crossover and *BD* the passing siding, which may be long enough to hold trains backed in from both main tracks.

In both of the sketches *P* and *Y*, Fig. 291, the crossover is located within the lap of the outside sidings. If it is intended to have the trains pull in at the tower, as in Sketch *Y*, it is convenient to arrange the switches entering the sidings to face each other and stand far enough apart to lay the crossover in between, as in Sketch 2, Fig. 292. In emergency this arrangement permits backing a train over from either track into the siding for the other track, by a direct movement, and when pulling back again the train moves straight ahead through the crossover. Such is the arrangement of passing sidings on the Philadelphia division of the Baltimore & Ohio R. R. The sidings are 6000 ft. long, extending each way from a crossover which stands opposite an interlocking cabin, from which the crossover and the switches entering the sidings are operated. The switches at the outgoing ends of the sidings are controlled from the cabin by electric locks. In connection with this lock there is a visual signal which gives the indication of the right of a train to leave the siding for the main track. For protection against fouling main line at the ends of these sidings there are the usual derailing switches, and as the main line is protected by automatic semaphore block signals, the switches are electrically connected with the block system to show "danger" at the first block signal in the rear whenever a switch is opened.

CHAPTER IX.

TRACK TOOLS.

115.—Reports of the Interstate Commerce Commission show that, on the average, about 62 per cent of the cost of track maintenance is represented in the pay rolls of the section men and foremen. The cost for labor in track maintenance is therefore a high figure. Now nearly all of the time of trackmen is necessarily employed in work which involves the use of tools; and hence the selection of proper tools, and a knowledge of how they should be used are matters of great importance in the expense of keeping track in repair. By looking attentively to these things the roadmaster or supervisor may sometimes find opportunity to reduce the expenses of his department without curtailing its effectiveness. By such supervision it is often possible to increase the output of labor in such a way that the laborer is unconscious of it. A poor tool will discourage even a good man, while a good tool gives a lazy man no excuse, mental or otherwise, why he should not do fair work. As track labor is usually paid about the lowest rates paid for any labor, it is not to be expected that all men will take an enthusiastic interest in the work. Many men, after they get somewhat acquainted with the work, acquire a sort of indifference to it and naturally fall into such an attitude, between the work on the one hand and the vigilance of the foreman on the other, as affords them, on the whole, the greatest ease of mind and body. Such being the case, it is highly important that any policy or measure which can increase the efficiency of the work in spite of any little faults common to human nature, shall be taken advantage of. Now there is nothing which will so induce a man to turn out good work, in both quantity and quality, as will a good tool. Out of curiosity he will wish to "see the thing work" and before this curiosity has entirely worn away he will have established a gait which he cannot consistently slacken.

It should be a rule with roadmasters to provide only the best tools; keep them in good working condition; teach men how to use them; and if they are ordinary men there is but little else concerning the work which will need special attention. The first cost of good track tools, as a rule, is but little, if any, more than that of poor ones, and the ultimate cost is far less. The points which should be looked after in selecting tools are two: first of all, tools should be of such form and weight as will best adapt them to the work and enable them to be handled with such facility that there can be turned out a maximum of work for the time they are in use; and secondly, tools should be durable. A set of tools which would work well on one section might need some modification in apparently minor but important particulars to adapt them to the work of another section where the conditions are different. Tools should be as light as is consistent with the strength of the material. Reduction in the weight decreases the load to be carried around by the men and, as many tools are paid for by the pound, such reduction effects a direct saving of expense to the company. On the selection of tools one might enlarge to a great extent. Of all track questions that laymen are sometimes called upon to settle, they never get farther at sea in any than when selecting track tools.

116. Tools Required.—Each section crew should be supplied with enough tools to keep each man busy while engaged at the different kinds of ordinary track work, and there should be some to spare of such kinds as usually have to be sent away at times for repairs. There may arise special occasions when all the men in a crew will need certain tools of the same kind, but if such occasions are only of seldom occurrence it is not worth while to provide for them. Take, for instance, the matter of wrenches. It is seldom that more than three wrenches will be in use at the same time in a crew of six men, for the reason that in most kinds of section work requiring the use of the wrench there will be other parts of the work requiring the use of hammers, claw bars, etc. The same applies also to the gage. A second gage may lie in the tool house for years unused; and besides, a gage is very easily duplicated, if emergency require. A narrow strip of board notched at the ends to fit over the rail heads answers very well for temporary use.

The item of tools for a whole division is such a large one that it is not advisable to place on each section all the tools that may possibly be needed there on some special occasion. Just enough to answer such needs as have been found in general experience should be furnished and no more. An over-abundance of tools has a tendency to make foremen careless of them and less watchful that all taken out of the tool house in the morning get back in the evening. Tools lost will be most diligently looked for when such deficiency creates a shortage in the number necessary to supply immediate needs. At headquarters, however, there should be kept a sufficient supply to be drawn upon as tools of the different sections become broken beyond repair, worn out or lost, and such will generally answer any unusual demand which may come suddenly in case of washouts, wrecks, slides, etc. Below is given a list of tools supposed to be a sufficient supply for a section crew consisting of a foreman and 6 men:

Adzes	2
Ax (chopping)	1
Hand Ax	1
Auger, 2-in.	1
Claw Bars	2
Crow Bars	0
Pinch Bars	6
Raising Bar	1
Tamping Bars	8
Brace and Bits	1
Brooms (coarse)	2
Brush Hooks	2
Hand Car	1
Push Car	1
Car Chains	2
Track Chisels	12
Cold Chisels	2
Wood Chisel	1
Curving Hooks	2
Chalk Line	100 ft.
Ditch Line	150 ft.
Drawshave	1
Cups or Dippers (tin)	2
Files	3
Flags, red	4
Flags, green	2
Ballast Forks*	4
Gage	1
Grindstone	1
Spike Hammers	4
Sledge Hammer (16 lbs)	1
Striking Ham'r (10 lbs)	1
Nail Hammer (claw)	1
Ballast Hammers*	6
Hatchet	1
Hoe (garden)	1
Jack (track)	1
Switch Key	1
White Lanterns	2
Red Lanterns	2
Green Lanterns	2
Level Board	1
Spirit Level (pocket)	1
Switch Locks (extra)	2
Mattocks	2
Oil Can, 1 gal.	1
Oil Can, 2 gals.	1
Squirt Oiler	1
Padlocks	2
Picks	8
Tamping Picks*	8
Hand Punch	1
Rake (garden)	1
Rail Drill	1
Drill Bits	6
Rule, 2 ft.	1
Grass Scythes	4
Brush Scythes	4
Snaths	4
Track Shovels	8
Scoop Shovels	4
Long-handle Shovel	1
Hack Saw Frame	1
Hack Saw Blades	12
Hand Saw	1
Crosscut Saw	1
Screw Driver	1
Spade	1
Steel Square	1
Tape Line (50 ft. graduated to tenths)	1
Rail Tongs	4
Tool Box	1
Tool Checks	6
Torpedoes (with box)	24
Verona Spike Puller	1
Vise	1
Water Pail or Jug	1
Weed Scuffles	6
Wheelbarrows	3
Whetstones	4
Wire Stretcher	1
Track Wrenches	3
Monkey Wrench (8-in.)	1

*Needed only in stone ballast.

A few extra handles for spike hammers, picks, axes and adzes, and an extra white and extra red globe for the lanterns should be kept on hand at all times. It is well to oil wooden handles for track tools, including shovel handles, before they are used, as it will prevent season checking and render them less absorptive of water when exposed to rain. In a wooded country 3 peavies (*K*, Fig. 309) or 3 cant hooks (*G*, Fig. 309), and 5 or 6 iron wedges for wood should be furnished each section. Where heavy rocks are liable to slide or roll upon the track, drills or jumpers, powder, fuse and wedges for stone should be kept on the section. Two or three jim-crows should also be kept at headquarters, and each foreman advised to send for one, if needed, and to return it when he is through with it. Sections which include large yards or numerous switches should be supplied with a rail bender or jim-crow each; or on roads where the switches are numerous and more or less evenly distributed, a jim-crow might be furnished alternate sections, so as to be conveniently accessible to each crew when wanted. If a day track-walker is employed he should be furnished with a spike hammer and wrench, each of lighter weight than ordinary. Night track-walkers should furnish their own lanterns. On sections where tie plates are used a tie plate gage, sets or followers and beetles should be furnished. In mellow soil at least one post-hole digger should be supplied each section. On sections where culverts or bridge openings are liable to be obstructed by floods a half dozen pike poles and 150 ft. of 1-in. rope, with single and double blocks, are useful appliances at times. A description of the most commonly used tools, with remarks upon their use, now follows.

117. Shovels.—First in importance among track tools—traditionally so, at any rate—is the shovel. The one best adapted to track work has a short handle and a square-pointed blade: in the parlance of trackmen it is known as the "Regulation No. 2." Its appearance is so generally familiar that it need not be illustrated here, but a reference to certain features of construction and the dimensions may prove of value. The proper size of blade is about 12 ins. long, and 9½ or 10 ins. wide at the working edge or "point." The handle should be about 27 ins. long (direct measurement), from the top of the blade, and so crooked that when the blade is in position for filling, on a level surface, the end of the handle is 18 ins. above the ground. This is the hight of the knee of a man of ordinary size when the leg is bent as in the act of shoving the blade forward to fill it. When a handle is crooked or hung to the blade in this manner the straight part of the handle makes an angle of about 33 deg. with the straight or flat part of the blade, which refers to the bottom of the blade for a length of about 6 ins. from the point. Owing to this angularity of the handle the over-all length of a shovel with parts of the above dimensions is about 38 ins. The diameter of the handle is about 1½ ins. at the straps, tapering to 1¼ ins. at the tip. The weight of such a shovel, with an ash handle and a blade $^3/_{32}$ in. thick, is 5¾ lbs. The weight should not exceed 6½ lbs. As the shovel is much used for tamping, the blade should be stiff. The best shovels are now made from a single piece of crucible cast steel, the blade, socket and straps all forming one piece, without weld or rivets. The thickness of the blade for light work is $^1/_{16}$ in., but for railroad service it should be at least $^3/_{32}$ in. or about No. 11 Brown & Sharp gage. The blade can also be made to increase slightly in thickness from point to socket, so as to give added strength or stiffness where the strain is most severe. A committee of the Roadmasters' Association of America, in 1894, recommended a shovel made from one piece of crucible cast steel, with "straps strengthened by a socket for the handle extending at least 1¾ ins. above the blade."

Where dirt ballast is not used an all-wood handle is preferable to a wood handle with a malleable tip. For adapting shovel handles to the work of tamping dirt ballast several forms of cast or malleable iron "D" tips are on the market. One form (Jackson's patent) is shown in Fig. 293. The grip is hollow and is formed in suitable shape for tamping, but is rounded at the corners so as to be easy on the hand. These metal tamping tips are also useful in repairing broken shovel handles. If shovels are properly cared for they will not be left out in the rain or exposed to a hot sun. In the former case the handle will swell and sliver itself, turn out the edges of the straps or burst the rivets and loosen the straps. In hot sun the grip is liable to check, get loose and revolve on the end rivet to the annoyance of the shoveler.

Although the work of shoveling with a short handle is somewhat severe on the back, at first, men can, after they get accustomed to it, handle a given quantity of material with a short-handle shovel more easily than with one having a long handle. The blade of a long-handle shovel is not as large as that of a short-handle shovel, for the reason that a man cannot lift as much material with a long handle as he can by taking hold up close to the load, as he necessarily does when using a short-handle shovel. A long handle has to be griped more firmly in the hands, although it is not so easy to gripe and hold as is the short handle; it is therefore more tiresome to the hands and arms than is a short handle. It takes up room and does not permit as many men to work in a given space as the short handle does. Even laying aside track work, the long handle is inferior to the short handle anywhere one takes it except in digging post holes and deep, narrow ditches. Notwithstanding such considerations, however, some roads use it in all kinds of track work.

Fig. 293.

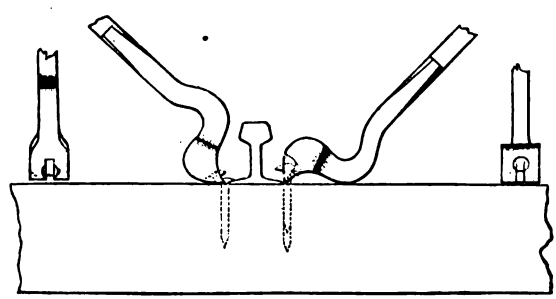

Fig. 294.—The Hamm Claw Bar.

One would naturally suppose that any man could learn to shovel dirt without instruction; but such is not the case. Some men tire themselves out at it and still do but very little. In casting material with a shovel there are two things to observe in order to make the work easy: the shoveler should continually make or seek a horizontal bed upon which his shovel may be easily pushed under the material, the end of the handle then coming at such a hight that the back of the hand grasping it may rest against the inside of the leg at the knee; and when casting an ordinary distance one heel should be kept in place. If one is casting toward the right he should keep the left heel in place, and simply turn toward the right by moving the right foot when in the act of making the cast; when casting toward the left he should keep the right heel in place, moving only the left foot. It is tiresome to keep up a fair gait with a shovel and at the same time to be needlessly stepping around. Some men while shoveling will, in addition thereto, in the course of a day, take enough unnecessary steps to walk several miles.

A shovel blade worn off to less than 9 ins. length is practically worn out for the purpose of handling material or tamping, and its further use becomes unprofitable. Every day's work with such a shovel will, compared with the use of a new tool, lose to the company at least one third of the price of a new shovel. After laying aside enough old shovels at the tool house to use for cutting grass in the track the rest should be turned in to headquarters, as the handles might be of further service. If the edge of a shovel blade turns up one should not flatten it out again with a hammer, but hold the blade on the rail and take a square cutting across it with a track chisel, cutting off also the sharp corners where the blade turns up at the side. Each man should be allowed to have his own shovel, if he so desires, as he will then be more interested to take care of it. The cost of shovels in track repairs is a large item.

The long-handle shovel included in the list of tools is for digging holes and narrow ditches, and should be round pointed. Scoop shovels are useful for handling snow and cinders. They will handle snow which is quite solidly compacted and, under such conditions, the scoop is a much better tool for the purpose than the snow shovel. Snow shovels with wooden blades are of but little account around the track. A snow shovel with wooden handle and sheet steel blade about 13 or 14 ins. wide and 13½ to 15½ ins. long is a good tool for clearing snow from depot platforms and from side-tracks and other places where the snow has not been compacted, but for all purposes the scoop shovel is better. Mention has heretofore been made of the ballast fork, for handling stone ballast. This tool is similar to a dungfork, but somewhat larger and stronger, and with closer tines. It has a track-shovel handle (Engraving *D*, Fig. 309). The standard fork adopted by the New England Roadmasters' Association has 10 tines 13¼ ins. long, spaced 1 in. apart, the width of the fork being 10⅞ ins. The Pennsylvania R. R. has two standard ballast forks, one being 12¾ ins. wide, with 14 tines ¼ in. wide and 13¼ ins. long, and another, for coarser material, 12 ins. wide, with eight tines $^5/_{16}$ in. wide and 13¼ ins. long.

118. Picks.—In railroading, the proverbial mate for the shovel is the pick. The kind used on railroads (*A*, Fig. 295) is commonly known as the "clay pick." One end should be wedge-shaped, having an edge about ⅞ in. wide, and the other end should be pyramidal; the two ends are generally known as "wedge-pointed" and "pick-pointed," respectively. The wedge point is useful for pulling ballast from the sides of ties in preparation for tamping with the bars, and also for picking material which is not very hard or compact. The pick point is made for picking hard material, or to enable the pick to hold fast when struck into timber or ties, without breaking off the point—as would happen to the wedge point. Picks having solid cast steel eyes are best, as they do not split. If properly made of wrought iron, however, they answer quite well. A pick made of iron is usually formed by welding together, over a properly shaped mandrel to form the eye, two pieces of iron, ½x2x12 ins., and drawing out. The ends or points are made by splitting the iron and welding pieces of cast steel into them. The eye should be oval, 2x3 ins., and 2½ or 3 ins. deep. The length of a new pick from point to point should be about 22 ins., and when worked down to about 18 ins. it should be pieced or drawn out again. A pick longer than 22 ins. is rather unwieldy, and one less than 18 ins. in length is too short. A weight of 6½ or 6¾ lbs. exclusive of the handle is heavy enough for a pick.

A pick, to work well, should be anchored to a radius of about 32 ins., and should have a handle 3 ft. long—which is the usual length. The anchoring of the pick is an important feature, for if the pick is straight or nearly so it will jar the user's hands in working it, and if it is curved too much the picker cannot strike a straight blow. When the pick is properly anchored, the secret of loosening material with it, if the material is not too hard and compacted, is to strike and draw a little at the same time. Unless the material is very hard there is no necessity for swinging the pick over the shoulder in striking: simply raise it up in front of the body and draw toward yourself as the point enters the ground. When using a pick for a lever, as when striking it into a tie to spring a rail, one should pull on the free end of the pick, so that it will not be necessary to bear too hard on the handle. In opening out a tie to be bar-tamped, after the tie has been raised, the proper way is to strike into the ballast a few blows, first toward the rail, each side of the tie, to loosen the material, and then turn and draw it out with the wedge-pointed end of the pick. Picks to do good work must be kept sharply pointed. When it is inconvenient to send them to the shop they may be easily and quickly sharpened for a few times by heating in a fire beside the track and drawing out the point with a spike hammer, using the rail for an anvil. An ingenious foreman or section hand ought, after practicing once or twice, to be able to give the metal the right temper.

A tamping pick differs from an ordinary pick only in having in place of the wedge point a tamping head or rectangular piece of steel welded on. A head $2\frac{1}{4}$ ins. long by 4 ins. wide by about $\frac{5}{8}$ or $\frac{3}{4}$ in. thick at the edge is a common size for this tamping end, and this form is called the "T" tamping pick, shown by Engraving *B*, Fig. 295. The standard tamping pick adopted by the Roadmasters' Association of America is of this form. It is $24\frac{1}{2}$ ins. long from tip to tip, the center of the eye being $12\frac{1}{2}$ ins. from the pick end and 12 ins. from the tamping end. The tamping head is $2\frac{1}{4}$ ins. long, 4 ins wide, and $\frac{1}{2}$ in. thick on the striking edge. The weight of the tool without the handle is $8\frac{1}{2}$ lbs. Another form, known as the "V" tamping pick (*C*, Fig. 295), differs from it slightly in having the tamping end of

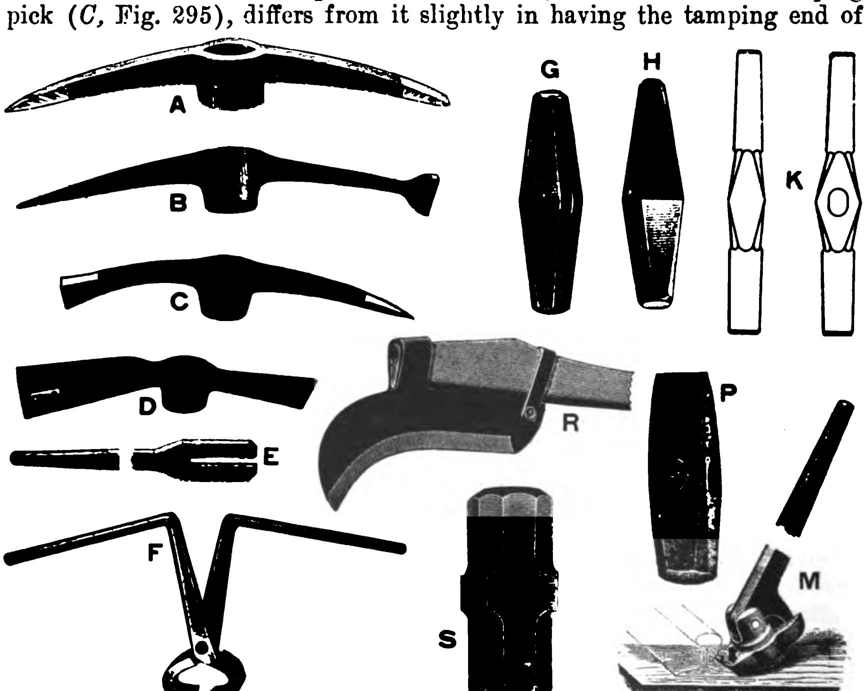

Fig. 295.—Various Track Tools.

the pick about 2½ to 3 ins. wide and the same thickness, but drawn out gradually back toward the eye, instead of having a rectangular piece welded to the end of the pick proper. It gives more metal to draw from when the pick needs repairing, but is heavier, weighing about 9 lbs.

Eyeless picks are extensively used. This pick is constructed of one solid bar of hard steel, to the middle of which two malleable iron lugs are riveted to form the socket. The handle is held in the socket by a bolt passing through one of the lugs and the handle, and screwing into the other lug, as shown in Fig. 301. These lugs protect the handle from being cut when striking under the rail with the pick, and if the handle shrinks and gets loose it may be tightened by screwing up on the bolt. The mattock (*D*, Fig. 295) is useful in cutting roots and sod, in ditching, and in other rough work at grubbing, for which an ax is not suitable. It has two long steel blades, one like an ax, the other like an adz. The two edges thus cut in planes at right angles to each other, the "cutter" being 4½ to 6 ins. long, with a 3 or 3½-in. edge, and the "hoe" end 8 to 8½ ins. long, with a 3½ to 4¼-in edge. The tool is 16 to 17½ ins. long over all and weighs 5 to 6 lbs. without the handle. The eye should be made to fit the common pick handle. The grub hoe, which is a mattock minus the cutter, is not as useful as the mattock for railroad work.

119. Hammers.—The spike hammer or maul should be made of solid steel. The blow from a hammer made wholly of steel is more effective than that from an iron hammer of equal weight faced with steel, swung with equal force: the softer material in the body of the hammer has the effect of cushioning the blow; that is, it undergoes more compression from the reaction of the blow than is the case with a hammer made of solid steel. This effect is most noticeable when spiking hardwood ties or striking chisels. The best weight for general section work is 8 lbs., without the handle. The proper length for section work is about 10¾ ins., and the hammer should be double faced, the two ends or faces being circular and about $1^7/_{16}$ ins. and ¾ in. diameter, respectively. These faces should be almost flat—that is, but very slightly convex—and their edges or circumferences should be rounded off but very little. At the eye the cross section should be rectangular, with slightly beveled corners, and between this and the faces the metal should be nicely drawn out so as to meet the faces without beveling. The shape of the eye is oval, and the usual size ¾x1¼ ins. The center point of the eye should be about 5 ins. from the larger face, so as to leave the other end a little longer for reaching spikes behind guard rails. Of the hammers shown in Fig. 295, Engraving *H* illustrates these requirements better than Engraving *G*. For track-laying, where heavy blows count, a hammer 1 or 2 lbs. heavier, or one weighing 9 or 10 lbs. (according to the quality of the timber—soft or hard), is better; and there is some advantage to be had if it is about 2 ins. longer—say 12½ or 13 ins. long—because then the spiker does not have to stoop so low in delivering the blow. For general section work, however, there is a great deal of spiking which does not require heavy blows continuously, and the spiker does not swing the hammer over his shoulder so frequently as in continuous driving in new timber. For such purposes the 9-lb. hammer is too heavy and a hammer 12½ ins. long is somewhat unwieldy for quick work. Men who do a good deal of work around switches will understand what I mean. In a general way it may be said that the contractor, whose work is mainly to lay track, needs a heavier and longer hammer than the one most serviceable for the purposes of general section work.

Spiking hammers are usually made from 2x2-in. bars of cast steel. The eye is formed by first punching the blank with a taper punch, allowing the stock to swell out, and then a round mandrel is inserted in the hole and the blank squared up, leaving an oval hole. The ends are drawn out on taper dies, under the hammer. Track chisels are made in much the same way. In order to hang the handle properly it is important that the eye should be straight through, or perpendicular to, the hammer head. If the hole is not just true it may be corrected by putting the hammer in a vise and filing the hole straight with a round file. Another hammer of quite different shape from the foregoing is used to some extent. The center portion for a length of about 5 ins., containing the eye, is of square section with beveled corners, tapering to ends of circular section, as shown by Engraving *K*, Fig. 295. The faces at the large and small ends are about $1\frac{1}{2}$ and $1\frac{1}{8}$ ins. diam., respectively, the usual length is 15 ins., with the center of the eye 8 ins. from the larger face, and the weight about 10 lbs. These hammers, commonly known as the "Pittsburg" pattern, do fairly well in track-laying, but are ill proportioned for general section work, being too long.

Experienced trackmen differ somewhat in their views regarding the proper shape and proportioning of hammers, and as much as 2 or 3 lbs. in weight. Those whose ties are principally or wholly of hard wood will naturally enough select the heavier hammers. The standard handle is 3 ft. long. If the edges of the face get battered off, the face should be repaired by heating and dressing down. A face too convex, but otherwise in good condition, may be flattened down by holding it in a fixed position against a grindstone. Like chopping with an ax, the knack of driving spikes requires some practice before good work can be done. To do it easily a man must acquire an easy swing, using the full length of the handle, and be able to strike accurately without walking around too much. Muscle-bound men never make good spikers, because they always measure themselves before striking; they first try to get the feet into some certain fixed position, and thus time is lost.

Ballast or "napping" hammers are for breaking stone. They should be solid steel, about $5\frac{1}{2}$ ins. long, and weigh 3 to $3\frac{1}{2}$ lbs. Each of the two faces should be about 1 or $1\frac{1}{4}$ ins. in diameter, or octagonal, and the faces should be quite convex, rather than flat like the face of a spike hammer. The handle of a napping hammer is made small, or considerably reduced in section near the head, so as to give it spring and save it from splitting from the shock of the blows, and to prevent stinging the striker's hands. For breaking up large stones a 12-lb. stone sledge with one convex face and a pein end (*P*, Fig. 295), somewhat similar to a mason's hammer, is used.

A railroad sledge hammer should be double-faced (Engraving *S*, Fig. 295) and weigh about 16 lbs. For striking chisels a 10 or 11-lb. sledge makes the best striking hammer. The faces being large, enables one to strike a fair blow which does not hack or batter the head of the chisel as badly as does the ordinary spike maul, which, except in emergency, should not be used for a striking hammer. Sledges and napping hammers, like spike hammers, should be made of solid steel. An ordinary carpenter's nail hammer or claw hammer is a tool always much needed in section work, but, strangely enough, is seldom furnished. A track-walker's hammer should weigh about 4 lbs. It should have a spiking face on one end and a narrow adz edge on the other end for digging the dirt from the flangeway in crossings and for "bleeding" the ends of ties that are "churning" water.

120. Wrenches.—Track wrenches are sometimes made of 1-in. round iron, with head and jaws of steel, about $\frac{7}{8}$ in. thick, welded on. It is considered better practice, however, to die-forge the tool out of solid steel, and it is to some extent the practice to punch the material out of old steel boiler plate. Short pieces cut from the ends of soft steel bars in the car shops are also worked up into wrenches and tamping bars to some extent. High carbon steel is not considered good material for track wrenches, as the tendency with this material is to break in the jaws. In order to catch a nut readily the jaws should be no longer than is necessary to engage the corners of the nut. Where hexagonal nuts are used the space between the jaws should conform to the shape of the nut; or at any rate the space should be so curved into the shank that an apex or corner of the nut cannot reach the shank and interfere with the proper function of the jaws. A track wrench should have two heads—one on each end—for several reasons. Almost all track nuts will vary in size slightly, and it is not possible to gage one pair of jaws to fit them all; besides, a wrench works better where it fits the nuts rather loosely. For this reason the jaws on one end should be made to fit the standard nut snugly, and those on the other end should make a loose fit. Such a wrench will answer for all ordinary variations, and it is a much better arrangement than to have single-headed wrenches of two different gages; or, as happens in some cases, to have no wrench at all which will fit nuts which are a little larger or smaller than the standard, or nuts with the corners somewhat worn. Another advantage is that a double-headed wrench can be handled with greater facility. There is an easier bearing for the hands and the wrench is balanced better; for the reason that, while turning on a nut, many turns must usually be given before the nut turns hard enough to require much force at the wrench handle, and hence the double-ended wrench has weight on the swinging end to receive momentum from the applied force and steady the motion of the hands. Any man who has used a double-headed wrench will readily notice how awkward it comes to afterward use a single-headed one. It is quite common practice to make wrenches single-headed and to taper down the last 3 or 4 ins. at the end of the handle to a smaller size, so as to enable it to be thrust through the holes in splice bars to bring them opposite the bolt holes in the rail, in splicing. This form is not a good one, as it makes the wrench too small just where the pressure from the hands comes when the most force has to be exerted; besides, by thrusting the wrench through bolt holes it usually becomes bent and cut about the end, thus rendering it disagreeable to handle. A chisel or pinch point on the end of a wrench is likewise a nuisance.

A track wrench should be straight. A crooked or S-shaped wrench handle is intended for use around machinery, or for catching a nut in close quarters which cannot be reached by a straight wrench, for lack of room. On track bolts, where there is clear space, it is not as serviceable as a straight wrench, for it cannot be so conveniently manipulated. Track wrenches are often made too long, rendering them unwieldy and making it possible to twist off or break bolts without the application of much strength. A wrench for the largest bolts should not be longer than 19 ins. over all. Wrenches wholly of steel can be made considerably lighter than those composed partly of iron, and are better. The usual weight is about 5 lbs. A track-walker's wrench is usually made flat the whole length, and if made of the best cast steel it need not weigh more than 3 lbs. If a wrench is but slightly too loose for the nuts, the jaws may be tightened sufficiently by hammering the shank, cold. Hold the shank of the wrench on the rail, edgewise, and strike it a few smart blows just far enough back on the shank not to bend the jaws. In this way the shank is squeezed and the gage of the jaws tightened without fracturing them. Wrenches should not be permitted to become worn so much that the jaws slip appreciably on the corners of the nuts. Such action is liable to break the wrench and it spoils the nuts, rendering them unfit for further service. When sending a wrench to the shops for regaging, a nut of the proper size should be tied fast to the wrench.

To use a wrench properly one should stand with the toe of the shoe against the bolt head, to hold it, and work with the wrench across the rail, thus affording a rest for the wrench head while catching the nut. If there is anything that is irritating when one is in a hurry it is to have to wait on the awkwardness of a man who will habitually stand on the same side of the rail with the nut in turning it on or off with a wrench, while the bolt is wiggling in its place, there being no rest for the wrench head, so that at each stroke it must be placed on the nut by a special effort with both hands.

Ordinary track wrenches will not fit the nuts of frog bolts, and trackmen often resort to turning them on or off by striking them around with hammer and chisel. Where a considerable number of bolted frogs are in use, wrenches should be had which fit both the nuts and heads of the frog bolts; and where thick beveled washers are not placed under the nut and head, so that they stand out clear from under the head of the rail, the wrenches ought to be of the box pattern.

121. Claw Bars.—A poor claw bar is a provoking thing, because it is wasteful of both time and effort. In order to pull a spike with reasonable rapidity the principal thing to accomplish is to readily get firm hold of it, and the thing of next importance is to be able in the quickest manner to get the spike started; all other objects which might be desired in connection with the pulling of spikes, if combined, are not so essential or important as these two. It is a wrong idea to sacrifice any advantages in these respects, no matter what accomplishments can be had in other ways. After a spike has been started, even as little as $\frac{1}{8}$ in., it can then be easily pulled by almost any kind of a claw bar, because a better hold can be had, and also because the holding power of the spike has been largely reduced. Now in order to get firm hold of a spike readily the claws must be of such shape that they can be shoved straddle the spike and under its head, in a manner not to slip back and let go when force is applied to the bar. Owing to the fact that the fibers of the tie are often broomed about the head of the spike, where the flange of the rail has cut into them, the ends of the claws should be cutting edges about $\frac{5}{8}$ in. wide; not necessarily sharp, but such an edge as can be thrust through or into the wood, so as to get the claws under the head of the spike. Back of the edges the claws should be dished out between and on top, so as to make a sort of notch to hold the head of the spike.

Having thus provided for a firm hold on the spike, the next essential, in order to start it most easily, is all the leverage possible for a proper length of bar. This means a short, thick heel, turning up more or less abruptly, so that, as the bar is revolved on the heel, the leverage will not be decreased by the point of contact moving farther away from the ends of the claws. Now it is clear that the leverage of a claw bar which turns up at the end by a long curve will vary widely with the slant of the bar, depending on how far the spike has been driven into the tie, and the shape of the surface of the tie just back of the spike; and depending somewhat, also, on whether the tie is soft enough to let the bar crush into it. Spikes in soft and springy ties are sometimes as hard to start as in oak, for the reason that the force exerted on the bar crushes or compresses the fulcrum over which it is acting, thus cushioning the blow or force applied, which has the effect of prolonging its time of application, thereby diminishing the intensity of the instantaneous applied force; at the same time it locates the heel farther back on the bar and consequently reduces its leverage. Of course, ties must be taken as they are found; and, consequently in pulling spikes, any drawbacks which arise from the condition of the tie surface can best be overcome by having a bar which as nearly as possible meets the conditions laid down. One other thing besides the firm hold and the leverage aids a great deal in starting a hard-pulling spike, and that is a stiff bar. A bar which will spring considerably when force is applied to it in pulling a spike has its efficiency for pulling reduced in the same manner as when pulling on springy wood; all the force exerted reaches the spike eventually, but the springing of the bar lengthens the time during which the force is applied, and makes of it a less force applied more or less uniformly during several instants or small portions of time, rather than a heavy force, applied instantly (or nearly so); which latter force, of course, has the greater starting effect on the spike.

From experience with many types of claw bars I have concluded that the one which most nearly fulfills the requirements above noted is the old-fashioned straight claw bar, often called the "bull's foot" bar; which term quite nearly expresses the shape of the bar. This bar answers more requirements which determine for speed in pulling spikes than any other with which I am acquainted. No bar as yet devised has been able to answer all the purposes which might be desired for it. The question of a proper form of claw bar is one of great importance, and it has been discussed for a great many years in conventions of track officials. Thousands of men have exercised their ingenuity in trying to design an all-around claw bar, but no change in the "bull's foot" has been made without impairing one or more of its three important features; viz., the readily-griping and firmly-holding claws, the short heel, and the possibility of making the bar stiff. The importance of combining these three features in one bar has in cases been so far overlooked that many worthless products have been turned out. It is no easy matter to properly shape a claw bar, but it is a tool well worthy of considerable attention.

Two objects, especially, men have sought to accomplish in designing claw bars: to pull the spike, either at a single stroke, or, at any rate, without having to place a fulcrum or "bait" under the heel of the bar after the spike has been partly drawn, in order to pull it the remainder of the way out; and to pull the spike all the way out at one stroke without bending it. Neither of these objects has been accomplished by a bar which is equal in efficiency to the plain straight bar. An idea having the first object in view is to place a U-bend in the bar back of the claws, to serve as a fulcrum after the spike has been started. Such a bend introduces the principle of the tuning fork and makes the bar quite springy, unless an amount of metal be placed in the bend such as would make the bar enormously heavy. In one form of claw bar of the "goose-neck" type the U-bend extends backward from the claws, so that in getting hold of the spike the bar must be held in a vertical position, or nearly so, thereby affording the operator no opportunity to throw his weight upon it. Another form of this type quite widely known is the Hamm bar, invented about 1883 by an employee of that name in the service of the Lehigh Valley R. R., where it was first introduced. The method of using the bar is made quite plain in Fig. 294. In the position of the bar at starting the spike the bend is upward. After the spike has been started and pulled part way out the bar is reversed and the pulling is completed by using the bend for a fulcrum.

A long curve at the end of a claw bar has the objection of locating the heel too far away, as heretofore explained, and requires also that the bar at starting the spike must stand nearly perpendicular to the tie, so that the operator must necessarily pull on the bar instead of being able to throw his weight down upon it. A bar having a pointed heel—that is, a heel formed into an edge or corner—will bend a spike while drawing it only part way, because the corner of the heel bites into the tie and holds it (the heel) in one position, so that the head of the spike as it comes out must revolve about the heel as a center, whereas it should move upward in a straight line. A short heel curved properly will turn around just enough in pulling a spike to lift it straight out, as far as the spike can be lifted at each stroke. Figure 296 is about my idea of a properly designed claw bar. The claws, to be strong, must be short without being so blunt that they cannot be readily thrust under the head of the spike; and to hold the head firmly they should be close together; say ⅝ in. for ordinary $^9/_{16}$x$^9/_{16}$-in. spikes. At their extremities, however, the claws should be about $^{11}/_{16}$ or ¾ in. apart, depending a good deal on whether the kind of spike in use is enlarged in the neck. Considerable material must be distributed about the claws and for a foot or so above them, to give strength. The width of the bar, taken just above the claws, should be about 2¾ ins., and the depth through it at the heel, 2⅞ ins. The angle which the main part of the bar makes with the under

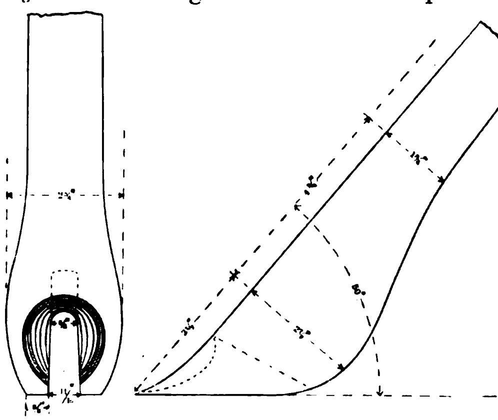

Fig. 296.—Bull's Foot Claw Bar.

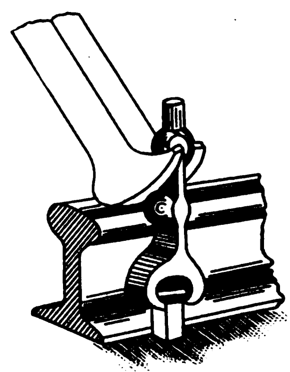

Fig. 297.—Verona Spike Puller.

sides of the claw should be about 50 degrees. From the heel the bar should curve away in cross section to about 1¾ ins. square (corners beveled or rounded off) at 8 or 9 ins. from the claws, and then gradually down to 1⅛ ins. round at the end of the bar. The bar need not be longer than 4 ft. 10 ins. over all—just long enough to reach over the opposite rail when pulling spikes inside the track. A long bar lacks stiffness. The weight of such a bar as is here described is about 30 lbs., which is heavy enough. A short bar of given weight is stronger than a longer one of same weight, and is more easily handled.

It is sometimes the practice to weld cast steel or crucible tool steel claws into an iron or soft steel bar, but it is better to have the claws, heel, and several inches of the bar one piece of steel, if welding of different materials is done at all. In considerable practice the entire bar, including the claws, is made out of soft steel.

Pulling spikes is the hardest kind of work, and the easier one tries to make it the harder does it become. If the spike head is down pretty close to, or against, the face of the tie, or into the broomed edge of the rut cut by the rail flange, turn the bar over and chip away the wood by jabbing into it with the ends of the claws; or, if the spike head and tie face are covered with grease, throw some sand around the spike or crush a pebble or chunk of cinder thereon with the bar. The bar should be grasped with the right hand at about 15 ins. from the claws (right-handed man) and with the left hand near the other end, raised high, so that the bar stands 50 or

60 degrees with the tie face. Then, standing close up to the spike and nearly over it, by a well aimed thrust, drive the claws forcibly straddle the spike and under the head. If the claws are of good steel there need be no fear of breaking them. When a firm hold is had, raise slightly the end of the bar with the left hand, bring the right hand up to the middle of the bar, and, by a quick move, shove the bar down, at the same time throwing considerable weight of the body with the arms. A hard-pulling spike must be started by a heavy, sudden jerk of the bar; it cannot be started easily by a steady push or pull. The operator should always stand over his bar. One cannot exert much force, nor do it so easily, by pulling down on the end of the bar; besides, if the bar slips or the spike head breaks off the operator is liable to take a tumble, with the bar on top of him. After the spike is started, give the bar a push or two and, when within a foot or so of the ground, push it farther down by stepping on it with the foot at about the middle of the bar, throwing the weight of the body thereon. A straight bar will not pull a spike more than half way out at one stroke, and if the tie is quite solid another stroke must be taken, using a fulcrum or "bait." In old ties, however, the spike may usually be pulled at one stroke. After the spike has been pulled as far as it can be at a single stroke, hold the bar at an angle of about 30 degrees with the tie, suddenly jerk the claws up against the head, and in three cases out of four the spike will come out; or, if pulling outside the rail at a place where the ballast is not filled in against the ends of the ties level with the tops, after the spike is started shove the bar down forcibly, catch it with the foot and keep it going right on down over the end of the tie, and generally the spike will fly into the air. One need not be a bit timid as to how he uses a well-made claw bar so long as he uses it for no other purpose than that of pulling spikes.

Now in pulling spikes with such a bar—that is, a straight bar—there is no need of bending the spikes. If the spikes pull hard all the way out, a stone or block of wood about 2 ins. thick should be used for a fulcrum; and, by catching the spike head, after it has been started, with the ends of the claws in line with the body of the spike instead of shoving the claws under the head so far that they take hold at the point of the head, the spike can be pulled straight out in two strokes. There is no need of having an extra man along to hold a spike hammer or pick for a fulcrum. A lively man can raise the bar with one hand while he places the fulcrum under with the other; but, as stated, in three cases out of four, while pulling spikes from ordinary ties, he will need no fulcrum. An aid in starting spikes in sound, oak ties, or in freezing weather, is to give the spike a slight tap down with a hammer, before attempting to pull. It is almost painful to witness the contortions of some men in pulling spikes. Men green at the business usually waste much strength, unless well instructed, and lazy men are liable to get their necks unjointed. The latter invariably go about the work as though the claw bar was the thing at fault instead of themselves. Wherever one sees two men pulling on one claw bar, or a man holding the bar while another is pounding the heel with a hammer to drive the claws under the head of the spike, it is a pretty sure indication that either a different kind of bar is needed or a different kind of man.

Where there is not room to use a claw bar, as, for instance, behind guard rails, spikes may be pulled by a sharp pinch bar, the spike being started by thrusting the point of the bar under the head of the spike. Such, however, is a slow and tedious operation. A special tool for griping the heads of spikes behind guard rails, or in other places where there is not sufficient room to use a claw bar, is made by the Verona Tool Company. It is used in connection with an ordinary claw bar, and is a labor-saving device.

It consists of a single straight piece of steel about 9½ ins. long, formed into solid jaws on one end for griping the spike head, and into two knots or bulges at and near the other end for engaging with the claw bar. When pulling the spike the claw bar rests on the top of the rail, as in Fig. 297. The stem is 1 in.x½ in. in section, the jaws ⅝ in. thick and the opening of the jaws ¾ in. It is simple and light, not being much larger than a track spike, and no section crew should be without one. For elevated roads, where guard rails or guard timbers are usually close to the rail, a special form of bar for pulling spikes is generally used. The Manhattan Elevated Ry., of New York, uses a bar with a curved foot, to the end of which there is hinged a shackle with solid jaws to catch the head of the spike. The curved foot rests on the rail, while the spikes are being pulled. The arrangement works in a manner similar to the use of the Verona device with a claw bar, except that the stem of the jaws is hinged to the bar instead of fitting in between the claws.

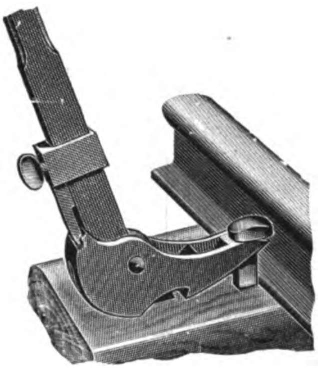

Fig. 298.

Fig. 299.

A form of shackle bar in common use for pulling drift bolts in bridge work is an ordinary pinch bar with a hinged shackle near the point, as in Engraving *H*, Fig. 309, the bar taking hold by slipping the shackle over the end of the bolt and placing a fulcrum under the heel of the bar. A shackle bar known as the Lewis "drift bolt and spike puller" is shown in Figs. 298 and 299. It takes the form of a heavy pinch bar, with a hinged foot or shackle, and a sleeve which slides along the bar and regulates the operation of the shackle in connection with the bar proper. In Fig. 298 the device is displayed as a spike puller or claw bar. The length of the shackle is such that it may be thrust between the rail and guard timber or guard rail and engage the spike without such interference as is experienced with the ordinary claw bar. By setting the sleeve thumb screw the shackle is held rigidly immovable with the bar proper. By loosening the sleeve and tilting the bar forward, with the shackle in the position shown in Fig. 299, the sleeve may be slipped farther down on the bar, so as to hold the bar at a new inclination with the shackle—that is, the inclination is changed from an obtuse to an acute angle. By this arrangement the bar is permitted a wider range of movement in front of the guard timber or guard rail. Figure 299 displays the arrangement of the parts for pulling drift bolts. The sleeve is moved upward on the bar and clamped in a position which holds it clear of the shackle. The drift bolt or other rod is then engaged between the point of the bar proper and an inner edge of the shackle, in a clutch-like manner. The device will pull a nail of any size, track spike, ship spike, bridge or drift bolt, with or without head. The length of the bar is 4 ft. 6 ins. and the weight 28 to 30 lbs. The Mogul spike and drift bolt puller, shown as Engraving *M*, Fig. 295, consists of a pair of jaws hinged to a head to which is pivoted a bar with a heavy lug which wedges between the jaws at the back and forces them tightly together at the pulling side when force is exerted on the bar. The jaws are the fulcrum of the bar. It is intended for use in pulling track spikes, drift bolts, boat spikes from crossing plank or track spikes without heads. By letting go of a spike that has been pulled part way out and raising the bar a new hold can be taken on the spike lower down, so that by repeating the process the spike can be pulled straight up. It is drop-forged from steel and is 5 ft. long.

122. Pinch Bars.—The working end of a bar, whether it be drawn to an apex or to an edge, is known as the "point." Plain, straight bars are pointed in several ways, each kind of bar taking its name from the way it is pointed. A wedge-pointed bar is generally known as a "crow bar;" and a bar with a common chisel point, a track "pinch bar"—as distinguished from another form of pinch bar which has both a round end and a sharp edge or heel, used exclusively for "pinching" or starting cars. A diamond-pointed bar—that is, one the end of which is drawn to an apex, like a right pyramid, so that the apex is on the axis of the bar—is called a "bridge" or "timber" bar; if the end of the bar is formed as an oblique pyramid, so that the apex or point lies in the plane of one of the sides of the bar, it is called (but for no special reason) a "lining" bar. To make these descriptions entirely clear, perspective and end views of each kind of bar are shown in Fig. 300.

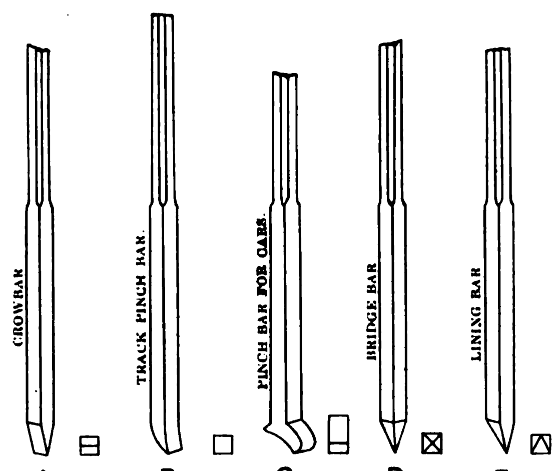

Fig. 300.—Various Ways of Pointing Bars.

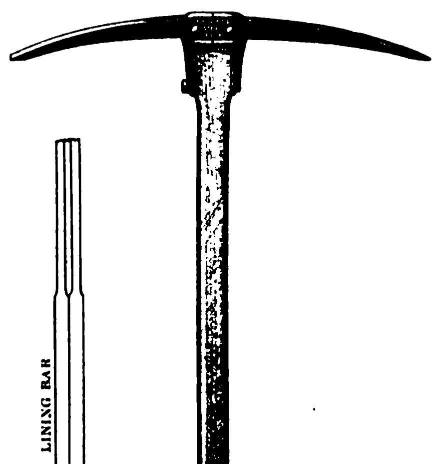

Fig. 301.—Eyeless Pick.

In track work a lever or plain bar of proper form answers a great variety of purposes. There is scarcely any piece of work undertaken where such a tool is not needed. The form of bar which gives best satisfaction is the pinch bar. The question of a proper form of point for bars used in track work is of the highest importance, and expensive track work is often chargeable to ignorance of this fact. As proof that such ignorance prevails to some extent, one may sometimes see trackmen working with crow bars. Now a crow bar, as such, is of no special use in track work, and the only use for it anywhere is for jabbing holes into the ground for driving fence posts. A crow bar can be used in lining, but for any other purpose on track it is indeed an irritating thing. It has been so customary with many to use the term "lining" bar for any kind of bar used as a lever in throwing or lining track, whether it be a crow bar, pinch bar, or other, that it is not generally understood by the term just what kind of bar is really meant. The term is not particularly significant when applied to any special form of bar, but the pinch bar is the best for lining track, on account of the bearing surface it presents at its extreme end when prying against the ground or the ballast—which is important in throwing track. A crow bar used flatwise the point gives the same bearing, but its tendency is to slip back, whereas a pinch bar tends to catch and hold when the prying force is exerted. Some prefer a bar like that shown as Engraving *E*, Fig. 300, because it can be poked through the ballast easily. Such advantage, however, is unimportant, for there is no difficulty in this respect with a pinch bar kept reasonably sharp. If there was any material advantage to be gained in this respect, a point like that shown at *D* would be superior to any; but either are poor points for holding against any ballast except broken stone. A bar for nipping or pinching rail, ties, etc., is in continual demand, is indispensable, and none but the pinch bar so well answers such purposes. It is an easy matter to keep its point in working condition, because it is broad and strong, whereas a point like that shown at *E* would soon break off while nipping or prying under rails, and thus render the bar worthless for this purpose until repaired. As, in any case, it would be impracticable to have differently pointed bars for all the different uses, it is fortunate that the pinch bar answers best for each and every one of them; and none other should therefore be used.

The pinch bar should be as light as is consistent with strength. As it is a tool which must be picked up frequently and swung around and handled quickly, any excess in length makes it cumbersome, and besides, the longer the bar the larger must it be made in cross section in order to withstand bending in service. Four feet 9 ins. is about the length at which a bar can be made stiff enough to withstand all one man can exert in throwing track, and at the same time be not too heavy to handle for other purposes. A bar of this length should weigh about 20 lbs. Beginning at the point it should be $1\frac{1}{4}$ ins. square for about 16 ins., $1\frac{1}{8}$ ins. octagon for 16 ins. more, and taper off to $1^1/_{16}$ ins. round in the remaining 25 ins. One can accomplish more with a bar of this length and weight than with a longer one weighing 25 to 30 lbs. The difference becomes very appreciable where a man has to carry a bar for several hours, and swing and thrust with it, as in lining track, or even to pick it up quickly for a moment's use every little while, as when laying a turnout, or while using it in tie renewals, etc. It is a mistake to make a bar heavy at one end and taper it off to $\frac{7}{8}$ in. or smaller at the other. There are several reasons for this. In the first place, anything less than 1 in. in diameter is too small to grasp in the hand and agreeably exert strength against. A man will unconsciously lift most on the bar which gives his fingers the most comfortable hold. If the end of the bar is small enough, it will be used in the bolt holes in rails and become badly cut, in time, and thus rendered disagreeable to handle. Too much weight at one end makes a bar unhandy to pick up and swing around at light work. Moreover, in lining track where the ballast is soft and the bar is thrust far in, it will be bent near the middle, if light at this point. While the distribution of metal in one end of the bar should be something more than at the other end, it should not, for the reasons stated, greatly preponderate over the weight at the middle. The bar which can be handled with greatest facility is the one which most nearly balances in the hand when picked up at or near the middle. Another mistake sometimes made is to point both ends of the bar; and the same applies also to pointing the ends of claw bars (sometimes done for chipping wood from around the heads of spikes) and tamping bars. For handling timber, both ends of a bar should be pointed, one end having a long or sharp diamond point, but in track work there is but little or no use for such, and it is actually detrimental to the serviceableness of the bar. Men will handle somewhat timorously any tool which has a sharp point or edge continually pointing toward them. The end of a pinch bar, tamping bar or claw bar which is uppermost, in ordinary usage should be nicely rounded off, so as not to be unpleasant to grasp. Men who have not handled these tools much might think such matters of little account.

Solid steel pinch bars are best, but if the bar is made of iron it should have a hard steel point or tip welded on. The point should be very slightly turned up, and its length should be about 1¾ times the thickness of the bar. Iron bars are easiest repaired, when broken. A very good pinch bar is made by cutting off to right length, and pointing, a piece of octagon steel bar of 1⅛ inches short diameter. While not quite as stiff as a bar having the same amount of metal distributed as above described, so that one end of the bar is heavier than the other, and of square cross section, it is quite stiff enough, and is more agreeable to handle than any other bar; besides, it is not far from the right weight (16 lbs.), and it is cheap. Many prefer this kind of bar to any other.

One of the best tests of the worth of a trackman is to observe how he handles himself when using a pinch bar. It is a tool with which much can be made to move if one uses it easily and with intelligence. Some men, if about to lift a rail slightly, will persistently attempt to pry it loose from the tie to which it is spiked, instead of nipping it upon a tie which is not spiked; and such men as are in the habit of lifting ties by prying over a fulcrum which is 12 to 18 ins. or farther from the end of the bar, or who will attempt to raise track by taking a "lubber lift" under the rail, should be taught (if possible) the simple principles of the lever.

123. Tamping Bars.—The tamping bar is frequently made too heavy. It should not weigh more than 10 lbs., and it should not be longer than 5 ft. 3 ins. over all. The handle should not be more than ¾ in. in diameter; if of steel it need not be more than $^{11}/_{16}$ in. diameter. Soft steel is the best material. A bar of the latter size is more severe on the hands than one of larger diameter, but this is easily remedied by holding a piece of leather in the hand which grasps the end of the bar. As tamping is very severe on the hands, anyhow, until after one's hands become very callous, many use a glove or piece of leather on one hand at all times, with any size of handle. A very good arrangement for making the bar easier on the hands is an enlargement of the handle at the end, the end being formed by welding on a 6-in. piece of 1-in. pipe, plugged at the end, thus making the bar of agreeable size where it is grasped, without adding appreciably to the weight of the bar. The pan or tamping head of the bar should be steel, about 3½ ins. long, 3½ ins. wide and ½ in. thick. Where the track is old and the bed hard, having been well kept up, so that the lift when tamping is small, the pan should be drawn down to ⅜ in. on the striking edge; for new track the thickness should be ½ or ⅝ in. The handle should be straight, except near the pan, where it should be reversely crooked, so that a man may stand nearly erect, with his feet between the ties, and, by swinging the bar at arm's length, the arms hanging downward, be able to drive the pan of the bar under the tie horizontally. The pan ought to make an angle of about 35 degrees with the direction of the handle. The flattening of the end of the tamping bar handle into a spade for removing ballast from the side of the tie is not approvable. In compacted gravel or other ballast such an arrangement amounts to but little or nothing, and in any kind of ballast the pick is a superior tool for this purpose, as heretofore stated. A handle of such form is also worked with less facility and comfort.

The knack of working a tamping bar with ease and effect is to let it swing at arm's length, as stated above, and not to strike with it as one would handle a spear in spearing fish; at the same time it should be given force by raising it vertically, as it is withdrawn, and allowing it to fall as it swings toward the tie. The practice of holding a tamping bar in front of the chest and striking with it from the shoulder is very tiresome. Rapidity in tamping depends on the gait rather than upon the force of the blow, altogether, and for this reason the bar should not be as heavy as some make it. Any man who will order a tamping bar made with a handle ⅞ in. in diameter and a head 4 ins. wide, the tool weighing 12 or 13 lbs., if obliged to use it, would certainly change his mind. In order that the work may be effectively done, the ballast between the ties, when tamping, should be kept at least as high as the lower edge of the tie, in order to form a backing to hold in the material which has been hardened. Tamping bar handles should be kept clean and free from abrasions. Rust can be quickly removed from the handle by drawing it a few times back and forth through a heap of gravel or cinders. To keep the handle from heating to an uncomfortable temperature while not in use, as during the noon hour on hot days, it may be run into the ground or into a heap of ballast.

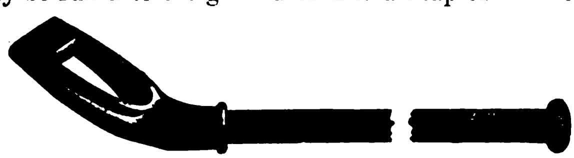

Fig. 302.—Jackson Tamping Bar for Dirt Ballast.

Tamping bars with wooden handles are used to some extent. The Hoxie patent tamping bar has a wooden handle about the size of a pitchfork handle, and the tamping part is made of cast steel with a socket, into which the wooden handle is fitted. It is so heavy and clumsy, however, that it is not as desirable to use as a bar with a smaller iron handle made all in one piece in the usual way. The Jackson tamping bar (Fig. 302) has a gas pipe handle combined with a malleable tamper, with the intention of securing strength and rigidity without excessive weight. The tamping head is an adaptation of the special shape in the Jackson tamping handle tip for shovels (Fig. 293). In dirt or sand ballast a bar of this kind ought to do good service. A tool called a "puddle" is sometimes used for tamping gravel, cinders, dirt ballast, or sand. It is essentially a tamping pick with the pick end of the tool cut off near the eye. There is really but little or no demand for a tool of this kind, because the tamping bar or shovel is better adapted for tamping in all kinds of ballast except broken stone or slag, in which materials the tamping pick is used to best effect.

124. Chisels.—A track chisel, or track cold chisel, when new, should be about 8 ins. long, so that there may be plenty of material to work upon as the tool becomes blunted and wears away. The center of the eye should be about 3 ins. from the striking face, and the eye should be punched squarely through the chisel. The head or upper portion should be about 1½ ins. square, in cross section, with corners beveled and tapered toward the top, and the cutting edge about 1⅜ ins. long. The chisel is made wholly of tool steel and its weight is 3¾ to 4½ lbs: a bar 1½x1½x6 ins. will make one. Much care is needed in tempering, so as to get the metal hard enough, and still not so hard as to be brittle. The edge or cutting end should be sharp, but rather bluntly drawn out; a chisel drawn out thinly near the edge will easily fracture. In using a chisel for the first time after sharpening, it is well to play lightly upon it for a few blows. In frosty weather the chisel should be warmed over a fire before using. Chisels cut faster and last longer if a little oil is applied while the rail is being cut. Chisels which become dulled without fracturing or breaking away at the edge may be sharpened on the grindstone for a few times, or until the end becomes so blunt as to require drawing out. In repairing chisels both ends should receive attention, for frequently the striking face will need truing. Many a man has lost an eye in being struck by a flying piece of steel from a track chisel, and danger of this kind is always greatest where the striking face of the chisel is in a battered or ragged condition. Steel is not so liable to fly from a chisel that is being struck by a sledge hammer as from one struck by a spike hammer, because the face of the sledge is large enough to more than cover the face of the chisel; and, being large, is not so liable to miss or make a glancing blow. Old hammer handles cut into pieces 12 or 15 ins. long make good handles for chisels. It is important that the eyes of track chisels should be uniform, so that the same handle will fit them all. The handle should fit the chisel just snugly enough to hold it steady while being struck, but not tightly. A handle that is driven in tightly will sting the holder's hands every time the chisel head is struck an unfair blow.

125. Rail Saws.—On certain occasions there is no more convenient or cheaper method of cutting rails than with a hack saw. In order to cut a rail with the chisel it is necessary to first take the rail out, if it be in the track, while with the hack saw this need not be done. And then, about the shortest piece that can be cut from the end of a rail successfully with hammer and chisel is 3 ins., whereas with the hack saw a piece of any length from $\frac{1}{8}$ in. up may be taken off. It frequently occurs, therefore, that the use of the hack saw can save the expense, waste and inconvenience of having to cut two rails in order to fill a gap a little shorter than the standard rail length. Thus, for instance, in case a piece of rail 29 ft. 10 ins. long was required, most trackmen, if provided with no other cutting tool than the chisel, would use two pieces of about a half rail's length each, making a cut for each or perhaps utilizing a piece already on hand and making a cut for the other. For want of a convenient means of cutting off very short pieces of rail (1 to 3 ins.) foremen will sometimes back the adjacent rails into the joint openings to gain space, so as to use a whole rail and avoid the cut; but since such practice interferes with the allowance for expansion it is not approvable.

The hack saw (*C*, Fig 309) consists of a small toothed blade of hard steel fitted into an adjustable frame resembling the frame of a meat saw. Ten inches is a common length of blade, but for cutting rails heavier than 60 lbs. per yd, the length should be 12 ins. The blades cost but a few cents each, and if carefully used a single blade will make an entire cut. Water is the best lubricant to use on the saw while cutting. For use at stub switches, when moving rails run tight, it is exceedingly serviceable. A small piece may be cut off the end of a rail, in place in the track, in a few minutes, without obstructing the track, and one man can do the work. No section having stub switches should be without hack saws.

Portable rail-sawing machines operated by hand are being extensively used. The Bryant rail saw is shown in Fig. 303. The circular saw is hollow ground and is turned by gearing which drives a sprocket wheel engaging with the back sides of the teeth. Two men are required to turn the cranks. The frame of the machine is clamped to the rail by adjustable jaws and the saw is fed into the rail automatically. The machine is made in different sizes, the diameter of the saw ranging from 16 to $20\frac{1}{2}$ ins. and the weight of the machine from 250 to 285 lbs. The frame is revolvable on its vertical axis, so that both square and miter cuttings can be made. The lubricant for the saw is a thin oil, which drips from a pot provided with a faucet, as shown. A fair estimate of the time required to cut a rail with this machine is stated to be (in minutes) the weight of the rail in pounds per yard divided by five, or 15 minutes for a 75-lb. rail. Each machine is provided with a small grinding attachment for sharpening the teeth. In the Smith portable rail saw (Fig. 304) the blade has a pendulum movement and is operated by two levers, like a hand car. The frame of the machine is clamped to the rail by the revolving wedge *A*, the bolt *B* and a sliding hook. The saw can be quickly raised or lowered by the hand-wheel, but, when cutting, it is fed automatically. The saw is kept taut or rigid in the swinging frame by the straining nut *E*. Soap-suds is the lubricant used. The weight of the machine is 120 lbs.

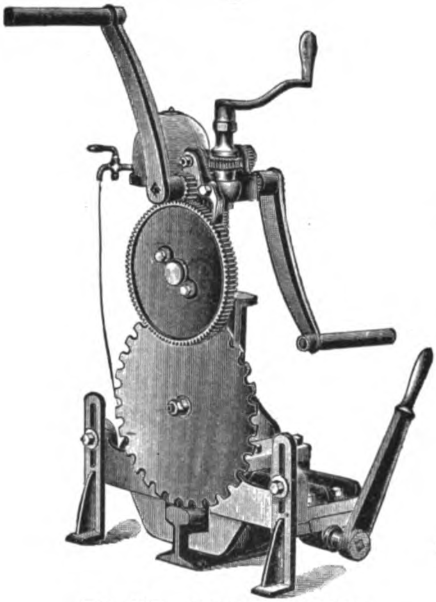

Fig. 303.—Bryant Rail Saw.

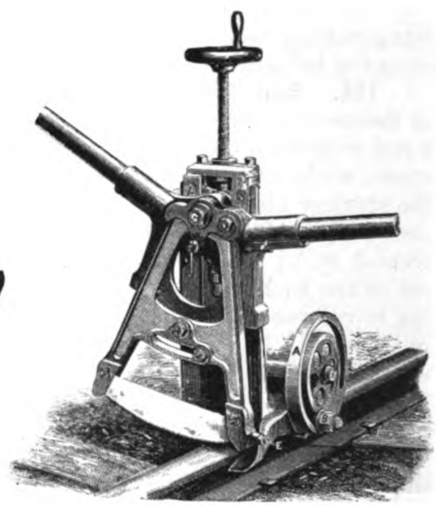

Fig. 304.—Smith Rail Saw.

For cutting rails at a skew, as at miter joints, some kind of rail saw is needed; otherwise the joint at the cut end of each piece of rail used in the track must be squarely cut, which makes it necessary to cut off the skew end of the whole rail meeting at such a joint—or two cuts for one, in many cases. On some roads where skew joints are used it is the practice to make square cuts when laying pieces of rail, while on others a rail saw is used to cut the rail at the proper angle to match with the skew or miter end of the rail that is not cut. Rail-cutting machines are rather too costly to be furnished each section, and, besides, they require more careful handling than track tools usually get. It is advisable, however, to have one or more of these machines on hand at the headquarters of each division, to be sent to points where a good deal of turnout laying or other work involving rail cutting is to be done, and to furnish one to each yard section crew, floating gang and wrecking car.

126. The Gage.—For general purposes the ordinary plain wooden gage with metal lugs is the best. A piece of $1\frac{1}{2}$x2-in. seasoned ash shod with cast iron or brass end lugs, set into the wood their thickness and well screwed fast, is about the proper thing. It should be handled with more care than iron tools usually get, and should be frequently tested. For

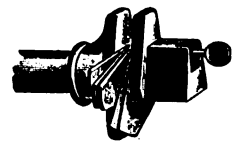

Fig. 305.—McHenry Adjustable Track Gage. **Fig. 306.**

this purpose two metallic lugs or blocks of wood may be screwed fast to a board on the side of the tool house, inside, at proper distance apart, where they are not liable to be disturbed, to serve as a gage tester. A gage tester used on the Michigan Central R. R. is a piece of rail about 6 ft. long with the head taken out between two saw cuts 4 ft. $8\frac{1}{2}$ins. apart.

A piece of $1\frac{1}{4}$-in. iron pipe with two lugs welded on makes a durable gage. In one form of iron or steel pipe gage each end of the pipe is shrunk upon an iron plug which projects beyond the pipe and carries the gaging lug. The change in length of such a gage between 40° F. below zero and 150° F. above, is only about .07 in. At either of these extremes the variation in length from that at average temperature would then be only about .035 in. It is somewhat heavier than a wooden gage, but not so liable to be broken or get out of adjustment. In another form the piece of pipe or cross bar is screwed into malleable end pieces forming the lugs. No form of all-metal gage can be used on track divided into insulated sections for block signal service, since it completes the electrical circuit between opposite rails, the same as a car axle. To interrupt the metallic connection between the rails the continuity of the metal is broken by a piece of wood spliced to the two parts forming the cross bar of the gage. One tool of this kind is the Sheffield pressed steel insulated gage of inverted U-section, illustrated by Fig. 323. The tool is pressed from a single sheet of steel and is light and strong. The central open part or cross bar of the gage is filled with wood, thus materially strengthening it without adding more than a trifle to its weight.

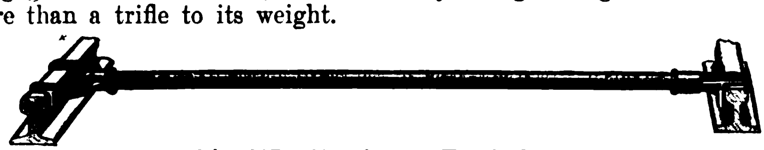

Fig. 307.—Huntington Track Gage.

For convenience and accuracy in gaging curves of widened gage, tool is sometimes provided with an adjustable end, which can be set to measure any desired gage within the limits of widening. A tool of this kind should be used only on curves, if used at all, since the adjustable feature involves the work in risk of mistake. It would therefore seem preferable to use a gage the lugs of which are rigidly set to the standard measure for straight line, and for widened gage on curves to use a shim of proper thickness in connection with the standard gage. On the Atchison, Topeka & Santa Fe Ry. gages with adjustable ends for use on curves are painted red, as a distinguishing mark to remind the foreman of the necessity of looking carefully to the proper adjustment of the tool for the curve on which it is being used. An adjustable gage designed by Mr. E. H. McHenry, when chief engineer of the Northern Pacific Ry., is provided at one end with steel shims, each $\frac{1}{8}$ in. thick, which are revolvable about the axis of the gage, but in standard-gage work are turned up out of the way and clamped to place in a fixed position, by a thumb-screw, as shown in Fig. 305. When it is desired to widen the gage, the proper number of shims to adjust for the required amount of widening are turned down in front of the gaging lug and clamped to place. In the practice of one road where this gage is used on curves, one shim is turned down for each increase in curvature of 3 deg., and the five shims provided allow gaging for all curves up to 15 deg. On easement curves an additional shim is turned down for each 3 deg. of curvature progressively, until the full maximum is reached. An enlarged view of the adjustable end is shown as Fig. 306. The late Mr. Richard Caffrey, of the Lehigh Valley R. R., was the designer of a gage on which one of the lugs is of proper thickness (1¾ ins.) to fit the flangeway of guard rails. In other words, the outer side of the lug is for gaging the running rail and the inner side for gaging the guard rail.

Some trackmen believe that much error creeps into the work of gaging through carelessness in not placing the gage squarely across the rails. With this idea in mind Mr. William S. Huntington many years ago devised a gage with a T-end, shown in Fig. 307. This is sometimes called the "horned" gage, and the device is in quite general use. The two lugs on the forked end are about 6 or 8 ins. apart, and it is generally supposed that in using it men will readily place the gage so that both lugs touch the rail, thus insuring that the cross bar of the gage is set squarely across the track. In my experience I have found such not to be the case, and I regard a gage of this form as a good deal of a nuisance. In the first place, a man who tries to be especially careful in placing the gage on the rails will waste several seconds swinging the gaging end of the tool slightly to and fro to see if both lugs on the other end of the gage are touching the rail; and then, three times out of four the gage will be brought to rest with only one lug touching. Men who do not resort to such "fussing" will seldom

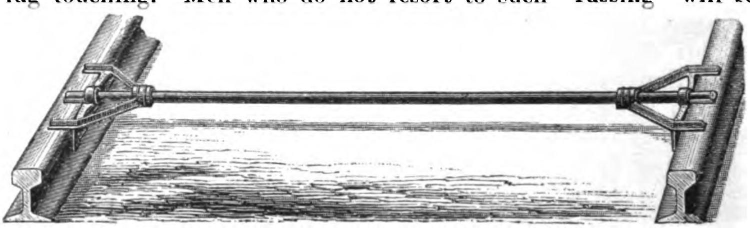

Fig. 308.—Warren Circular-End Track Gage.

get both lugs on the forked end of the gage in touch with the rail. The trouble arises from the circumstance that the T-end of the gage is entirely too short in proportion to the length of the cross bar. In the second place, it should be noted that a careless use of a gage of this form involves the work in greater error than is liable to ensue from the careless use of a straight gage. In swinging a straight gage out of the square or perpendicular position the tool revolves about one end of the cross bar and the error in measurement is a decrease in gage amounting to the versed sine of the arc moved through. In a like movement through a small arc with one end of a Huntington gage, however, the error in measurement is always an increase in gage, because the tool does not swing about one end of the cross bar, but at one extremity of the T-end—that is, at one or the other of the two lugs, thus virtually changing the form of the gage from a "T" to an "L." It will be readily seen how a slight movement of this gage out of the perpendicular position will throw the gaging end out of gage much faster than will a like movement with a straight gage. In other words, if both lugs of the forked end do not coincide with the gage line of the rail, the true length of the gage is not interposed between the rails, but a greater length. Notwithstanding that the Huntington gage is in much favor, the truth of the above statement is, I think, easily demonstrable to the satisfaction of any person who will observe carefully the manner in which the tool is usually handled in actual practice. A committee of the Roadmasters' Association of America, in 1895, reported unfavorably on a gage with a forked end.

It is a very easy matter to place a straight gage on the rails closely enough to the perpendicular position for all practical purposes; and men exercising only ordinary care will do it without loss of time. Men who are inclined to be careless will not do as good work with the Huntington gage as they will with a straight gage. Coming down to fine points, the only gage which eliminates the errors of handling is the Warren tool, shown in Fig. 308. The ends or gaging lugs of this tool are formed as arcs of a circle, of which the diameter is the required gage of the track. By this form of construction the proper gage distance is always had whenever the circular lugs are in contact with both rails, whether the gage is applied to the rails squarely or obliquely. If a circular lug is used on only one end of the gage the curvature of the same should conform to an arc of radius equal to the gage of the track. The same degree of accuracy may be had with the straight gage by swinging one end so as to get the maximum measurement between the rails, which is, of course, the perpendicular distance. Many trackmen make a practice of doing this, and for sake of the moral effect it is to be recommended. For practical use the straight gage is reliable enough, and it lends itself to rapidity of movement better than any other. Gages with segmental or forked ends are somewhat cumbersome and require too much manipulation. The practice of combining a level bubble with a track gage is carrying refinements rather too far, as the usage of a gage is too rough for a level.

For T-rails the lugs on a gage should be deep enough to reach below the rounded corner of the rail head. The question of gage measurement

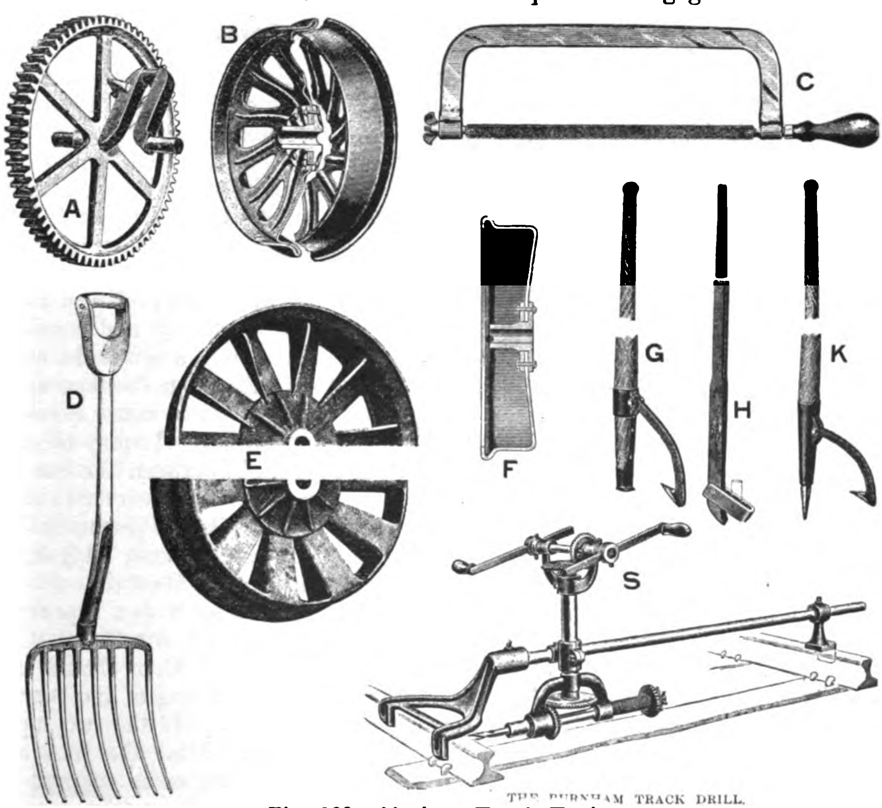

Fig. 309.—Various Track Tools.

between rails having heads with sloping sides is discussed in connection with the subject of rail design (§6, Chap. II). Gages used in street railway work, on girder rails, should have short lugs which will not quite reach the tram. If the lugs are too long they interfere with placing the gage on the top of the rail head, and as a consequence the lug will touch at a point somewhere on the fillet between head and tram. The middle point of a gage should be marked by a tack or notch, for use in throwing track to center. In using a gage of any form trackmen should be careful not to let the rail spring in against the lugs, as in this way the lugs are liable to be loosened or bent.

127. Level Boards.—A level board should be made of a strip of well seasoned white pine, or other soft, light wood, $1\frac{1}{4}$ or $1\frac{1}{2}$ ins. thick. Soft wood is better than hard wood for the purpose, because it forms a better cushion to protect ths spirit tube from hard jarring when the board is set down or falls over on its side. As a means of setting the board for curve elevation the best arrangement is to notch one end of the board into steps. These steps usually rise by increments of $\frac{1}{2}$ in., but sometimes the increment is made $\frac{1}{4}$ in. In the former case the length of the step is usually made 3 ins. and in the latter case $1\frac{1}{2}$ ins. For roads or sections where

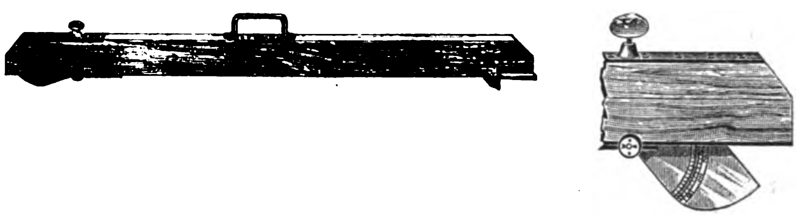

Fig. 310.—McHenry Involute Track Level.

the curves are easy the board need not be notched higher than 4 ins.; but if the curves are sharp the notching should provide for an elevation of 5 ins., or as much higher as is practiced on the particular road. After the board is notched a hand-hole should be cut in such position that the board will balance when carried. An iron handle adds weight to the board, makes it top-heavy, and is always in the way, either to be caught by something and wrenched off or loosened or to be held down by other tools when carried on the hand car; if placed over the spirit tube it obstructs the view to the same. It is a bothersome appendage and not necessarily of any use. The spirit level should be fairly sensitive, responding quickly and considerably at a $\frac{1}{4}$ in. lift in the rail, but of course it need not, and should not, be of the finest grade—that is, one which responds with great freedom and quickness. On the other hand, a sluggish bubble is liable to cause considerable variation in the elevation, and bad work generally. It may be set at any point along the top of the board, but preferably between the hand-hole and the notched end, so as to come under the eye of the observer as the board is set down; for when placing the board on the rails the person holding the board will necessarily be looking toward the notched end. A guard plate set into the board its thickness should be placed over the tube.

It is, of course, an easy matter to set a spirit tube if two supports known to be level are at hand. The tube is simply pressed into the plastic plaster of Paris until the bubble stands at the center. Care should be taken to get the tube parallel with the board, else any leaning of the board out of the vertical will affect the showing of the bubble. If the two supports are not level (but they should be nearly so), adjust the tube so that the bubble remains on one side—that is, toward the same support—and the same distance from the center mark, upon reversing the board.

Then by changing one of the supports, so as to bring the bubble to center, it (the bubble) should remain there upon reversing the board. This done, a coat of oil or varnish should be given the board and, to facilitate finding the right notch, as well as a means of guarding against the use of the wrong notch, in any case, the notches should be numbered on both sides of the board, by integers, as in Fig. 339(A), or every notch, if desired. For the purpose of lightening the board it is the practice with some roads to take out portions of the interior, making two or three openings through the board a foot or so in length and 3 or 4 ins. wide. On some roads very careful preparation is made to facilitate precision of work in setting level tubes. Thus, for instance, the Chicago, Burlington & Quincy Ry. has provided for the purpose, in its shops at West Burlington, Ia., two masonry piers with stone caps, set at the proper distance apart, and steel plates are set in the caps and precisely leveled by scientific methods. All level boards repaired or sent out from the shop are adjusted to perfect level, but as a means of preventing errors which might arise from the absorption of moisture, the board is first boiled in oil before the abjustment is made. The rules of the New York Central & Hudson River R. R. require that during the month of December each year track levels shall be sent to the supervisor for adjustment. They are then painted a color (the same color as tested track gages) to indicate that they have been tested at headquarters.

Instead of a notched level board some use a plain rectangular board about 5 ft. long and 3 or 4 ins. wide, in connection with a "curve block." The latter is simply a piece of board of same thickness as the level board, about 2 ft. long and of proper width, notched or stepped for various amounts of elevation. In using this block, it is, obviously, placed under the level board, and on the inner rail of the curve. If the level board or curve block is notched only to the half inch and it is desired to work to the quarter inch, a shim of ¼ in. thickness is carried in the pocket to give the half step, in case of need. Some disapprove of a notched arrangement of any kind, from fear that error in the work might arise from the use of a wrong notch. A very common substitute for the notched level board is one having an elevation bar sliding vertically in guides in one end of the board and adjustable by means of a thumb-screw. The elevation bar is usually a strip of brass, graduated and provided at the foot with a base plate about 6 ins. long, set at right angles to the board to support it laterally and prevent it from falling over sidewise. In some cases this base plate is flanged, so that it will not slip off the rail. In the use of this form of level board there is, of course, the advantage that the manipulation for the proper elevation is done once for all, in any piece of work, but there is also the disadvantage that when wanted for use the elevation bar will sometimes be found bent or the thumb-screw lost; whereas, in the use of the notched board there is nothing, aside from the spirit level, to get out of order.

Figure 310 shows the "Involute" level, designed by Mr. E. H. McHenry when chief engineer of the Northern Pacific Ry. The desired amount of elevation is secured by means of a plate of hardened tool steel ground to an involute curve and fitted into a slot at one end of the level, as shown by the enlarged end view. The plate is curved in such a way as to touch the rail always at the lowest point as it is drawn out, while the contact with the rail at the other end of the level is maintained stationary by a gage lug. In connection with the gage lug there is also a base plate somewhat wider than the thickness of the level board, to prevent the board from falling over sidewise. The curved plate is graduated both sides for various amounts of elevation up to 6 ins., and is held to the position in which it is set, by a thumb-screw. The "Duplex" level board (Fig. 311) has two spirit tubes—one fixed in the board, and a supplementary level attached to a steel plate "level bar" or movable indicator arm pivoted to the middle of the board at the side and swinging against a graduated arc. The length of the indicator arm is equal to half the distance between the rail centers, carries a pointer at the end and can be clamped to place by a thumb-nut. For use on curves the arm is set at the proper elevation for the outside rail, which is then raised until the bubble indicates the level position. By placing the board across the rails and moving the indicator arm until the bubble in the attached tube comes to center, the amount by which the track is out of level is measured or shown on the scale.

Many trackmen and others have turned their attention to a combination level board and gage, quite unmindful of the fact that these two tools are seldom or never used simultaneously or on the same piece of work. The jarring to which a gage is subjected would soon "paralyze" the spirit tube of a level board and throw it out of adjustment; and moreover, the combination tool is necessarily heavier than either ought to be, which means, of course, less speed in the work. There are many contrivances of this kind, some finished off in grand style, at handsome cost, but all to no worthy purpose. Trackmen should not attempt to work with pocket level and straightedge, because the level, being applied to only a very short length of straightedge, will be thrown badly off by any unevenness in the upper surface or edge of the same, or if placed oblique to the straightedge in the least. A carpenter's level does better and may be

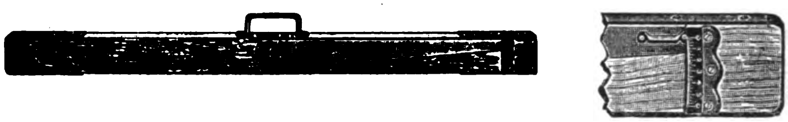

Fig. 311.—Duplex Track Level.

used if a track level is not at hand. Level boards should not be ironed off or shod with metal wear plates. Such construction increases the weight and also the severity of whatever jarring to which the tool is subject. The metal protection (?) and the work of putting it on also cost more than the board, which will wear many years without it, and when worn out it is, after all, nothing but a piece of board to be thrown away. Slight wear of the edge amounts to nothing, or at any rate nothing more than the amount of the wear. As the proper elevation of a curve cannot be determined with mathematical precision, and since in ballasting or tamping track some allowance must always be made for the track to settle, it is folly to split hairs on so many points respecting a track level. Too great care or attention cannot be given the spirit tube, however, since a slight error in setting it is multiplied many times at the end of the level board.

Level boards should be frequently tested, before using, the performance consisting simply in reversing the board on the same supports and noting the position of the bubble, as above explained. It should then be required that when the bubble fails to center on level supports by a certain amount the board should be sent to the shop for repairs. A writer in the "Roadmaster and Foreman" at one time described a level board with an adjustable guard plate used in the following manner: The guard plate is held to the board by bead-head screws through slots near the ends of the plate. In adjusting the plate to the proper position the board is either placed on two supports known to be level, in which case the center mark on the plate is moved to position over the middle of the bubble, or the board is reversed on supports nearly level and the center mark brought to a position midway between the two positions of the bubble for the reversal.

128. Track Jacks.—Not a few are opposed to the use of the track jack, but it is nevertheless a money-saving device on any section, especially if the crew or force is small. With the aid of a jack a crew as small as two men can raise and tamp track to advantage, because the jack can be set to hold the rail while both tamp, whereas, did they use a bar or lever for raising the rail one man must necessarily hold it down ("roost on the bar," as one roadmaster has expressed it) while the other blocks or tamps the tie, unaided. And more than this, the jack has to be set only once, but in a considerable lift with a raising bar the fulcrum may have to be adjusted two or three times before the track is lifted to the desired hight. A man can also raise a heavier load with a jack, because the leverage is greater than it can readily be made with a bar and fulcrum.

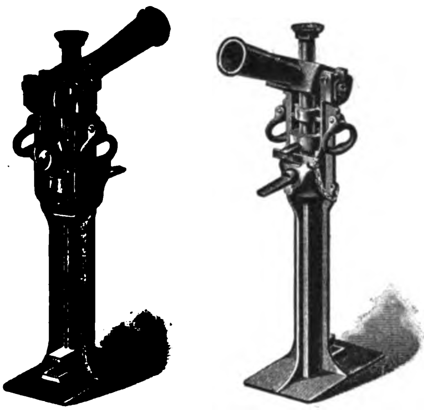

Fig. 312.—Jenne Track Jack.

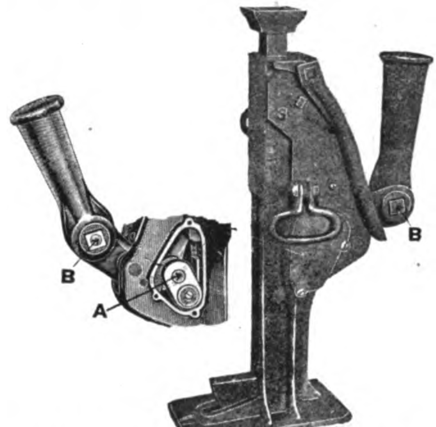

Fig. 313.—Q & C Compound-Lever Jack.

There are track jacks of many patterns. In the most general form there is an upright frame carrying a lifting bar provided with a projecting foot or claw to engage with the rail, the lifting bar being operated by a lever. In an old form the rail is raised by the direct action of a screw turned in an upright frame by a double-handed crank. The screw operates a malleable lifting nut which slides up and down in the frame and engages the rail. In jacks of the common form the lifting bar is operated either on the principle of the ratchet or the friction clutch. One of the best known jacks is the Jenne, shown in Fig. 312. The lifting bar is encircled by two stout rings bored at an angle and $^1/_{32}$ to $^1/_{16}$ in. larger than the diameter of the bar, so that when held in a horizontal position they clutch the bar. The upper ring engages with a hanger or link attached to the lever, and is known as the lifting ring. The lower ring is known as the retaining ring, and rests by a tail piece which projects through a hole in the frame. The support of both rings is by a tail piece or spur, so that a leverage is had on the bar to facilitate the clutching action of the ring. The load is dropped instantly by placing the cross pin under the tail piece of the lifting ring, bearing down on the lever to release the lifting bar from the grip of the retaining ring, and then pressing the tail piece of the retaining ring with the foot; bearing down still farther on the lever, the tail piece of the lifting ring meets with the cross pin and trips the lifting bar. Some trackmen do not use the cross pin at all, but trip the jack simply by removing the lever from its socket and with it jabbing the tail piece of the retaining ring. If the track has not far to drop this can be done, but otherwise the lifting bar will be caught and held by the upper ring. The load can be lowered slowly or by a small amount by bearing down on the lever until the lifting ring holds the load, and then holding the retaining ring with the foot until the load has been lowered the desired distance. If the load is to be lowered some considerable distance, the lifting ring must be held by the tail piece while the lever is pressed down, so as to get a new grip higher up on the lifting bar. The frame and lever socket of this jack are made of malleable iron and the lifting bar and rings of wrought iron. It seldom or never gets out of order and, being readily taken apart, is easily repaired when broken or worn. The jack is made in sizes, ranging from a jack standing 35 ins. high (bar down), with a 15-in. lift, capacity 10 tons and weight 90 lbs., for heavy lifting in ballasting new track, down to a jack 27 ins. high with 10-in. lift and weighing 40 lbs., for light section work, such as raising low joints, etc. No oil or other lubricant should be used on this jack, for the rustier it gets the better it works. Oil and grease may be removed from the bar and rings by scouring them with sand or cinders or better by burning. The bar will not hold when it is frosty, but the frost may be quickly melted with lighted paper. When the lifting bar wears smooth and bright some hack it with a cold chisel to make it hold, but it is better to take it out and burn it.

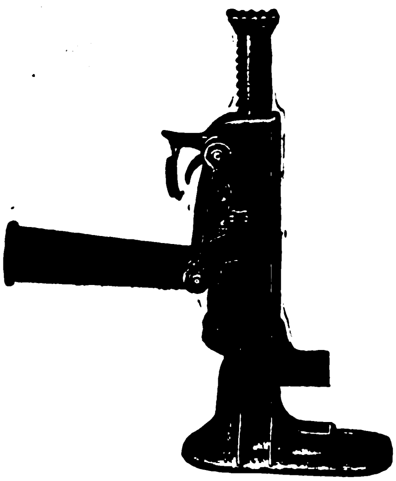

Fig. 314.—Boyer & Radford Jack.

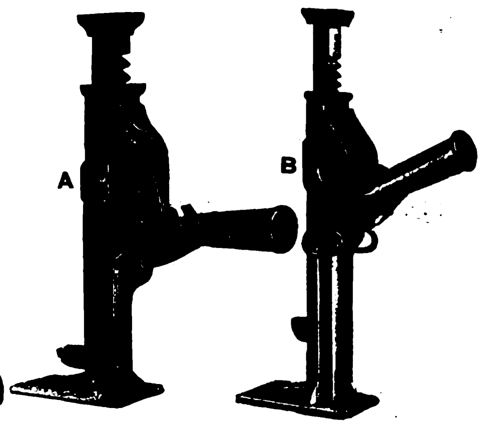

Fig. 315.—Barrett "Trip" Jacks.

The Hawkins jack operates also on the clutch or grip principle, the lifting bar being of circular section, as in the Jenne jack. In principle the operation is very similar to that of the Jenne jack, and about the only essential difference in construction is in the clutching mechanism. In place of rings for the lifting and retaining clutches there is, in each instance, a pair of knuckles engaging opposite sides of the lifting bar. The Q. & C. friction jack (Fig. 322) is quite similar in principle of construction to the Jenne jack, but the arrangement for tripping is simpler. The smallest size has a capacity of 10 tons, lifts 6 ins., stands 17 ins. high with bar down and weighs 55 lbs. Friction clutch jacks possess the advantage that the load can be raised and held at any desired hight, whereas in ratchet jacks the hight lifted cannot be adjusted closer than the length between teeth on the lifting bar, for single-stroke jacks, and half this length for double-acting jacks.

In ratchet jacks there is usually a notched or toothed lifting bar operated by a lifting pawl hinged to the end of a lever, and secured in position by a holding pawl hinged to the frame. In double-acting jacks there are two pawls hinged to the lever, at either side of its fulcrum, alternating as lifting and holding pawls according as the lever is moved on the up or down stroke; hence by this arrangement the lifting bar is moved on both strokes of the lever. In some jacks the lever is compounded, so as to effect a gain in leverage. The Norton "sure drop" jack (Fig. 320) of 10 tons' capacity is 24 ins. high, lifts 15 ins. and weighs 60 lbs. The jack can be tripped without lifting the load. The Verona jack (Fig. 318), of 10 tons' capacity, weighs only 51 lbs. The hight of the jack is 21 ins. and the lift 14 ins. The holding pawl *D* is pivoted to the frame astraddle the rack or lifting bar *B*, and the lifting pawl *E* is hinged with the lever shank *C*. The lever consists of a piece of pipe fitting loosely over the stem of the shank, as shown by the dotted lines. The lifting bar is tripped by pulling back the lower or lifting pawl and bearing down on the lever. By this action the lower pawl is shoved up against the holding pawl, thereby disengaging it. The load can also be let down one tooth at a time. The jack is carried about by taking hold of the stub lever.

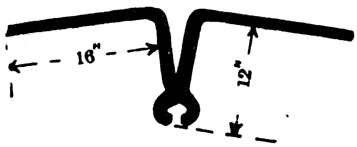

Fig. 316.—Rail Tongs.

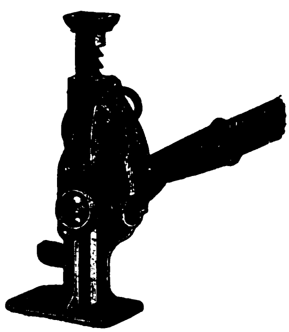

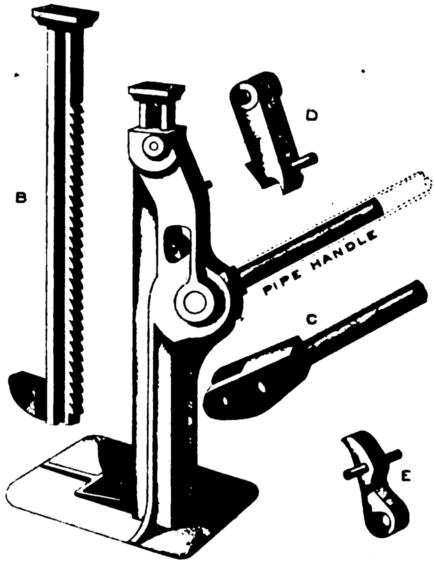

Fig. 317.—Barrett Automatic Lowering Jack. **Fig. 318.—Verona Track Jack.**

Among ratchet jacks the Barrett pattern is very well known and is made in a large variety of sizes and designs, ranging from a capacity of 10 tons, hight (bar down) 17¾ ins., lift 8 ins. and weight 50 lbs., to capacity 15 tons, hight 31 ins., lift 19 ins. and weight 110 lbs. Figure 315(*A*) is a view of "trip" jack No. 1. This jack stands 24 ins. high (with bar down), lifts 13½ ins., has a capacity of 10 tons and weighs 62 lbs. It is double acting, lifting the load on both upward and downward strokes of the lever, a half notch per full stroke. The load is tripped, from any elevation of the lifting bar, by a hook-shaped piece pivoted to the lever socket, which, when thrown forward, catches a pin projecting from the lower pawl and disengages both pawls, upon lowering the lever. View *B*, Fig. 315, shows a larger size of this jack, with a slightly different tripping arrangement, for heavy work in ballasting. The capacity is 15 tons, hight 31 ins., weight 105 lbs. and the lift 19 ins. To trip the lifting bar a small dog, pivoted to the lower pawl, is flipped forward, catching in a notch in the frame of the jack and disengaging both pawls, when the lever is actuated. This jack, and another of similar but lighter design, is also made single acting, elevating the load only on the downward stroke of the lever. The Barrett double-acting automatic lowering jack (Fig. 317) is designed to either raise or lower the load at both upward and downward strokes of the lever. The pawls are held to their work by coiled springs, and there is a thumb-screw at the side of the frame for reversing the order of engagement of the pawls, when it is desired to reverse the motion of the lifting bar. The jack shown is the smallest of four sizes, having a capacity of 10 tons, lift 10 ins., weight 63 lbs. and hight 21 ins. In a modified form of this automatic-lowering jack the lever is single acting, and in another form the double acting, automatic lowering and tripping features are all combined.

The Q. & C. compound-lever jack (Fig. 313), an improvement of the Moore jack, embraces still other features. The lever, instead of operating the lifting pawl direct, actuates two links forming a toggle joint or compound lever, and the lifting pawl is pivoted to this toggle joint, or at *A*, shown in the interior view. By this arrangement a powerful leverage is secured. The lever socket is jointed (at *B*) and is adjustable, as shown by the different angles at which it is set, thereby enabling the jack to be used in places where there is not room for a straight lever. The lifting bar travels one notch per half stroke or two notches per full

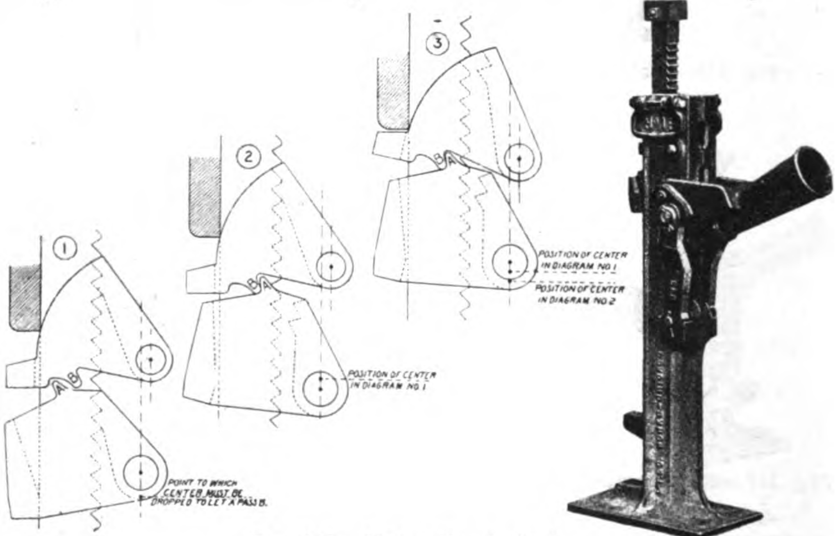

Fig. 319.—Union Track Jack.

stroke of the lever, which is single acting, and is tripped by a small lever or handle on the left side of the jack, as shown. There are three designs of this jack, one being provided with the tripping attachment, another with an automatic lowering arrangement, while the third design combines both these features—namely, tripping and automatic lowering devices. Each design is made in six sizes, ranging as follows: Hight, 18 to 32 ins., lift, 8 to 21 ins.; weight, 45 to 115 lbs.; capacity, 10 to 15 tons.

In the Boyer & Radford jack (Fig. 314) the lifting bar is reinforced the full length by a $\frac{3}{4}$-in. wrought iron bolt, to which the head is screwed. In other respects, also, this jack has some special features. The lever socket is pivoted to a pair of links hanging from the frame of the jack and the lifting pawl has seven teeth which fit into the ratchet of the lifting bar, thereby affording a very secure hold. The holding pawl also engages the lifting bar by teeth. The lifting bar has $^7/_{16}$-in. teeth, and it is raised or lowered two notches per full stroke of the lever. The jack is tripped by means of a floating hook attached to the upper pawl, which can be pushed down and in and fastened so as to hold the pawl out of position: upon raising the lever slightly the lower pawl is released and the bar drops. The lifting pawl is provided with projecting pins at top and bottom, which work loosely in slots in the sides of the frame, thereby limiting the movement of the pawl. The jack shown in the figure weighs 50 lbs., lifts 11½ ins. and has a capacity of 10 tons.

The Union track jack (Fig. 319) is designed with plenty of open space around the lifting bar, so that sand and dirt will not collect inside to clog the movement of the parts. The teeth in the lifting bar are spaced ½ in. apart and a full stroke of the lever moves the lifting bar through a vertical hight of 1½ ins., or a distance corresponding to the length of three teeth. The lifting bar and pawls are of hardened steel, the latter engaging with the lifting bar by double teeth. The lever is supported on a pair of links, and the manner of support is such that a movable fulcrum is obtained, thereby admitting of a variable leverage on the toggle-joint principle. By this arrangement it is possible, with the lever well down, by means of a short stroke, lifting through a distance corresponding to the length of one tooth, to obtain very powerful leverage, since, as the lever reaches the lower position of the stroke, the three joints or points of support come very nearly in a straight line. The movable fulcrum also permits the pin carrying the lifting pawl to travel in a vertical line, so that there is neither rocking motion of the pawl in the teeth of the bar, to cause wear and friction and

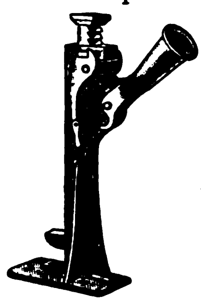

Fig. 320.—Norton Jack.

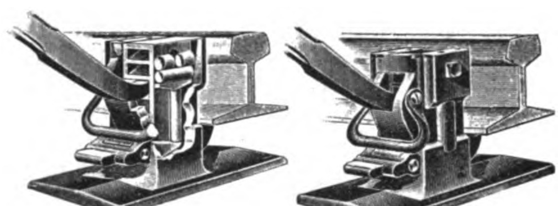

Fig. 321.—Anderson Track Jack.

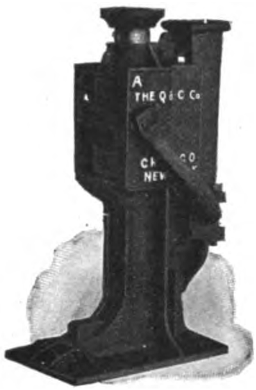
consume part of the force exerted, in overcoming friction, nor is there a horizontal thrust tending to push the bar against the frame of the jack which, did it occur, would consume a considerable part of the force applied, in overcoming friction. The jack is tripped by the engagement of the lower or lifting pawl with the upper or holding pawl, and a depression of the lever, so that the lower pawl pushes the upper pawl out of its engagement with the lifting bar. Diagram 1 shows the position of the pawls when the bar has been raised to the full extent of a single stroke of the lever, and is at the point where both pawls are in engagement with the teeth of the lifting bar It will be noticed that there are two hooks or lugs, *A* and *B*, on the lifting and holding pawls, respectively. When it is desired to set the pawls to trip, the wooden handle is removed from the lever socket, the lever socket is raised so as to depress the lower pawl, and the lower pawl is swung outward, so that *A* passes *B*. The socket is then depressed until *A* passes upward into position back of *B*, as in Diagram 2. In this position the lower pawl is securely held out of engagement with the teeth of the lifting bar by the lug *B*, the upper pawl still sustaining the load. By pressing the lever socket farther down the lower pawl moves upward, throwing the upper pawl out of engagement, and the lifting bar is released and drops the load. In this position (Diagram 3) both pawls are held securely away from the teeth of the lifting bar, so that it descends without obstruction or hindrance. The first upward stroke of the lever releases both pawls and they engage the bar without further attention. With this jack it is possible to set the pawls for tripping as soon as the track has been raised to the proper hight, and it will remain in such position without dropping its load, while tamping or other work is being done. In case of emergency, therefore, the jack can be tripped instantly and removed without stopping to adjust any of the parts which have to do with the tripping action.

As a jack, at best, is quite heavy, it should be made as light as is com-



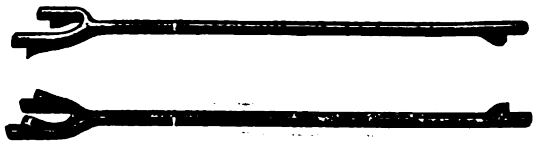


Fig. 323.—Sheffield Pressed Steel Insulated Gage.

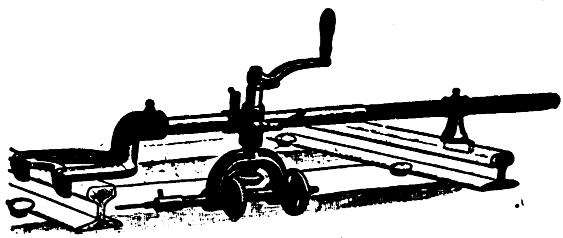

Fig. 322.—Q & C Friction Jack. Fig. 324.—Rail Bonding Drill.

mensurable with the strength required for the work. For general track repairs the weight should not exceed 55 lbs. For use in ballasting new track, jacks weighing 80 to 100 lbs. are commonly employed. A very important point in the design of a track jack is that is shall drop its load easily and without fail upon every attempt to trip the lifting bar. A jack of ordinary hight set between the rails forms an ugly and dangerous obstruction for a train to run against, as the cowcatcher is almost sure to fling it across the rail. A disastrous wreck caused by a track jack on the Old Colony R. R. in 1890 (the particulars of which are related in § 113, Chap. VIII) had for some years the effect of bringing this tool into disrepute with railway officials, and on practically all roads the rules forbid the use of a jack between the rails. When used outside the rail and between the ties it interferes with the tamping of one side of the tie, to hold the rail to place at the point raised, and in most cases the plan of lifting against the bottom of a tie involves so much digging that it is impracticable. It must be admitted, however, that on curves and at points where the view is obstructed the use of a jack between the rails is attended with considerable danger to trains, for no matter how "sure drop" the jack may be, the unexpected arrival of a train will throw some men into confusion; or at any rate queer movements have been known to take place on occasions of this kind. Such considerations make it desirable that for old track a jack may be had which can be used between the rails and still stand so low as to be clear of trains which might pass over it unexpectedly while set in the track. Some short-lift jacks of this description have been devised and put to use. One of these is the Anderson friction jack, which has been used on the Chicago Great Western, New York, New Haven & Hartford and some other roads. This jack stands only 8 ins. high and, as appears in Fig. 321, does not project above the top of rail. It therefore presents no danger of derailment if a train passes over the jack in service. The lifting bar of the jack is raised by a ratchet arrangement and held by a friction clutch, thereby enabling the device to raise and hold the rail, or lower it, to any fraction of an inch. The range of movement of the lifting bar is 5 ins. As shown in the figure, the back of the lifting bar is notched and is operated by an ordinary pinch bar. At each side of the lifting bar there is a wedge-shaped pocket in which are placed three roller gravity pawls, the upper two being separated by a bolt passing entirely through the jack, the lifting bar being slotted. The jack is released by a foot trip, which appears directly under the handle. This trip consists of a lever which throws up a stem against the under side of the pawls, thereby disengaging them and allowing the lifting bar to drop. The body or frame of the jack is cast in one piece and the entire weight of the tool is but 33 lbs. The pawls can be taken from each pocket by removing two screws and lifting the top plate. The Fisher jack is made to work under the rail base, requiring that considerable digging must be done, in order to set it, thereby seriously delaying the work; it also forms as much of a hindrance to tamping the tie next it as does a jack of ordinary hight set outside the rail. It consists essentially of a toggle joint carrying a bearing plate at the apex to engage the rail. The two legs of the toggle are worked by a ratchet lever and screw, the latter passing horizontally through nuts at the feet of the toggle legs, the thread on the two ends of the screw being right and left-handed.

It is important that a track jack should have a base of good size, so that it will not settle deeply into the ballast when lifting the track, or tilt over and throw the track out of line. The size of base recommended by the Roadmasters' Association of America is 7x12 ins. To prevent the jack from tipping, the base projects farther in front of the upright frame than behind it. In using the jack trackmen should get in the habit of planting it squarely or setting it perpendicular to the plane of the track, so as to disturb the alignment of the track as little as possible. Tools with parts subject to wear, like jacks, rail drills, rail-sawing machines, hand cars, etc., should be bought under a guarantee that interchangeable parts will be supplied if desired.

129. Raising Bars.—Although a jack is the best raising tool for general purposes, every section ought to be provided with a long, stout bar. It comes into use occasionally and is a good tool to fall back upon in case the jack gets broken or is sent for repairs. A wooden lever shod with iron at the tip (Fig. 32) is out of date in section work. Being heavy and unwieldy, too many men are required to carry it around and operate it, and in a lift of any consequence it is bound to throw the track out of line, more or less. When such tools were commonly used a rope was sometimes tied to the end of the lever to pull it down when setting it for a high lift. On old track which has been well kept up, and where the bed is hardened, so that most low places do not require raising more than an inch, good work can be done with a raising bar, providing the operator knows how to use it. If, however, the track is on a new bed, and places settle 1½ ins. or more before they are raised, the jack is the better tool. The bar should, of course, be a pinch bar, with the point turned up slightly more than on ordinary pinch bars, so as to give more of a heel. It should be about 6 ft. 3 ins. long and weigh about 40 lbs. The large end of it should be about 1¾ ins. square for about 2 ft. and then taper off gradually, first to octagonal section and finally to 1⅛ ins. round, at the end. The man operating a raising bar carries with it a block of hard wood, about 2x6x15 ins. in size, with one end beveled. This block is shoved under the rail base, so that the bar rests upon it at about the middle. By raising once on the block, if it be not set too far below the rail base, and then using a nut or hard stone about an inch thick, for a fulcrum, track can be thrown up 1 or 1½ ins. pretty lively and satisfactorily.

130. Rail Tongs.—Rail tongs should be about 12 ins. long, from the jaw to the bend in the reins or handle (Fig. 316). All the tongs on the same division should be of the same length, so that in case they get mixed

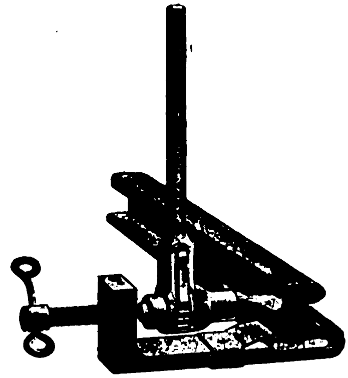

Fig. 325.—Doyle & Williamson Drill.

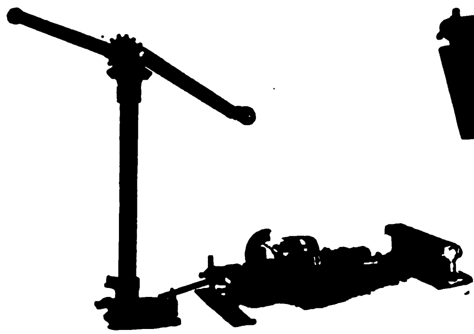

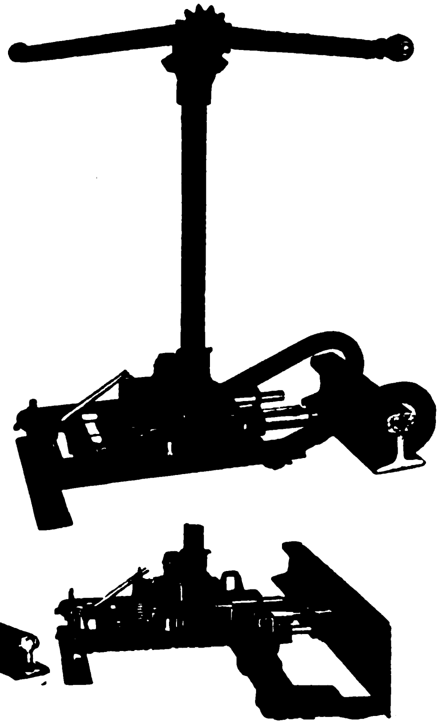

Fig. 327.—Drill Taken Down for Train. Fig. 326.—Q & C Track Drills.

up one crew will not get hold of different lengths. The reins should each be about 16 ins. long, or 32 ins. long over all. The tool is made from two pieces of 1-in. round iron, each 26 ins. long, to which the jaws are welded. The jaws should be about 1½x¾ in. at the pivot, which is held by a ½-in. rivet. The weight of such a pair of tongs is about 11½ lbs. Tongs of heavier construction, as shown in Engraving *F*, Fig. 295, weigh about 15 lbs. Soft steel is good material for tongs. Tongs are very useful when laying turnouts, where many rails have to be handled, but especially if the weather is very hot and bright, making the rails exceedingly uncomfortable to handle with the bare hands. Four men with two pairs of tongs can handle rails more easily than six men bare-handed. In case six men with three pairs of tongs are given a rail to carry, the men with the third pair of tongs should not carry at the middle of the rail, because in going over uneven ground the rail will be either too high or too low for their reach and put them to a disadvantage. In order to distribute the weight equally among all six men and enable them to carry the rail over uneven ground without disadvantage to any one, one pair should carry at one end and the other two pairs, as near together as they can walk conveniently, at ¼ the length of the rail from the other end. The same manner of distribution applies when three men carry a tie; one man at the rear end, the other two carrying with a stick at ¼ the tie length from the front end. The question of properly distributing the weight of a tie on three men, when two of the three carry with a stick, is frequently debated among trackmen.

131. Rail Drills.—The simplest device for drilling rails is the ratchet drill. The simplest form of ratchet drill consists of a stock or bit holder, operated by a ratchet wheel, hand lever and pawl. Some kind of a clamp must be provided as a backing for the stock, and the bit is fed by a screw working into the stock and against the clamp. Drill clamps are made to engage the rail in two ways—the "underclutch," fitting under the base of rail, and the "overclutch," fitting over the rail head. The underclutch arrangement has the advantage that the clamp need not be removed for the passage of a train, and the disadvantage that spikes must sometimes be pulled and the rail raised in order to place the clamp properly (over a tie, for instance) for drilling through a rail in place in the track. The overclutch arrangement can be applied to a rail at any point, without preparation, but the clamp must be removed to let trains pass. In yards and at other points where the ties are covered up an overclutch fastening for a drill is very convenient, and sometimes saves a great deal of digging. An underclutch clamp may consist simply in a stout bar of iron or steel of proper length bent up at both ends. In the Doyle & Williamson drill (Fig. 325) the clamp has a sliding collar and clasp, as a means of securing the clamp to the rail flange, and the feeding screw works through one leg of the clamp and against the bit stock. A more convenient underclutching arrangement is formed by two clamps placed 15 to 18 ins. apart and joined by a back piece parallel with the rail, thus forming a frame along which the drill may slide, so that several holes may be drilled at one setting of the clamp. In this form of clamp the range of adjustment for the drill is such that it seldom becomes necessary to clamp the frame to the rail over a tie, which requires, as above noted, the spikes to be pulled and the rail raised. The frame is sometimes made solid, in one piece, as in Fig. 329, and sometimes the back piece (B) is held at an adjustable distance from the rail by pins

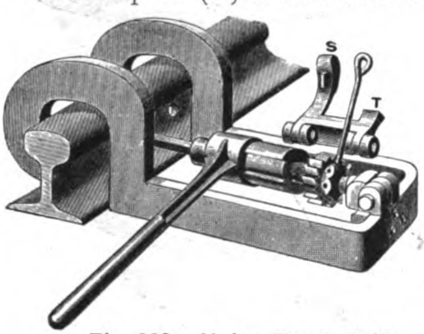

Fig. 328.—Union Track Drill.

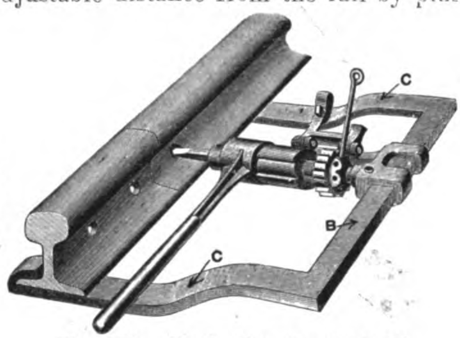

Fig. 329.—Perfection Track Drill.

in the slotted ends of the two clamping pieces (C), as shown in Fig. 330. In the clamping frame for the Beland drill the back piece is formed by two flat bars, with the shank of the drill sliding between them. The back piece is sometimes provided with a projection of some kind on the under side, to hold the frame up and keep the drill clear of the ties.

One of the oldest track drills is the Victor (Fig. 332), designed by Mr. J. H. Lakey, master mechanic with the Chicago & Northwestern Ry. It works with a clamp of the overclutch kind, fastening to the head of the rail by a cast iron wedge W, which is driven in between the rail and a depending lug on the clamp. The drill may be unclamped from the rail in an instant by knocking out the wedge. The feeding screw acts directly on the bit, which has a square shank. With this form of clamp it is possible to drill a short, loose piece of rail without having to spike it to a tie or otherwise make it fast against overturning as the bit is worked. With most forms of clamp this cannot be done. The principal trouble with this drill is that the clamp can be made for a rail of only one size and shape, and as the rail head wears down it becomes more and more difficult to hold the clamp to the rail securely. The Union drill (Fig. 328) has a clamp or frame which hooks over the rail head and bears against the web on the opposite side, fitting rails of any section. The ratchet is encased and the bit is fed either automatically or by hand, as desired. In order to remove the clamp from the rail quickly a pry is taken under the feed drum or feed ratchet with a bar, pick, wrench or other convenient lever, throwing the drill out of center. In this drill, as with the Perfection drill (Fig. 329), the automatic feeding arrangement consists in a slotted drum and a finger (S) bearing thereon by a nub, the finger being joined to a pawl (T), as shown. Once in every turn the slot permits the finger to drop, thereby throwing the pawl into engagement with the feeding ratchet while the nub on the finger is down in the slot.

A drill possessing several novel features is the Warren, shown in Fig. 333. The bit stock and feed work through a block with two ratchet sides (R), and this block is adjustable on the ratchet seat (S) of the clamping frame, and is held in the same by a pin. The feed screw is of sufficient length to drill four holes through the rail web without backing the screw, so that in resetting the drill for the last three of the four holes it is only necessary to move the block farther back on the ratchet seat. As the bit

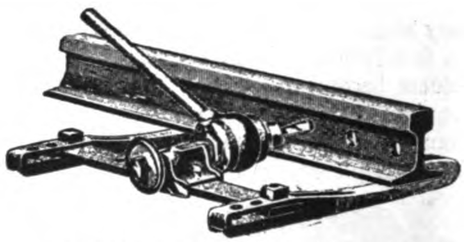

Fig. 330.—Schuttler Track Drill.

Fig. 331.—Paulus Track Drill.

stock is not centered in the block, the drill is adjustable to two hights of rail by reversing the block. A shankless twist bit is used and it is forced into the rail by a friction feed which can be regulated (increased or decreased) by means of a thumb-screw. The same drill is worked with an underclutching clamp, the only change required being a ratchet seat attached to that form of clamp.

In the drills thus far considered the lever has been single acting—that is, the bit stock is turned by the lever only one way of the stroke. In the Schuttler drill (Fig. 330) the bit is turned continuously forward at both forward and back strokes of the lever, thus dispensing with all idle movement in the lever. The continuous action of the drill spindle upon the reversal of the lever is obtained by means of a pair of gears between which is meshed a pair of beveled pinions. One of the gears is rigidly attached to the spindle and the other is loose, and in the outer circumference of each gear are ratchet teeth set to do service in opposite directions. There are two pawls. When the lever is moved in one direction a pawl engages the fixed gear and the action on the spindle is direct. When the lever is reversed, a pawl engages the loose gear, and, by means of the intermediate bevel pinions, the fixed gear is turned in the same direction as before, so that the spindle is driven always forward. To keep dust out of the turning mechanism the gears and pinions are enclosed by a case in two pieces held together by hexagonal nuts.

Continuous-motion drills operated by hand cranks do the work most rapidly, and are extensively in use, particularly with yard gangs or wherever a good deal of switch work is to be done. In these machines there is usually an upright shaft with two cranks and bevel gear connection at the top, and a horizontal bit stock and bevel gear connection at the bottom; some means for clamping to the rail, and provision for quickly removing the drill from the reach of passing trains. The Waterman, Buda and Paulus drills are all very similar in respect to these particulars. Figure 331 shows the Paulus drill in position for work and also thrown back to allow a train to pass. More in detail, the apparatus consists of a firmly stayed upright frame supporting a shaft, to which are attached two handles, enabling the machine to be worked in continuous motion by either one or two men. At the back of the horizontal portion of the frame there is a sole plate serving as a support for this part of the machine and for the automatic screw feed mechanism. Attached to the horizontal portion of the frame there are two rail hooks, which hold the drill to its work. The motion of the handles is transmitted to the stock spindle by bevel gears on a vertical

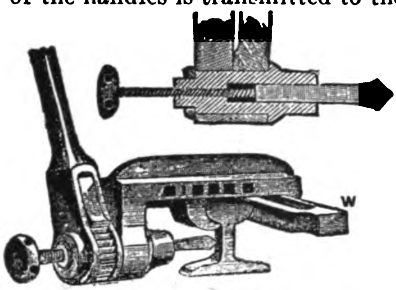

Fig. 332.—Victor Track Drill.

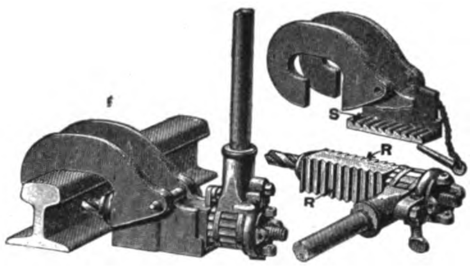

Fig. 333.—Warren Track Drill.

shaft. A simple ratchet device, actuated by an eccentric, feeds the drill automatically. The upright is held firmly in place by a back brace, formed by rule-jointed stay rods joined by a wooden handle. When it is desired to unclamp the machine the back brace is folded by pulling out the wooden handle, the operation requiring but a few seconds. The rail hooks are pivoted to L-like extensions of the upright frame, so that when the latter is tilted backwards the hooks are swung forward far enough to clear the rail head. As the upright frame is being tilted backward the bevel gear which transmits the turning motion from the vertical shaft disengages from its companion on the horizontal spindle holding the bit. With this machine a $\frac{7}{8}$-in. hole can be drilled through the web of an 80-lb. rail in about two minutes The weight of the machine is 60 lbs., but for very heavy work a drill is made of the same pattern weighing 90 lbs. For special work the drill is made with a hook to fit under the base of the rail instead of over the head of it, as shown in the figure. In the Q & C self-feeding rail drill (Fig. 326) the upright shaft is detachable from the horizontal portion of the mechanism and can be quickly lifted out of the way of passing trains. By folding back the hooks all remaining parts of the drill are out of reach, as shown in Fig. 327. It is made with either underclutch or overclutch fastenings (Fig. 326), the drilling mechanism proper being substantially the same in either case. The main frame slides forward on guides carrying the drill spindle with it and a small lever at the back clamps the hooks to the rail, or releases them when thrown back.

In bonding rails for track circuit, in signal or electric railway work, the holes drilled usually run from ¼ to ½ in. in diameter. For such light work a drill is required which is easily portable, rapid in action and light in weight. One of the best known devices for this work is shown in Fig. 324. The drill stock is turned by crank and bevel gear and the bit is fed by a screw and hand wheel. The drill in this machine is adjustably clamped to a piece of 1¼ or 1½-in. pipe laid across the rails. One end of the piece of pipe is screwed into a fork with lugs to catch over the rail and hold the drill up to its work, and the other end may lie across the rail or on a supporting block, as shown. The bit can be set at any desired hight by turning the drill about the pipe and clamping it at the proper point. The man who operates the drill either sits on the pipe while he turns the crank, or holds it down by foot pressure. The weight is 68 lbs. A drill of similar pattern for heavier work is shown as Engraving *S,* Fig. 309. The machine has two extension cranks, facilitating the application of a greater turning force on the bit, when necessary, and there is an automatic friction feed which can be adjusted for fast or slow feeding. Arranged as shown in the illustration, the speed of crank and spindle are geared as 1 to 1, but by removing the top yoke and placing one of the cranks on the upright shaft the gearing is changed to give two revolutions of the spindle to one of the crank. This latter arrangement is adapted for light work and rapid drilling, as when drilling holes for bond wires. The machine weighs 85 lbs.

IN POSITION FOR WORK.

THROWN BACK TO DETACH FROM RAIL.

Fig. 334.—Wilson Drill for Rail Bonding.

The Wilson machine (Fig. 334) is designed specially for light drilling, its weight being only 20 lbs. The machine is clamped to the rail by overhanging hooks and a lever and link motion, which moves the upright part of the drill forward to its work, when the lever is thrown up, and withdraws it when the lever is thrown down. In the latter position the frame slides back far enough to clear the drill point from the head of the rail, so that the machine is entirely free and can be taken direct from the rail. The driving gear consists of sprocket wheel and chain. On the crank shaft are two sprocket wheels: one, fastened rigidly to the shaft and revolving with it, drives the feed nut on the drill spindle; the other is placed loosely on the shaft and does not revolve unless engaged by a pawl on the end of the shaft; when so engaged it drives the drill spindle. Thus the drill spindle and the feed nut both revolve in the same direction, but are so geared that the feed nut travels a little faster than the drill spindle, and so imparts a continuous feed, either forward or back, as the crank is turned. By disengaging the pawl on the sprocket wheel which drives the drill spindle the latter may be held from turning while the feed nut is revolved, thus imparting a quick forward or back movement to the drill spindle which can be utilized to good advantage in setting the drill.

For drilling bolt holes 1-in. bits or larger are used. Twist bits usually give better satisfaction than flat bits. When bits get dull they may be sharpened on the grindstone. With twist bits this method of sharpening can be repeated indefinitely, but flat bits must be heated and worked over occasionally. Before starting a bit it is well to spot the place with a center punch. A desirable feature in a drill is to be able to adjust the bit to the required hight of the bolt hole, so that it will do accurate work on rails of more than one particular section. Unless this adjustment can be made it is sometimes necessary to block up the frame and drill the hole obliquely, in order to get it at the desired hight.

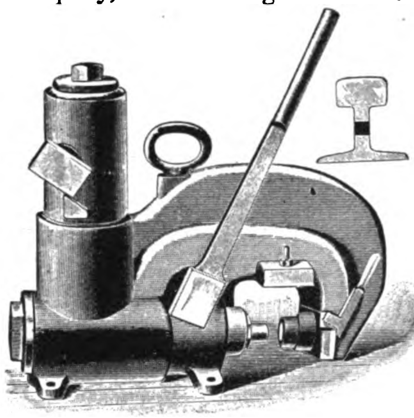

Fig. 335.—Hydraulic Rail Punch.

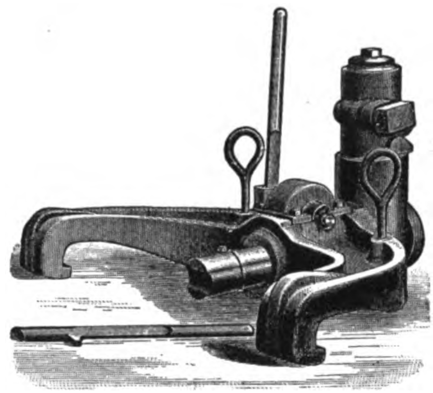

Fig. 336.—Hydraulic Rail Bender.

In the days of iron rails bolt holes were frequently made with hammer and punch, but this method has nearly disappeared from practice with steel rails. The method of procedure in punching a rail by hand is to notch in a square hole on one side of the web, as far as may be practicable with a cold chisel, and then turn the rail over and punch through with a round punch, driving the core toward the side on which the notching was done. The punching of bolt holes with hydraulic machinery is done to some extent. Figure 335 is a view of the Watson-Stillman hydraulic rail punch. It is portable and may be used on rails in place in the track. The lever shown in the middle of the view is for quick action, being used to work the ram in and out a distance of about 2 ins. without loss of time and labor of pumping. At the top of the jaw there is a guide which can be set to suit the pattern of rail handled, so that all holes punched will be at the same hight on the web of the rail. For punching rails weighing 70 lbs. per yard, or less, a machine of 50 tons' capacity, weighing 200 lbs., is used; for heavier rails there is a machine having a capacity of 120 tons, weighing 375 lbs. For punching slots in the rail flange, for spikes, there is a machine of similar construction in which the ram acts vertically.

132. Rail Benders.—The most common form of rail bender is the jim-crow, Fig. 337. It consists of a heavy U-shaped forging of iron or steel, the two legs of which have their ends hooked for holding against the head of the rail, while a screw working through the center or bend of the frame bends the rail midway between its bearings against the two hooks. The screw is usually made to do its work on the rail by exerting pressure against a cast iron block of proper shape, placed against the side of the rail. The screw usually has a capstan head and is turned by an ordinary pinch bar, but sometimes the head is made to be turned by a long wrench. For turning screws of this kind the Pennsylvania Steel Company supplies a large wrench with a ratchet head. Jim-crows for ordinary service are about 2 ft. wide, c. to c. of arms, have a screw $2\frac{1}{2}$ to 3 ins. in diameter and weigh 150 to 200 lbs. The "Eccentric" rail bender (Fig. 338) has two hooked legs forming an A-frame, with a pressure rod worked by a lever and eccentric. The pressure rod is made adjustable by a sleeve nut, so that the amount of bending or the leverage can be changed to suit the circumstances. The weight of the tool is about 180 lbs. The Emerson rail bender is very similar to or like the Eccentric design. With benders of this type it is sometimes necessary to use the lever several times, readjusting the sleeve nut each time, in order to bend the rail the desired amount. The Fairbanks-Morse bender, which works on the eccentric or cam principle, has self feeding wedges on the ram which automatically feed it forward at each stroke of the lever. The Samson rail bender (Engraving *B*, Fig. 339) is a heavy cast steel lever with a capstan-headed screw at one end and a stout claw near the other end. The screw works into a cast steel cap with phosphor bronze and tool steel bearings, this cap being grooved to fit against the rail head. The lever or frame has a broad web with heavy flanges, and the tool weighs 113 lbs.

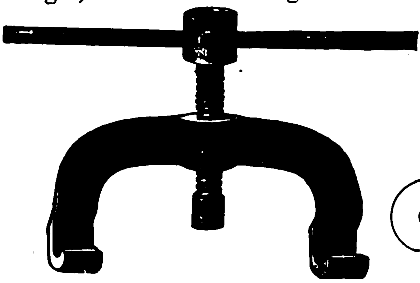

Fig. 337.—Jim-Crow Rail Bender

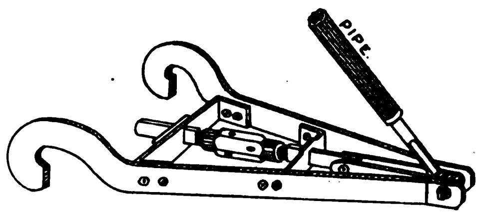

Fig. 338.—Eccentric Rail Bender.

Figure 336 shows the Watson-Stillman hydraulic rail bender, designed especially for work on heavy rails. It is made in two sizes: one weighing 200 lbs., for rails of 70 lbs. per yd., or lighter, and one weighing 275 lbs. for rails heavier than 70 lbs. per yd. The ram has a loose steel head which fits against the rail head and the ram is graduated to show the spring of the rail.

133. Hand Cars.—The term hand car signifies, of course, any car propelled by hand, and, in a general sense, it might as well be understood to include all cars propelled in any manner which are lifted on or off the track by hand. As commonly used, however, the term applies only to vehicles for carrying section or bridge crews with their tools (Fig. 340). Cars for this purpose differ but little in general features of construction. There is usually a platform carried on four wheels, on which is mounted an A-frame or gallows frame supporting a walking beam or lever with cross handles, attached by connecting rod and crank to spur gear wheels operating on the axle of the car. Cars for section crews are usually about the same size on all standard-gage roads and are made in about the same way. The platform is usually 6 to 6½ ft. long and 4 ft. 4 ins. or 4 ft. 5 ins. wide, formed upon four longitudinal sills about 2½x1½ ins. in section, the sills extending beyond the platform on both ends and rounded off for handles. The two outer sills rest on the journals or axle bearings and the two inner or middle sills carry the gallows frame. The longitudinal sills support cross pieces, on which is laid a floor of matched lumber. The axles are of steel and about 1½ ins. in diameter. Roller bearings are used to some extent. The lever has forked ends, each prong terminating in an eye band which holds the handle. Six men can usually "pump" without interference and two or three more men standing between the handles can help a little. A dozen men can easily stand on the car, and at a pinch the car will carry

18 or 20 men. Years ago hand cars were sometimes made large enough to carry easily a crew of 25 or 30 men, the car being propelled by means of two long wooden levers. Such cars, however, were heavy to handle and, notwithstanding the large crews carried, were lifted to or from the track with some difficulty. The smaller cars in common use with section crews are to be preferred for large crews also, two or more cars being furnished as the size of the crew may require. Hand cars propelled by two cranks were formerly used to some extent, but have largely gone out of service. Such cars give opportunity for only two men to work at propulsion, and the motion of the cranks, unless carefully and continually watched, is somewhat dangerous to men standing on the car. On account of the larger and heavier tools carried a hand car for a bridge gang is made heavier than the section hand car. The platform is usually about 8 ft. long and 5 ft. 6 or 8 ins. wide, extending over the wheels. In order to obtain a desired width of platform on hand cars for narrow-gage track, the platform is extended over the wheels. An important feature of design in all hand cars is to get the wheels far enough apart to obviate the danger of upsetting the car when the two ends are unequally loaded to the extent of a man or two.

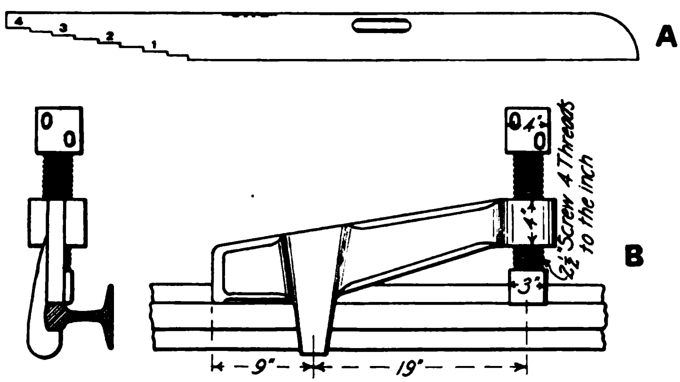

Fig. 339.

The most important considerations in a hand car are the weight and the speed, or the distance the car travels for a stroke of the lever. A feature which has to do largely with the weight is the manner of construction of the wheels. The old form of wheel, where the tire and hub were cast-welded around wrought spokes, is too heavy and is not so good a wheel as some of the lighter forms now made. One difficulty with this old form of wheel was that an extraordinary load on the car would loosen the spokes, after which the wheels would wabble in running. Wheels of pressed steel or wheels made with wooden rim and spokes, or steel plate center, with steel tire, are best for hand cars, as such construction can be made sufficiently strong and save much weight over the older forms of cast or cast-welded wheels. On roads using automatic electrical block signals with track circuit the hand car wheels must have wooden centers or insulated axles. The web of pressed steel wheels is usually dished and ribbed or corrugated radially, so as to effect a gain in stiffness. In the Buda steel wheel (*B*, Fig. 309), made from a single plate, the tread is doubled back upon itself half its width, so that the wheel center is in line with the middle of the tread, or in the direct line through which the weight on the wheel bears. The metal is shaped by drawing and spinning, without seam or weld, and the wheel complete weighs 40 lbs. The Kalamazoo wheel has a steel plate center and a pressed steel tire or tread. The "Cyrus Roberts" hand car wheel has a hub cast-welded around steel spokes which are screwed firmly into the felloe.

A steel flanged tire is then shrunk over the felloe. The style of wheel in most extensive use is a dished steel plate with portions of the metal cut away or bent back, leaving the spokes. A section of the Sheffield pressed steel wheel is shown as *F*, Fig. 309. The Donovan hand car wheel (Engraving *E*, Fig. 309), like several others, is pressed from one piece of steel plate. The engraving shows views of both the outside and inside of the wheel. The metal struck out between the spokes is turned inward at right angles to support the tread. The hub plate is cast-welded on both sides of the web and through the spaces between the spokes, forming a single casting which closely binds the parts together without bolt or rivet.

The frame of a hand car can be much lightened by a proper disposition of brace rods. Both longitudinal and cross sills should be trussed and the platform should be braced diagonally to keep the wheels in tram or in position to track properly. The gallows frame, if of wood construction, should be braced diagonally, to keep it from getting rickety. Section hand cars sufficiently strong to carry as many men as can conveniently get on them, with their tools, need not weigh more than 500 lbs. A heavy car is

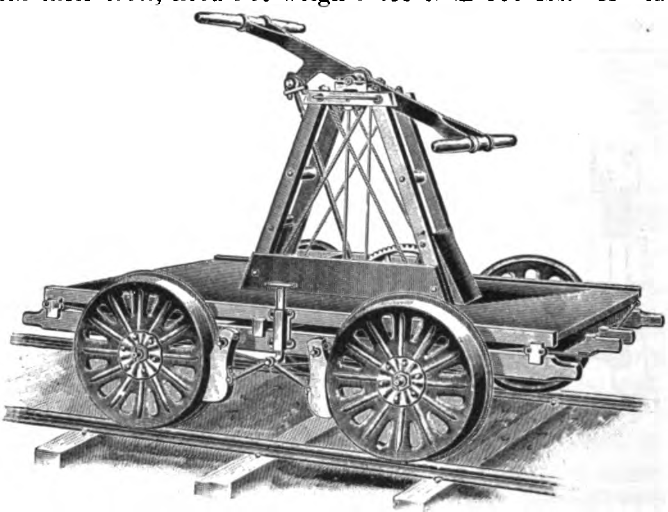

Fig. 340.—Sheffield Section Hand Car.

unwieldy to get on or off the track, is more liable to be damaged in being moved to or from the track, and runs hard; which means that it cannot be propelled as fast as a lighter car well constructed. The car illustrated as Fig. 340 weighs 480 to 545 lbs, according to the thickness of metal in the wheels, but the car of this pattern weighing 510 lbs. is considered heavy enough and strong enough for all ordinary purposes. All parts of a hand car should be made as light as possible for the strength required, and manufacturers, who, as a rule, have studied the matter closely, and experimented a good deal with the materials required, have the business down to its finest points. As a general proposition better and cheaper hand cars can be had from them than are turned out from railway shops.

The two features of hand car design which determine speed, for a given outlay of strength, are the sweep of the handles and the distance the car travels per stroke of the lever. In a mechanical sense a hand car is propelled by prime movers working in parallel. The physical exertion of pumping the car may be analyzed into two processes—the expenditure of "elbow grease" and the movement of the body in bending the back. As a matter of efficiency, therefore, a large part of the energy generated is lost in the prime mover. It is for this reason that the sweep of the handles and the travel of the car per stroke of the lever are all-important considerations; because the former has to do with the extent of, and the latter with the rapidity of, the back-bending action. The lever handles should have a sweep up and down of about 24 ins. and the sweep of both ends of the lever should be the same, or equal, and between the same limiting distances from the car floor. In order that this condition may obtain, the lever or walking beam must be equally divided across its axis or supporting shaft and the connecting rod must be of a certain fixed length. A sweep of the handles exceeding 24 ins. requires rather too much motion or bending of the back. Since large wheels are run at a given speed easier than small ones, the wheels of a hand car should be not less than 20 ins. in diameter. These two requirements—the sweep of the lever handles and the diameter of the wheels—being fixed, and a gear ratio to produce a given speed being determined upon, it matters not how the driving gear is otherwise arranged. The length of the crank and the leverage of the handles are dependent upon each other; the longer the crank of the speed wheel or driver, the less can be the leverage or purchase given to the handles, the length of the lever to which the handles are attached being unimportant so long as the sweep of the handles remains fixed. So it matters not whether the crank be longer and the leverage less, or the crank shorter and the leverage greater. The ratio between the number of gear teeth on the driver and pinion depends upon the required number of revolutions of the wheels in order to travel the given distance per stroke of the lever; and it matters not whether these two gear wheels be larger or smaller, so long as the number of teeth on each bear the same ratio to each other.

In general, two speeds for hand cars are required: viz., one speed for grades and another for the level. A car operated up grade will necessarily run slower for a given outlay of strength than when operated on the level. As the speed up grade must then be comparatively slow, necessarily, and as to accomplish the same work in propelling the car less force or pressure on the handles is required at a quick stroke than at a slower one, the car best suited for grades favors the quick stroke. On the level the opposite obtains; that is, the car best suited for the level favors the slow stroke, because at a high speed of the lever men can put less force on it, and much work developed in rapidly bending the back is lost, as far as the work done upon the car is concerned. For sections having heavy grades—say over 1½ per cent—hand cars ought to be speeded to run not over 15 ft. per full stroke of the lever (up and down), and an arrangement should be provided by which the pinion may be slipped and the drive wheel thrown out of gear while running down grade. For ordinary grades 17 ft. run per stroke is about right. For the level or slight grades, 22 to 25 ft. run per stroke of the lever enables men to run a car at good speed with a minimum rate of work developed in the back and arms. The Roberts Car & Wheel Co. makes a special double gear, with slip pinions, for hand cars. The crank shaft carries two speed wheels of different diameters, and the driver axle, which is of square cross section at the middle, carries two slip pinions, worked by horizontal levers extending under the platform to the end of the car. The larger pinion matches with the smaller speed wheel, forming the "slow gear," for grades, and the small pinion and larger speed wheel provide the "fast gear," for level track. To stop the motion of the lever when coasting down heavy grades both pinions may be thrown out of gear. This matter of speeding hand cars is important, because for use on grades a high-speed car—that is, a car having a slow-moving lever—requires so much force applied to the lever to move the car at all that it sometimes becomes easier to walk and push the car than to propel it; whereas, on the level, with a slow-speed car—which means one having a fast-moving lever—the wind and sweat are taken out of men in rapidly bending the back, without being able to attain good speed. A road having long stretches of both level track and grades ought, in procuring hand cars for its section crews, to get for each section that hand car which is best suited to the grades on it, and thus save much time for the company and much unnecessary labor for its men.

For men of average stature 30½ ins. to center is about the proper hight above the floor of the car to support the shaft or axis which carries the lever. All lost motion in boxes and keys should be carefully taken up. As it is difficult to keep a tight key between crank shaft and speed wheel, the wheel should be cast with a wide spoke carrying two lugs, between which the crank is fitted and held independently of the key in the hub, as shown by Engraving *A*, Fig. 309. On Buda hand cars there is a set screw in one of these lugs to tighten up on the crank when the parts become worn. The oil holes and tubes should be arranged where they can be easily got at and they should be provided with dust guards or flaps of leather or painted canvas, or wire nails may be stuck into them to keep the dirt out. The main axle boxes should be provided with packing, so as to hold the oil up to the axles, underneath. In winter time a small amount of kerosene may be mixed with the black oil to keep it properly thinned. The bearings holding the main axle from springing at the pinion should be fixed so as to slide up when an unusual weight is bearing down on the floor above it; otherwise that axle may sometimes become cramped and prevented from turning truly. One wheel on the axle not driven should be loose, so that the car may be easily turned by lifting one end and swinging it around. The loose wheel also reduces the resistance to rolling motion on curves, and on tangents too, if there be an inequality in the circumferences of the two wheels. The best way to secure the wheels to the axles and the pinion gear to the driving axle is by a tapering fit, with jam nuts, screwed against the hub. The method of fitting by driving a key usually forces the wheel or gear out of center with the axle. An eccentric pinion is known by the sound thereof, the harsh music pealing forth to the tune of once each revolution. All available space inside the gallows frame should be used for a box to carry the oil can, a few bolts, spikes, track chisels, etc. A small, long box is sometimes placed alongside the gallows frame, lengthwise the car, for keeping flags dry and out of the way; otherwise flags ought to be carried in a tin case. Hand irons should be placed along the side of the top pieces of the gallows frame, so that shovels, hammers, picks, etc., can be stood up inside them and be out of the way of the men's feet. The brake should be at the side, because if the car is running fast the rapid motion of the lever will not permit a man to throw his full weight upon an end brake. The brake blocks should be faced with leather, so as to take good hold, and everything connected with the brake should be maintained in good condition. In a long experience with hand cars, I have always thought there should be two brakes —one on each side—so as to be able to get "quick action" in cases of emergency, which will happen occasionally. A chain and lock should be carried for locking the car in case it should be left standing without any of the section hands near. This chain gives least bother if hung by a link, near its middle, to a staple or eye bolt in the side of the car close by one of the wheels, so that when not used it may hang out of the way.

The knack of running a hand car fast is to get force to the handles, and this cannot be done as easily by trying to bear down and pull up hard against them while they are moving rapidly as it can by using moderate strength and trying to make the hands race with the handle. In this way more force can be put to the lever while it is moving rapidly than by trying to exert so much strength. When the rails are covered with frost and the driver wheels slip it helps matters considerably to increase the weight on these wheels for traction, and this may be done by having most of the men stand on and toward that end of the car, running the loose wheels ahead, to clear the rail of frost and give better traction to the drivers. The loss of traction from frost on the rails is very provoking, sometimes, and is frequently the cause of much delay in getting to work. It might be a good plan to place sprocket wheels on the axles of hand cars, to be coupled up with sprocket chain temporarily, during the frosty season, in order to obtain four wheels for traction.

Hand cars are often needlessly smashed by being run into by irregular trains. All irregular trains should blow the whistle before rounding each curve. When running a hand car either against or before a train which is late or a train which may be expected at any moment, it is well while rounding curves to keep a man running between the hand car and the train, as far away as he can see the hand car, so that he may signal the latter in case the train comes near. At least one man of a hand car crew should always face the rear and keep a lookout for trains. Hand cars run at night or through dark tunnels should display a white light in front and a red light at the rear. During foggy weather it is dangerous to attempt to run hand cars, for there is no practicable way to protect the car that will permit it to run faster than a walk, and even then there is considerable risk. On some roads the foremen are forbidden to take hand cars out in a heavy fog. On other roads they are instructed not to take the car out in fogs if the destination is less than a mile distant. Hand-car platforms should be built at intervals of one fifth to one third mile along the section, to save time and trouble in taking off the car when it is loaded with tools, and also to provide places at which to take off the car in cases of emergency. In long cuts it is well to dig away, if necessary to make room, about the middle of the cut and put in one of these platforms. The platform may consist simply of two wooden rails, blocked up with a pile or cribbing of old ties, if on a fill, running away from the track at a slightly descending grade far enough to give clearance. Hand car "turnouts" of earth filling, covered with a shallow layer of gravel or cinders, are more convenient than rail or timber platforms, and on shallow embankments they are to be recommended. To improve the appearance, as well as to prevent the filling from being tramped down, the slopes are sometimes paved with cobble stones. The standard earth turnout of the Southern Pacific Co. is 9 ft. wide and extends 11 ft. from the rail. It is well to lay a covering of inch boards over the ties inside the rails, opposite the platform or turnout, so as to facilitate turning the car; the boards should be well nailed to the ties. It is a good plan to habitually take the car off the track, when working in one vicinity for any considerable length of time, whether a train is expected soon or not. If the car is set off on uneven ground the wheel which does not have a bearing should be blocked up. For hand cars of ordinary weight, portable turntables or "jiggers" used opposite tool houses for turning the car are usually more bother than they are worth. It is more convenient and expeditious to turn the car by hand, and for this purpose the track, between the rails, opposite the tool house should be planked over with 2-in. plank well nailed or spiked fast, for a distance of 8 or 10 ft. In putting a hand car off or on track that is not filled in, the car should be lifted; an attempt to turn it on the ties may result in a wrenched wheel or sprung axle. It is frequent observation that the wear and tear on hand cars in putting them on and taking them off the track is greater than in any other way.

At all times when running the hand car the following tools should be carried: shovel, claw bar, hammer, gage, wrench, 2 chisels, flags, spare bolts and spikes, plugs and oil can; and in a wooded country an ax. These tools will answer in almost any emergency and do not make much of a load to carry. On railroads one can never know what moment a call for men will come, and for this reason the tools referred to should always be near by. It is also a good plan to have a small wooden box, with a cover, conveniently fitted up inside to hold such tools as hack saws and frame, hand cold chisels, small hammer, monkey wrench, assortment of wire nails and spikes, fence staples, files, hand punch, a piece of waste, and a few of such other minor articles as may suggest themselves. If not kept in some like system such tools, which are often very much needed, will not be at hand half of the time, and if habitually thrown into the open box inside the gallows frame together with spikes, bolts, etc., they will be either broken or daubed with oil when needed. Rails and heavy loads of ties should not be carried on hand cars for a common thing, as cars soon get broken down if so used.

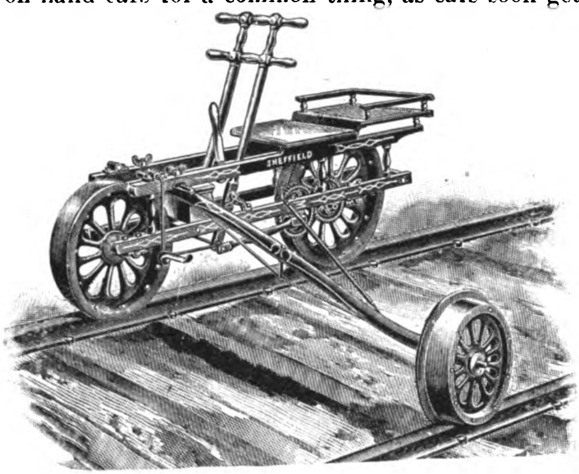

Fig. 341.—Sheffield Velocipede Car.

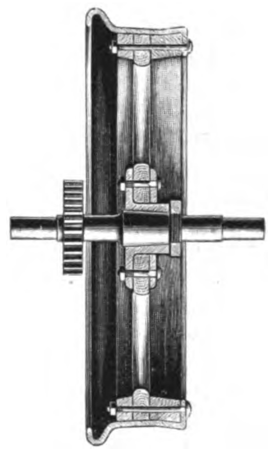

Fig. 342.

For sections on heavy mountain grades push cars may be substituted for hand cars, as when moving up grade the men must walk and push the car, and when coming down grade a push car will coast as fast as a hand car. If the push car is braked with a handspike it is a good plan to carry two of them, so as to have one to fall back upon in case the one in service falls out of the hand of the man applying it. In running a hand car down a mountain grade where the view is clear along the valley below, the experience in looking for trains coming up is similar in one respect to looking for steamships at sea—the heavy black smoke of the hard-working engine is usually the first indication.

The proper care of hand cars is an important consideration in section work, and must be directed by some degree of intelligence, especially with respect to the adjustment of the bracing and truss rods. A car may readily be spoiled for easy running by an ignorant use of the monkey wrench in straining on the brace rods. All of the rods should be kept in even tension and they should not be drawn up so tightly as to bend portions of the platform or frame. Particularly is this rule applicable to the diagonal bracing and vertical rods in the gallows frame. A heavy strain on the vertical rods will give the platform an upward curve in the middle and an uneven tension in the diagonal rods will twist the frame out of shape and warp the platform, causing the bearings to cramp the shafts and axles and make the car run hard. Such ill usage of machinery is inexcusable and will not occur with men possessed with ordinary powers of observation; but it sometimes does occur, and for this reason some manufacturers have been led to dispense with the adjustable feature and design a gallows frame intended to be rigid enough without diagonal rods or other devices which can be tampered with. One of the Buda designs of hand cars has an angle-iron gallows frame without adjustable bracing.

Track Velocipedes.—Hand cars for light service, capable of carrying one or two, or perhaps three, persons, are made in many forms. Such cars are in demand among track forces principally for the use of watchmen, for track inspection and for carrying switch lamps; to telegraph linemen they are indispensable. Perhaps the best known form is the 3-wheel car with one or two seats, commonly known as a velocipede car or "speeder," shown in Figure 341. The rider sits over the rail, on one side of the track, and operates the car by lever and treadle, using both hands and feet. As they are shown in the figures there is but one seat, the cover over the frame in rear of the operator being enclosed by a low guard, forming a receptacle for carrying tools, lunch pail, packages, etc. In another pattern of Sheffield car this guard is dispensed with and a seat is provided for a second person, with a foot rest, the latter hanging on the inner side of the frame. Some vehicles of this kind (used principally by telegraph linemen) are

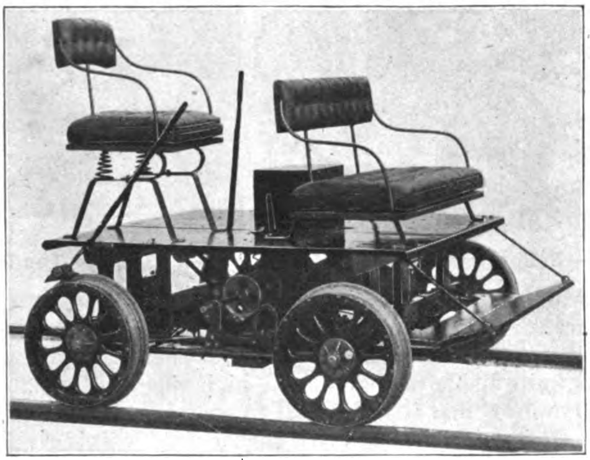

Fig. 343—Hartley and Teeter Gasoline Motor Car.

made double seated, so that two operators may work on the same lever and treadles. The two seats are arranged either in tandem—one seat forward of the lever and the other in rear of it—or side by side, in which case the two operators sit at a balance on either side of the car frame, on a plank swung across the frame in rear of the lever. If the riders are not of similar avoirdupois the heavier man should sit on the inside end of the plank. In the latter arrangement both riders face the front; in the former, one faces the front and the other the rear, and in this respect it is the more desirable arrangement. The diameter of the wheels on the rider's side is usually 17 ins. The third wheel, known as the guide wheel, is made about 12 ins. in diameter and runs opposite the front wheel on the rider's side, at the end of a braced cross arm. For convenience of shipment by train this arm is made detachable and may be folded against the side of the frame when taken down. As the guide wheel carries but little weight it would easily mount the outside rail of curves if the car was permitted to run freely from side to side of the track. One way of providing against derailment is to give the car a side draft toward the rider's side, by setting either the guide wheel or the front wheel (usually the front wheel)to lead slightly that way in running; and another arrangement is to make the treads of the forward wheel and driver slightly concave, or beaded on the outer side. Figure 342 shows the construction of the wheel for the Sheffield 3-wheel cars. The wheel center is of wood and the tire is steel, concaved.

Three-wheel cars for one operator, of the forms above considered, weigh from 130 to 165 lbs. and are easily lifted to or from the track by one man. The lightest car made is the No. 16 Sheffield velocipede car, weighing but 50 lbs. It has 3 rubber-tired wheels with wire spokes, bicycle style, and a frame of seamless steel tubing. The propelling mechanism consists of lever, with treadles at the bottom end, sprocket wheel and chain. The car is equipped with anti-friction bearings. Double-seated cars used by telegraph linemen have a shallow box on the cross arm for carrying wire, tools, etc., and weigh 175 to 200 lbs.

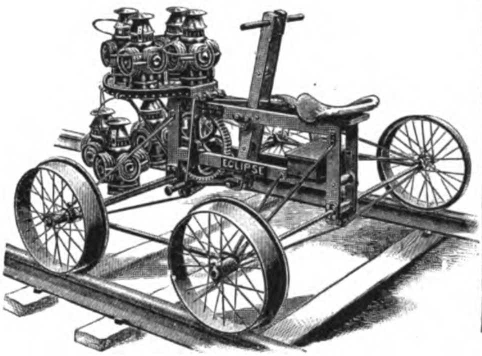

Fig. 344.—Eclipse Hand Car.

Fig. 344 A.—The Pony Car.

The 3-wheel car is very serviceable and is used in greater numbers, perhaps, than any other form of light car. It cannot be run backward, however, without running off the track, and when the rails are frosty the rear wheel is quite liable to slide off the high side of curves. It should be understood, however, that it is difficult to operate any form of hand car on frosty rails. It is said that cars with rubber-tired wheels give best satisfaction in this respect. A slight variation in the set of either wheel on the rider's side will run a 3-wheel car off the track. The advantages claimed for 4-wheel velocipede cars are that the wheels cannot slide off or swing off the rails and that the rider sits over the middle of the track where he can get a better view of both rails and their fastenings than when sitting over one of the rails, as on a 3-wheel vehicle. Moreover, the rider of the four-wheeler need pay no attention to the poise of his body, whereas the rider of the three-wheeler must be somewhat careful of his movements: by leaning heavily toward the outside he will tip the car over, and on curves he cautiously leans toward the middle of the track from force of habit. On the other hand the four-wheeler is cumbersome for shipment in the baggage car, will not carry so heavy a load, and is not so conveniently arranged for taking on an extra load.

The Eclipse velocipede car is a light four-wheeler with saddles for one or two riders, as desired. Its weight is 85 lbs. In Fig. 344 it is shown as rigged for carrying switch lamps. It is equipped with ball and roller bearings and has trussed axles and frame, with diagonal adjustment rods for keeping the wheels in tram. The wheels have rubber tires, to insure noise-less running, and the brake is applied to the drive axle by a lever just in front of the seat. The Hartley & Teeter 4-wheel car (Fig. 345) for a single rider weighs but 60 lbs. The frame is of bicycle tubing, propulsion is by foot gear of the bicycle kind, and the rider steadies himself by leaning forward on bicycle handles. The wheels (17 ins. in diameter) are faced with a pebbled rubber band $^3/_{16}$ in. thick, cemented on. The car has ball bearings and the brake, of the band pattern, is applied to a friction wheel beside the sprocket wheel on the rear axle. The brake lever is operated by hand. Its position being just under the handle bars, at the side of the head piece of the frame, it does not show in the figure. The car has a luggage basket and tool pouch. The car is also made with two seats, arranged side by side, in which form it weighs 75 lbs. To either of these cars an extra front seat, made of bent three-ply veneer and supported by a strong steel frame, may be attached to the framing, immediately above the front axle. This seat adds only 15 lbs. to the weight of the car and is a popular attachment, inasmuch as it increases the carrying capacity of the car and affords a position for a person disinclined to work his passage.

Fig. 345.—Hartley & Teeter Hand Car.

For purely inspection purposes light hand cars are arranged in many ways not stated above. On 4-wheel cars there is sometimes a seat extending across the car in front of a bobtailed lever or walking beam; in other cases swing chairs are mounted on supports at either side of the car, forward of the lever. Hand cars have been arranged with canopy tops and in other ways too numerous to mention. Twelve or 15 miles per hour, on level track, is good speed with hand-propelled cars, although a much higher rate may be made in short spurts while racing.

As the propulsion of cars by hand is not without labor, the "mother of invention" has come to the rescue with small steam and gasoline engines, and even with sails. The Sheffield gasoline motor car is shown in Fig. 346. In construction the car is essentially a Sheffield velocipede car with the frame slightly changed to suit the requirements of power installation. The device which furnishes the motive power is essentially a double gasoline engine, the connecting rods from the engine cylinders operating directly on cranks at either end of the axle of the driving wheel, as shown, the shield or foot guard having been removed to exhibit this feature. While it will not be necessary to go into all the details of explaining the operation of the engine (such being similar to gas engines ordinarily in use), it may be well to explain that the control of the car is effected by three levers or devices—one having to do with the quantity of oil supplied; another with the quantity of air supplied, which determines the number of explosions in relation to the number of strokes; and a third lever which controls the igniting spark. In starting, the car is given a push and the

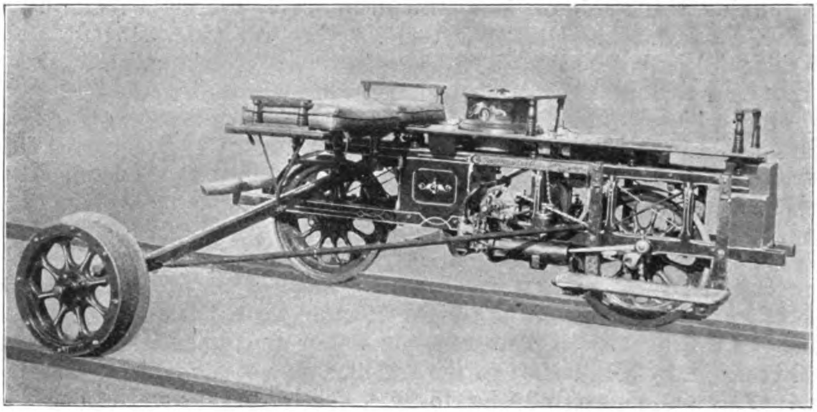

Fig. 346.—Sheffield Gasoline Motor Velocipede Car.

oil is turned on and ignited by the spark, after which the speed can be regulated at will. The igniting spark is furnished by a sealed battery stored under the seat of the car. There are three seats on the car, arranged for as many riders, the operator sitting on the rear seat within reach of the controlling apparatus. Brakes are provided for both the front and rear wheels, so that the car is constantly under the control of the operator and the person or persons riding in front. This car weighs 275 lbs., can readily be placed on, or removed from, the track by one man, and is capable of running 25 or 30 miles per hour, if the rider so desires.

There are several designs of gasoline motor cars built with four wheels and a platform, with a seat extending across the front end. On the Hartley & Teeter car (Fig. 343) the gasoline engine, of 2½ horse power, drives the rear axle, and the operator sits in a chair at a rear corner. The car is equipped with gear for two speeds, the slower for use in ascending heavy grades, and reversing gear is sometimes provided. The motor is started with a starting crank and then thrown in gear with the car axle. The car starts from a standstill without pushing, and can be stopped without stopping the motor. The weight is 500 lbs. The tanks hold enough gasoline to run the car 175 miles.

134. Push Cars.—Besides the hand car (the propulsion hand car) the section outfit includes two kinds of slow-speed vehicles known as the push car and the wheelbarrow. The former is also called a "truck," or "rubble car," and is used for carrying materials, such as rails, ties, ballast and other supplies too heavy or too bulky to carry on the hand car. Owing to the heavier loads it is required to carry it must necessarily be made stronger than the hand car. The severest test on the car is a full load of rails, because they overhang the car and ride with a teetering motion. For ordinary section work the axles should be of steel, 1¾ ins. in diameter, and to save lifting too high in loading, the wheels should be lower than ordinary hand car wheels. Sixteen inches is about the right diameter, being a compromise between high lifting and hard running; for the smaller the wheel diameter the harder the car runs. There is another important advantage with the low push car not always taken into consideration, and that is the facility with which low cars can be propelled by "kicking." When the car is running light or empty four men can sit at the corners of the car and send it along at good speed by kicking against the ends of the ties. A high platform places the men out of convenient reach of the ties, so that the operation of kicking becomes extremely fatiguing, and practically of no effect as a motive power.

The length of wheel base or distance between the axles should be about 4½ ft. for a 7-ft. car. The platform is usually made 5½ ft. wide, extending over the wheels; and pieces of 2x½-in. strap iron should be placed across the ends to protect them against being cut into when the car is loaded with rails. The platform of the car is usually formed upon two 2x6-in. side sills, to which are bolted the journal bearings, and across which are placed the pieces upon which the floor is laid. As a rule these cross pieces are notched in the ends, where they fit over the side sills, as shown by sketch in Fig. 347. This is a bad arrangement, for the piece is almost sure to split, as indicated by the heavy line, when the first heavy load of rails is carried, and if cross-grained (as it frequently is) the truck is greatly weakened. It is better to make up this 2x6-in. piece with a straight-grained piece of 2x4 and one of 2x2, bolted together near the ends. The lower part is needed to act as a strut between the side sills. To prevent spreading of the side sills under heavy load they are usually held against the struts by long bolts passing entirely across the frame, and to keep the car body properly squared truss rods are sometimes run between diagonally opposite corners. Most push cars turned out by manufacturers, have the end cross timbers strengthened by truss rods. To keep dirt out of the bearings the axle boxes may be shielded with flaps of leather or painted canvas.

Fig. 347.—Improper Form of Cross Piece for Push Car.

The weight of the car can be got down to 450 or 500 lbs. At least four men are required to lift such a car bodily and carry it to or from the track. The ends of the side sills are usually made to project beyond the car and are rounded off for handles. Two handles at each end of the car are enough, but a horizontal hand iron at the middle of each end cross piece affords opportunity for a third man at each end, in lifting the car, and is a serviceable attachment. To facilitate handling the car with less than four men there should be a loose wheel on one or both axles, so that the car may be easily turned in the track. For a small crew the best form of push car is one having the body detachable from the axles, so that two men can easily put it on or off the track in sections. With this form of car, however, the boxes cannot be packed and the oiling must be attended to frequently. For trucking cinders or other ballast material the car body may be provided with stake pockets and removable side and end boards, which are usually made about 12 ins. high. For quickly dumping loads when working on main track, dumping beds or platforms are sometimes provided for push cars. This device consists of a platform of boards nailed across a half-round stick and sided up on three sides. The platform (or shallow three-sided box) is about 8 ft. long and 6 or 7 ft. wide, and it is placed for service with the rounded support (which runs longitudinally under the center of the platform) near the side of the car, with the open side of the platform or box outward. The platform is dumped by tilting it over the side of the car. Push cars, when not in use, should be kept at a safe distance from the track and the wheels should be secured by chain and lock. Neither push cars nor hand cars should be taken off the track and left where they will obstruct highways.

Push cars to be used on grades should by all means be provided with a strong brake at the side, for when such a car with a heavy load gets beyond control, on a grade of any consequence, it runs away like the boy's yoke of oxen—"powerful stout." A Sheffield push car with brake rigging is shown in Fig. 348. The weight of the car complete is 490 lbs. Brake blocks are applied to all of the wheels. In a device of this kind the brake lever should drop down out of the way of loading, when not in use; or the lever might consist of handle and socket, as arranged for a track jack. When the car is not equipped in some such way it is braked by taking a pry over a wheel with a handspike, through a hole in the decking; but the application of braking power to one wheel only has a tendency to wrench the car out of shape and the method interferes to some extent with the loading.

Any man who has helped to kick a push car some considerable distance must have been impressed with the desirability for some speedier and easier means of locomotion. The idea of providing hand cars with a detachable gallows frame and lever, by the removal of which the vehicle can be changed to a push car, and vice versa, has been put into practice in two or three different arrangements or designs. The construction of a certain pattern of Cyrus Roberts hand cars provides for ready conversion into push cars. All of the driving gearing is located beneath the decking or floor and the gallows frame is not built in with the platform, but constitutes an independent framework which is held to place by a "clamping bolt," when in position to propel the car. All that is required to remove the gallows frame and make the change is to loosen the clamping bolt and disconnect a turnbuckle on the pitman or connecting rod. On another combination car known

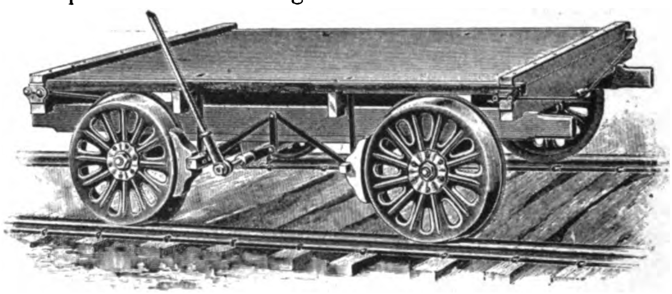

Fig. 348.—Sheffield Push Car With Brake.

as the Imperial pattern the support for the operating lever consists of a single upright standard fitting into a 3-in. square hole through a 9-in. iron plate and then into a socket under the deck of the car secured by brace rods. The lower end of this standard is tapered on all four sides, so that the tendency from wear of parts is to fit the standard more firmly into the iron base. For the connection of the driving rod with the large gear or "speed" wheel the latter is provided with four holes, so that in event of wear to one of them there are still three others available. The operation of removing or replacing the supporting standard and driving rod is a momentary affair, as there are no bolts or nuts to be removed, requiring time, and nothing to be misplaced or lost. Another interesting feature of the car is an arrangement whereby the position of the connecting rod can be changed on the handle bar or lever, so as to regulate the leverage according to the load on the car or the grade of the track. This position of the connecting rod can be changed by simply adjusting a screw, while the car is in motion, if desirable. By this means of adjustment the handles may be made to describe an arc of only 8 or 9 ins. on level track, where quick movement is essential to speed, or 18 to 20 ins. on heavy grade, where leverage is required rather than quick movement.

There is a handy little push-car vehicle known as the "Pony" car, which is particularly convenient for carrying light loads of ties, poles, lumber, tools, etc. in busy yards or wherever trains are frequent. It consists of a light frame on two double-flanged wheels arranged in tandem, to run on one rail (Fig. 344A). It is held in balance and pushed by a lever or handspike at the middle, and in case of emergency the car and its load can be quickly overturned, outside the rail, so as to put it clear of the track.

135. Other Tools.—The ax should be double-bitted. At least one bit is bound to see hard usage, but if there are two it is possible that one of them may be kept in good condition. A single-bitted ax with trackmen will usually be found in the same condition as a boy's jackknife—always dull—and it comes so handy for use as a wedge that the head is usually found badly battered from hammer blows. A bush hook or brush ax (Engraving *R,* Fig. 295) is a stout hooked blade carrying a strap and shank to which a single-bitted ax handle can be fitted. It is useful in cutting brush too heavy for the scythe, but too light for the ordinary ax. Brush scythes should be short, wide, and heavy. The brush scythe is a more suitable tool for cutting sprouts and small brush than is the brush ax. For grass also the scythe should be rather heavier than the ordinary grass scythe used by farmers, owing to the heavy weeds which usually grow along track. The snaths should be stout and interchangeable with either the brush scythe or the grass scythe. The list of tools for a section outfit (§ 116) includes two adzes. The necessity for two tools of this kind is that one is required for old ties and in rough work, where it cannot very well be kept sharp or in the best of condition all of the time. The other may be used exclusively on new ties and in new work, and in this way can be kept in good condition. The crosscut saw should have a wooden guard to fit against the teeth, to save them from being injured or dulled while it is being carried on the hand car.

A curving hook is made by bending a bar of inch round iron, 3 ft. long, into U-shape, and then bending about 6 ins. of each leg of the "U" at right angles, to hook under the base of the rail, turning up the extreme ends of the hooks about an inch to keep them from pulling off. Two flat files of medium size, one fine and the other coarse, and one round file, are often useful tools to have on hand.

If good water is handy along the section, a 3-gallon, heavy, galvanized pail, and two dippers or cups are needed. The best vessel for carrying water any considerable length of time is a stone jug covered with two or three layers of coarse canvas or gunny cloth. By wetting this outside covering the evaporation of the water from it will cool the water in the jug. Railway section hands, above all other men, are inveterate drinkers of water, and it requires a large jug indeed to hold a supply of water sufficient to last three or four of them during a hot day. Where water is scarce along the line a wooden keg, with iron handles, holding 15 or 20 gallons, is sometimes used. Another water receptacle used on some roads is a pine box lined with zinc or galvanized iron, leaving an air space between the metal and the sides of the box, for cooling purposes.

The wheelbarrow should have a box large enough to hold a good load. The wheel should be of iron and it should be of rather large diameter, so that the man pushing the barrow can see it (the wheel) over his load when turning corners on running plank, thus necessarily throwing more of the load on the arms than is the case with some wheelbarrows used elsewhere. The large wheel, however, enables the barrow to be easily pushed over a rough way. It is not usual to find on the market wheelbarrows strong enough for railroad service. The most accurate tape line is a steel one, but such is rather too expensive for the usage it would get among most section men. A linen tape with steel or brass strands running through it lengthwise is accurate enough. Such a tape will not stretch, but it will shrink if it gets wet, and care must be taken, therefore, that it is not used in the rain or trailed in wet grass or on wet ground. A 50-ft. tape will answer, and it should be graduated to feet and tenths. The foreman should at all times, while on duty, carry a 2-ft. rule in his pocket.

The plan of straightening angle bars at elbowed joints on curves or exchanging places with the outside and inside splice bars at the joints, to correct the alignment of the rail, is elsewhere referred to. While it is an easy matter to straighten an angle bar bent horizontally, by suspending it between two supports and striking the middle of the bar with a hammer, such method of treatment will not straighten a bar which is surface-bent. Mr. John Wirley, roadmaster with the Lake Shore & Michigan Southern Ry., is the designer of a tool for straightening surface-bent angle bars. The device is in general use on that and other roads with satisfactory results. The right of manufacture being in the hands of the Elkhart Frog & Crossing Works, the tool is commonly known as the Elkhart angle-bar straightener. Briefly, the tool (Fig. 349) consists of a screw clamp and a pair of blocks notched to accommodate the legs of an angle bar in any one of the four positions in which it may be desirable to place the bar for straightening, namely: with the vertical leg of the bar right side up, or upside down; or with the vertical leg lying horizontally and inside up, or outside up. In

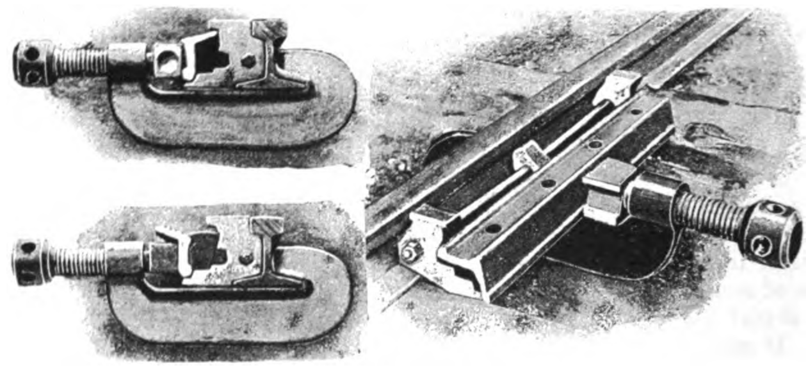

Fig. 349.—Elkhart Angle-Bar Straightener.

straightening a bar the clamp is hooked over the flange of a rail in the track and the blocks or rests for the angle bar are placed against the web of the rail, on the opposite side. The splice bar is then fitted against the blocks and is bent by turning the screw against its middle, as shown in the illustration. It is thus seen that it is possible to straighten the bar when bent in any one of the four ways in which it is possible for an angle bar to become distorted in the track; that is, bent in surface, either up or down; or in alignment, either outward or inward.

136. The Use and Care of Tools.—While the proper use of track tools cannot be said to require skill of the hand to a high degree, still it takes some time for men to learn to use them readily, and a fair degree of intelligence with the exercise of good judgment are essential in order to turn out good work with them. When breaking in new men foremen should insist at the start that they learn to use tools properly, so as to be able to perform a satisfactory amount of work for a fair amount of exertion. A man who can handle all track tools well can make himself quite handy in a good many other occupations. Men should get into the habit of using such tools as the shovel, tamping bar and hammer either handed. It makes the work easier, for to change hands gives a sort of rest; and it also helps to keep the laborer's shoulders even.

Foremen should be held strictly accountable for all the tools intrusted to their care, and they should be made to pay for such as they cannot show up. A good plan to inaugurate is to have a number stamped upon every tool (in Arabic numerals) on some portion of it where it will not be worn off, and a book account or record should be kept of the same from the time the tool is issued from the headquarters until it gets back there again, after being worn out or broken. In this way could be stopped the practice of stealing tools, for which section crews are notorious. A tool found on a section, having a number not corresponding to any charged against that section, or having no number at all, would indicate that that tool has no business there, and unless the number has been effaced it could be returned to the section to which it had been charged; at all events a wrong number or the absence of a number would place the foreman in position to show cause therefor. Each section foreman usually marks his tools in Roman characters to correspond to the number of his section. The practice serves as a ready means of picking out the tool at sight, but is no guard against the dishonesty of other section men, it being an easy matter to take a hammer and cold chisel and add an "I," and "X," or a "V" or to change an "I" to an "X" or to a "V." A method sometimes followed, with the intention of preventing additions to Roman numerals without being detected, is to make a horizontal chisel mark each side the number, thus: —XII—. This method of marking is not, however, invulnerable, for it is an easy matter to change either letter "I" to a "V" without cutting across the horizontal mark, or if, using the present case for illustration, the horizontal chisel marks be lengthened so as to cut across the last "I" of the "XII," then Section XI might claim the tool, since, to all appearances, it would seem as if Section XII had stolen the tool from Section XI and put on an extra "I." A discussion of this matter of changing marks on track tools, somewhat more at length, was published in the Railway and Engineering Review of Feb. 4, 1899, in which I concluded with the following remarks: "There are numerous other ways by which section men get around any system of marking by straight lines. A stolen tool—a bar, for instance—is sometimes purposely bent at the point where the marking is made and then hammered, as if to straighten the bar, thus obliterating the marking. The bar is then thrust into a heap of dirt, or thrown into a mud puddle to rust awhile, and then sent to the shop for repairs. After it comes back any marking may be placed upon it which the new owner chooses, and who else can establish a claim to it? But if all track tools were stamped at headquarters, in Arabic numerals, a stop would be put to the practice of revising the markings on tools, because the would-be counterfeiters would not have the stamps and would not likely go to the trouble of procuring them."

Worn-out tools and those broken beyond repair, no matter in what condition, should always be sent to headquarters, so that when sending new ones in exchange the roadmaster's department may know what became of the old ones, before removing the charge from the books. The division track official should occasionally review the tool reports of his section foremen in search of excess accumulations. A few surplus tools do not seem like a matter of much importance to the foremen, individually, but when such lists are multiplied by the number of all or of a large portion of the sections of a division, the stock becomes a large one and represents a considerable idle investment. Like importance attaches to the practice of storing materials on the various sections, over and above the local requirements. The proper place for storage of tools and track materials is at the division headquarters or some other one point convenient for distribution. If a foreman's outfit of tools is augmented for a temporary increase in the size of his crew, as when taking up some special piece of work, he should, after his crew has been reduced to the normal basis, be required to return the surplus tools to the division storekeeper. In instances of this kind large supplies of tools are liable to be needlessly withheld from service for several years.

137. Tool Houses.—Every section should by all means be provided with a tool house. The practice of keeping tools in a box unprotected from the weather, as is the case on many of the less prosperous roads, is destructive of tools, is inconvenient and is time lost. At the end of the day, when quitting work, men will usually throw the tools into the box in haste, and in this way they are frequently broken or otherwise injured. Many times when a particular tool is wanted it will be found in the bottom of the box, and so the whole pile must be handled over in order to get at it. Tools kept in a box out of doors during wet weather will be found damp or wet much of the time, so that the iron ones will, if not used every day, soon be heavily coated with rust, and wooden handles will decay in short order. Hand cars habitually left out of doors over night deteriorate rapidly; besides, in winter the handles will often be covered with frost or the body with snow, at starting out in the morning. On the other hand, a tool house affords a place where the tools can be kept dry, everything may have its place, and, when wanted, the hand may be placed upon it without having to overhaul a half dozen other things. Such tools as are habitually carried on the hand car, and such tools as are in daily use during the particular season of the year, may remain on the car when it is run into the house at quitting time, thus saving considerable time and labor which otherwise would be expended in loading the car in the morning and unloading it at night.

If possible, the tool house should be so located that in taking the hand car from or to it mornings and evenings the crew will not be hindered by standing trains. As a rule, therefore, it should be outside of the switches, in case there are side-tracks in the vicinity. If the room on the right of way will permit, the house should be far enough from the track to allow the hand car to stand between it and the track, clear of trains, and still leave room for the door to swing. One large door gives less trouble than two smaller ones, and if the house cannot be placed far enough from the track to have a swing door and give the desired clearance, a sliding door or one hung on rollers should be used. The tool house floor should be level with or slightly lower than the top of rail, but not higher; if lower, the track leading into a house having a swing door must be level for a sufficient distance in front of the house to permit the door to swing. If the track leading into the house is of metal rails, they should be laid to slope from the track, so that a hand car left standing without being trigged will not run toward the track. It is a matter of some convenience to have the space between the track and the tool house planked over, the plank laid parallel with the track. In such a case the hand car track running into the house may consist of 2x4-in. wooden rails spiked to the platform. These rails may be omitted within the swing of the door, so that a door may be used which will close tightly at the bottom.

The architecture of a tool house is not very complicated, but as the building is intended to serve a special purpose the proper plans for it require some study. The typical section tool house of American railways is a frame building, oblong in plan and sheathed with upright boards and battens on the outside. The ordinary hight from floor to top of plate is 7 ft., the roof is double pitched, is laid with shingles or sheet metal, and the frame has corner posts, sometimes braced, but no studding. The floor is generally, or should be, laid with 2-in. plank. So far as the purposes of the building are concerned, construction on this order is sufficiently elaborate. The character of the finery that may be added, for the sake of external appearance, depends upon the financial status of the road and concerns more especially the buildings and the traffic departments; the trackman is concerned with other things.

The building should contain ample room for the hand car, push car, grindstone and other tools, and additional space for three or four men to do tinkering work occasionally, as on rainy days, when waiting for the weather to clear up. A building 14x18 ft. in plan just about fulfills these requirements properly. About the smallest tool house heard of is 9x12 ft. in plan. A building of this size affords room to put the hand car and tools under lock and key and that is about all. A small tool house should be placed with the longer side facing the track. The car will then enter through the longer side of the house and it should enter near one end, so that as much clear space as possible may be had between the car and the other end. As a matter of illustration, if the hand-car track enters the long side of a 10x14-ft. house, 18 ins. clear of one end, there will be a clear space of 7x10 ft. in the other end of the house. This is the standard arrangement on the Bessemer & Lake Erie and a number of other roads. With a house of ample size it does not matter so much which side of the building faces the track, providing there is plenty of room on the right of way. If it be the gable end, the hand car or cars can be run farther into the building, thereby leaving more clear space just inside the large door than could be had if the car entered the longer side of the building; and clear space at this point is oftentimes desirable because of the better light, especially during a cloudy or stormy day. In any case the car should enter the building near one side rather than at the middle. In a house of proper size the car should stand not less than 3 ft. clear of the nearest side, so that one may easily walk all the way around it. In a 14x18-ft. house, gable end to the track, this arrangement would leave a clear space 6 ft. wide the length of the house.

Along the sides of the house there should be arranged a few shelves for the small tools, racks for holding bars and other long tools in an upright position, hooks for water-proof clothing, etc. Shovels should be hung from pegs, and all other tools arranged conveniently, instead of being thrown into a heap in the corner. There ought to be small 4-pane windows in three sides of the house, guarded outside by board shutters, and a small work bench, say 18 ins. x 5 ft., made of 3-in. plank, should be placed under one of the windows. The bench should be fitted with a drawer and a 4-in. machinist's vise, or a blacksmith's vise. With the vise should be furnished a drawing knife, which is useful in fitting handles to tools. Attached to the side of the house near another of the windows should be a box or locker with a sloping hinged cover to serve as a writing desk for the foreman and a depository for report blanks, shipping tags, writing materials, small expensive tools, etc. On some roads the tool houses are provided with a small room for the foreman's use, and with a chimney and stove. The latter, in winter time is a desirable affair, from the trackman's standpoint, but generally too comfortable and attractive for profit to the railway company. The surroundings of a tool house are sometimes such that inside privy facilities are desirable, and such may be provided for by partitioning off a small room in one corner.

The standard section tool house of the Toledo, St. Louis & Western R. R. is 13x18 ft. in plan, standing gable end to the track. A 5x13-ft. room is partitioned off in the back end for the foreman's office and each room has two windows. The foreman's room is provided with a stove with a Dickerson cast iron watch box smoke jack on the comb of the roof. The standard section tool house plans of the Erie R. R. are shown as Fig. 350. The house is 12x18 ft. inside and stands with the longer dimension parallel with the track, the hand-car track being at the middle of the house, with a clear space 6½ ft. wide on either side. The plans show a slate roof, but not all the tool houses of the road conform to specifications in this respect. There are windows in the gable ends, with shutters, and a double slide door. Entering the house, there is a covered box for oil and lanterns, at the right side of the door, and under the window on the left side of the house there is a stationary tool box built in with the floor and window studding. The grindstone is properly in front of a window. The rear side of the house is occupied by racks nailed to 2x4-in. studding, as shown in detail. The rack on which tools are laid horizontally consists of three tiers of 2½x1¼-in. chestnut pins 10 ins. apart vertically. The rack from which tools are hung consists of a 2x4-in. piece nailed across four studdings, 5 ft. 10 ins. from the floor, and set with eleven 1⅜-in. round chestnut pegs. Other details of the general construction, of the door guide and rail, of the windows, racks, etc., are clearly shown.

In the ordinary tool house, such tools as scythes, snaths, pails and other extra tools, shims and extra supplies carried in stock, are usually in the way, some being piled up in corners or stored where they will encroach upon room that is needed occasionally for odd jobs that can be done on rainy days. In winter time, especially, it is desirable to store the summer tools in some place where they will be out of the way; otherwise they discommode necessary movements about the tool house, and they are also liable to be broken or injured. This storage room in the Boston & Maine standard tool house is provided for in the attic, overhead. The standard plans provide for two classes of structures, namely single and double tool houses. The plans for the single house are shown as Fig. 351. The building is 24 ft. long and 15½ ft. wide, the longer dimension being parallel with the track. The hand-car track enters the long side of the house,

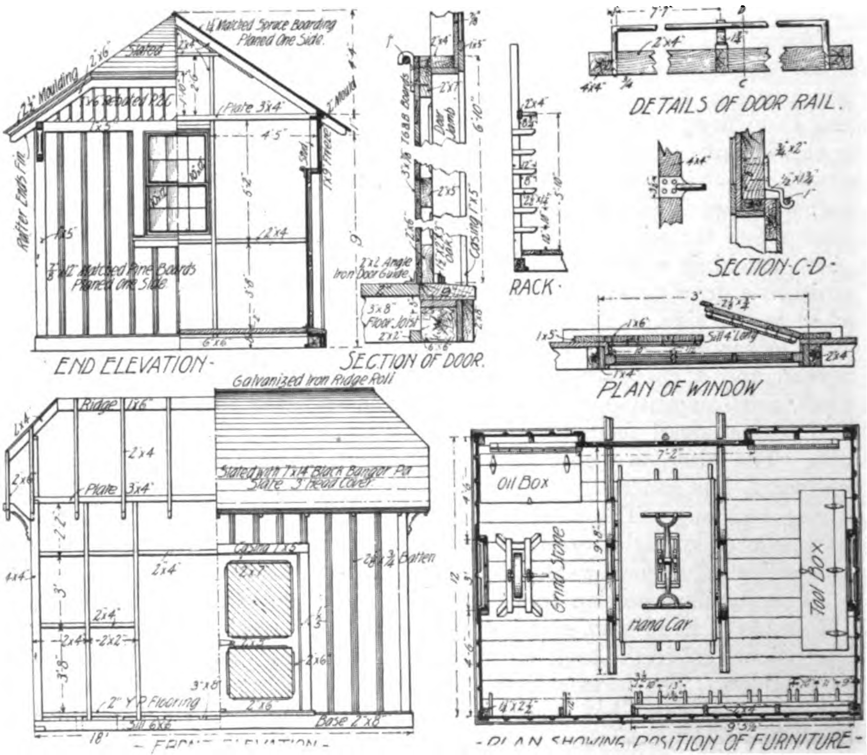

Fig. 350.—Section Tool House, Erie R. R.

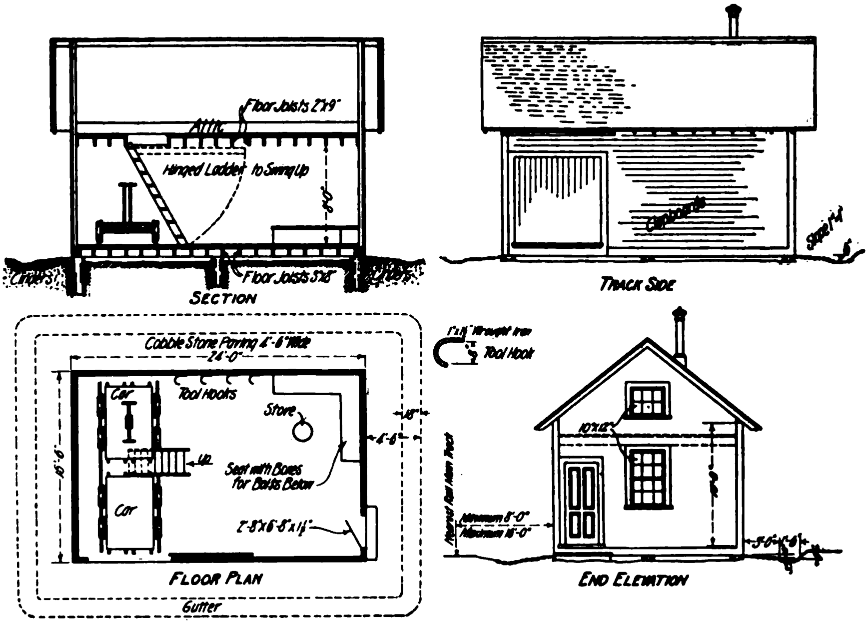

Fig. 351.—Standard Single Section Tool House, Boston & Maine R. R.

near one end, and the house is wide enough to hold a hand-car and push-car, with the door closed. A sliding door is provided at the hand-car entrance, and at the other end of the house there is a swing door of usual size. There is a chimney for a stove and in the corner of the house, near the location for the stove, there are seats arranged, with boxes underneath for holding bolts, spikes, etc. The first story is 8 ft. high, from the floor to the under side of the joists of the second floor. Access to the attic is by means of a ladder hinged at the top, so that it may be swung up out of the way. Other details and dimensions are made clear in the illustration. The standard double section tool house is shown in Fig. 351A. It is 40 ft. long and 13 ft. wide, with a 12x14-ft tool room at either end. Between

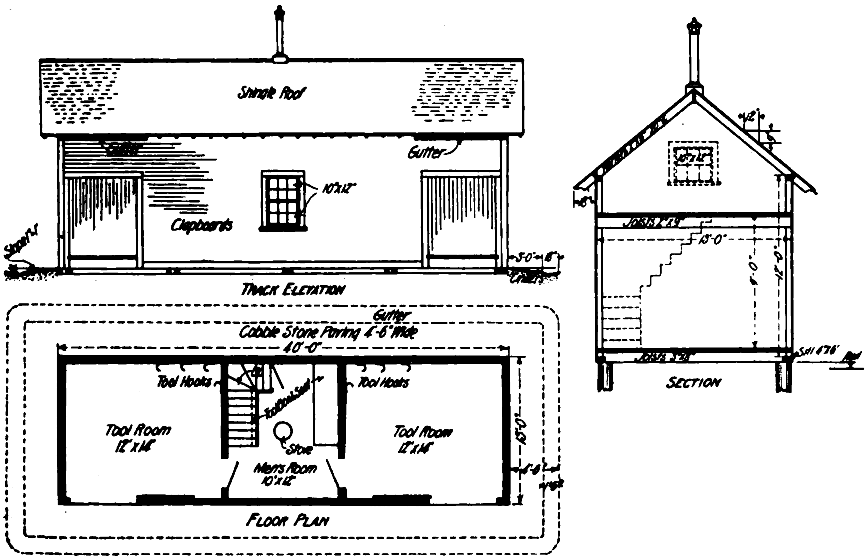

Fig. 351 A.—Standard Double Section Tool House, Boston & Maine R. R.

these two tool rooms there is a 10x12-ft. room for the men to sit in. There is a window in either side, a stove and a conveniently arranged seat. The entrance to the attic is by stairs leading up from this room. This building is higher than the single section house, the studdings being 12 ft. high. The house is well lighted with windows at the gable ends and at the back side in each room.

The plans for each class of building show a strip of cobblestone paving 4½ ft. wide extending entirely around the house, with a 1½-ft. gutter 3 ft. from the house. Wherever the situation permits this pavement is laid and painted with Aquol paint. Some of the houses have small desks, and some have closets. A feature of the design that is commendable, in each case, is the generous provision for working space and storage room.

The floor of a tool house should be swept occasionally. Spare bolts, spikes, nut locks, etc., should be kept in boxes or kegs, and other supplies in neat piles, each kind by itself. A quantity of spikes, bolts, angle bars, switch rods (where there are stub switches), and other supplies commonly used in track repairs, should always be kept on hand in the tool house. During winter time, scythes, snaths, and such tools as will not be used, should be stored overhead, where they will be out of the way. Space for such purposes may be had next the rafters by laying boards on the plates, across the corners of the house. When storing away scythes in such places the blades should be taken from the snaths. Lanterns necessary for use as night signals should be kept filled and cleaned and otherwise in good condition, at all times, and oil cans, unless otherwise specially provided for, should be set in a shallow box or wooden tray filled with sand. Locks for hand cars and tool houses should not be the regulation switch lock, else trainmen and others having switch keys may help themselves. In cases of emergency on railroads there is never any trouble about opening any kind of a lock. Scrap must be stored outside the tool house, and on some roads specially constructed bins are built for the purpose. The standard scrap bin of the Southern Pacific Co. is a box 8 ft. square walled up with four layers of old ties halved together at the corners and spiked. The bottom of the box is a layer of old ties, and the interior is partitioned off with walls of old ties toe-nailed to the sides of the box. Two of the compartments, 3x3 ft. each, are used for assortments of track scrap and the other compartment, about 3 ft. x 6 ft. 8 ins., is used for car scrap.

138. Tool Repairs.—Tools should be kept in good repair. It seems unnecessary that this should be said, yet how many foremen are negligent of so obvious a duty! And then there are foremen—and a goodly number, too—who withhold tools from the repair shop longer than they should, out of fear that seemingly frequent repair bills charged against their sections may in some way affect their standing, or possibly their tenure of position. Such practice is bad economy for the railway company, because both the quality and quantity of the work turned out by trackmen is in many cases largely dependent upon the condition of the tool used. Possibly some roadmasters are to be blamed for the prevalence of such a foolish notion among their section foremen. At any rate some sticklers for close inspection of track work have put themselves on record as favoring low cost of tool repairs and maintenance of tools as one of the conditions to be considered in awarding prizes or premiums at times of annual inspection. I doubt the wisdom of such a plan, as fear of repair bills incurred might beget the custom of wearing tools beyond the point where they cease to be effective. The manipulations of the trackman are not as delicate as those of some other mechanics, and first-class trackmen will wear out tools faster than some other trackmen; while a tool in the hands of a "rambunctious" man will occasionally meet with an accident. If, however, tools are being frequently and recklessly broken or discarded before they are sufficiently worn, that is another question, and a proper knowledge of the use of tools on the part of the division officer, in connection with a proper system of calling in old tools whenever new ones are forwarded, is a sufficient check against extravagance.

The work of repairing track tools at headquarters should, as far as possible, be managed by one man, who should carefully study the shapes, dimensions, temper, etc., best suited to the tools for their uses. Of course the bulk of the repairing must be done in the blacksmith shop, and the blacksmith should have at his command such aid, whenever needed, as will enable him to keep abreast of his work and return promptly the tools sent to him for repairs. On some roads tools sent for repairs are exchanged at the storeroom for others in good repair, thus facilitating quick return. But such practice necessarily dispenses with any system by which each foreman can identify his own tools, or have them repaired to suit special conditions existing on his section.

There should be a well regulated system of sending tools to and from the repair shops. It is usual to tag the tools, throw them into the baggage car and let them go. In this way tools frequently get lost, delayed, or mixed with those belonging to different section crews, due to tags pulling off, illegible writing, or other cause. Mr. W. B. Parsons, Jr., in his book "Track," suggests that in sending tools to and fro for repairs they should be checked, after the familiar manner of checking baggage. Brass checks, similar to baggage checks, have the number of the section and the station address stamped upon one face of the check and the address of the repair shops upon the reverse face. The check strap is slipped through two slots, in opposite edges of the check plate, so as to cover one face and leave the other face exposed to indicate the address to which the tool or package of tools is going. When the tools are to be returned the strap has simply to be slipped through the check plate from the other side, exposing the address on the reverse face and covering the address not wanted.

In case there are special instructions with reference to the repairs of the tools the foreman should forward a note to the repair shop or blacksmith, stating what is wanted. Such information, if written on a tag attached to the tools, may easily be lost before the tools reach the shops. It might be well, however, to note on a tag that instructions have been sent by separate letter. When sending tools for repairs the foreman should forward a note to the roadmaster, giving a list of the tools sent and the date and train, this note to be kept on file in the roadmaster's office to serve as an aid in tracing the tools, should they for any reason fail to get back. On some roads the foremen are supplied with printed blank forms for com-

municating to the shops and the roadmaster such information as is noted above. One form is gotten up in the style of a card about $3\frac{1}{2}$x5 ins. One side bears the address of the roadmaster, and on the reverse is printed the report blank. The accompanying form is a sample.

Another form similarly worded is addressed to the master mechanic or master blacksmith. On some roads tools sent for repairs are billed by the agent, the same as ordinary freight, but such is not always practicable, since in many cases tools have to be put on at flag stations where there are not facilities for billing or keeping record of freight or baggage.

139. Section Houses.—It is sometimes incumbent upon railway companies to furnish dwellings for their trackmen, especially on some western roads where the distances between settlements are great, and where there could be no inducement for a man to build a house for himself, and, of course, no opportunity to rent one. Under such circumstances it is frequently the case that a station, or at least a flag station, is established, and part of the building is used as quarters for the foreman and crew. Again, since it is important that at least the foreman of the section crew should be within easy call, many railway companies make it a practice to build a house for every section, on the right of way, regardless of opportunities for renting, in order that the foreman may remain near the track while off duty. For well settled districts, however, there are many companies which think it not worth while to furnish section houses, as foremen who are single men usually hire their board and do not care to bother with a house. And then, some foremen choose to own homes of their own in the near vicinity of the track. In such an event a company house might have to stand empty, unless the foreman was required to occupy it—which would not be a good policy to insist upon, for such would partake more of the nature of a system of tenancy than of railroading. The less a railway, or any other, company has to do with the private affairs of its employees the less trouble will the company have, and, as a rule, the more dependence can it place upon its employees. On eastern roads generally the practice of providing quarters for the track employees is not as common as it is in the South and West. Through purchase of land, however, railway companies sometimes come into possession of houses which are rented to track foremen, agents or other employees. Where rent is charged for section houses it is, as a rule, only nominal. Since it is for the company's benefit that the track force, or at least part of it, should be near the track during off hours, it should not be the policy of the company to make profit on its rents. Many companies make no formal charge for rent to the occupants of its section houses, while in other cases no formal charge is made, but an allowance of a few dollars each month is made to such of their foremen as are not furnished with a house, or to foremen who are single men and do not keep house.

A building or dwelling for the use of the trackmen, if owned by the company, is commonly known on American railways by the name "section house," and for convenience it is here treated in the same chapter with tool houses. Such a building is usually a framed structure, roofed with shingles or sheet metal, sheathed on the outside with upright boards and battens or with horizontal weather-boarding, and finished inside with either ceiling or lath and plaster; quite frequently with ceiling, on account of the liability of plaster to crack or loosen from the jarring of trains, if the building is close to the track. A typical section house would probably look something like a one-story building with a double-pitched roof, a small entrance porch in front and an "L" or "T" portion in the rear with reference to the track. The capacity of the house will depend upon the question as to whether it is to be occupied by a single family only, or by a family and a number of boarders. In outlying districts it is customary for the foreman to board part or all of the single men working in his crew. In all cases the section house should afford plenty of room for a family of good size, and it should be two-storied, so that space for sleeping rooms may be had on second floor. Some scetion houses appear as if built on the idea that the occupants need facilities only for eating and sleeping. If the family occupying the house is to live in American style, provision should be made for a sitting room, on ground floor, and to fulfill this requirement the ground plan must usually include four rooms—a kitchen, sitting room, dining room and bed room; although if the kitchen be of good size and the family small, the kitchen and dining room would usually be combined in one; or if the dining room be large and the family small, the same room might easily serve the two purposes of dining room and sitting room. If the surface conditions in the locality will permit, the house should have a cellar, with both outside and inside entrances. If the house is located near a water tank or water station fed by gravity supply, it would be a matter of small expense, and certainly a great convenience, to pipe water into the kitchen. It would probably be best to lead the pipe from some point at about half the depth of the tank instead of from the bottom, such arrangement thereby serving as a water gage to persons who are interested and who are supposed to be responsible for the condition of the feed pipe leading to the tank. If the tank is supplied by pumping, it might be questionable whether the plan of supplying the section house with "running water" would be advisable.

As for the exterior design of the house and the arrangement of the rooms there is, of course, wide latitude for selection. While nothing fancy is required, the house should be comfortable and convenient, for such pro-

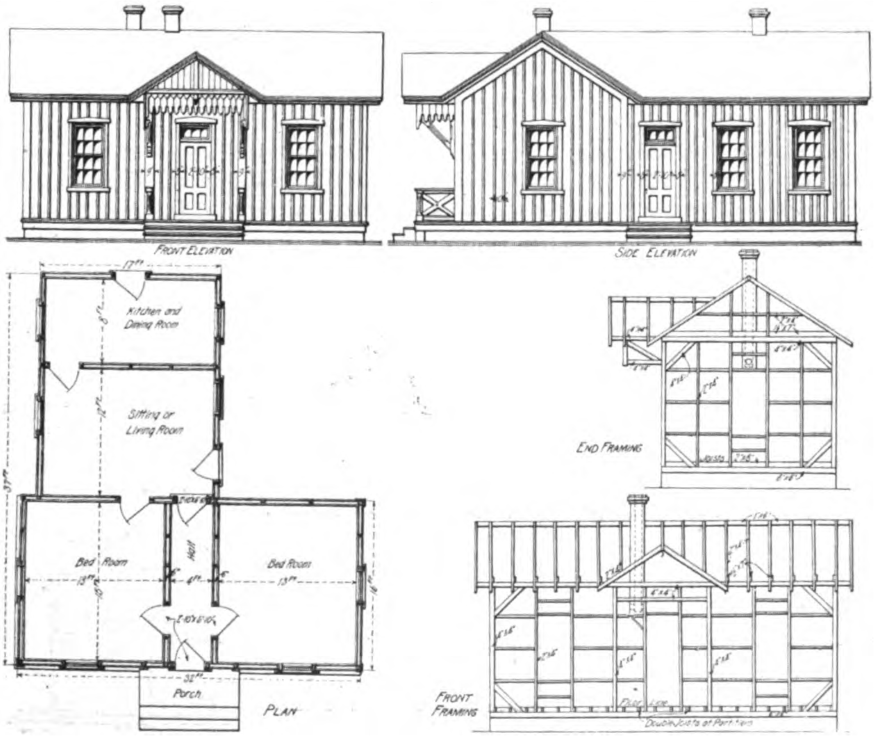

Fig. 352.—Standard Section House, Norfolk & Western R. R.

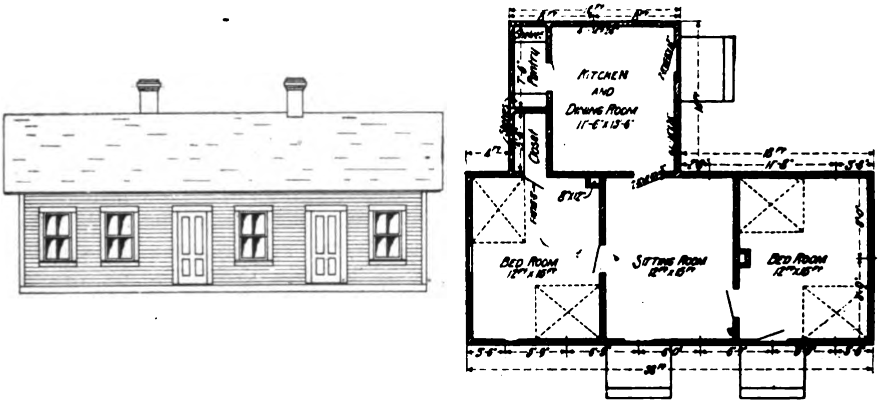

Fig. 353.—One-Story Section House.

vision will be found an inducement in getting a good class of men as foremen. It should be finished off inside with such quality of material that it can be kept clean and homelike. Matters of this kind which please the women folks will work together to encourage the foreman to take a lively interest in his work and to stay where he is. Aside from the arrangement of the rooms with respect to convenience in passing from one to the other, on the part of those engaged in the various duties about the house, the arrangement of the rooms and the openings and entrances thereto should be made with a view to comfort, taking into consideration the climatic conditions of the locality. Thus, for instance, in a hot country good ventilation will require that the house be of open construction, well provided with doors and windows, and so arranged that a draft may be had throughout the house. In a cold country, however, the principal aim should be toward compact construction, so as to economize in the heating arrangements necessary to keep the house warm. In dry portions of the country, as in the Southwest, where water is usually scarce, it is incumbent upon the railway company to provide the house with a cistern of good capacity, for catching rain-water.

In the southern part of the United States the railway section houses are usually one story in hight, with a plentiful supply of windows and doors, wide porches or verandas, and a separate building in the rear to serve as a kitchen. The standard section house of the Savannah, Florida & Western Ry. (Atlantic Coast Line) is designed especially to meet the conditions of a southern climate. The house is a one-story framed building, well spread out, being 33 ft. 6 ins. x 31 ft. in plan, and divided into five rooms. The kitchen is 13x16 ft. in size and is separated from the rear of the main building 15 ft., the two being connected by a covered walk. The house has a high garret, ventilated at the gable ends with louver windows, and a wide porch extends along the entire front of the house. The house is set on brick or stone pillars and the space below the floor is left open, to give

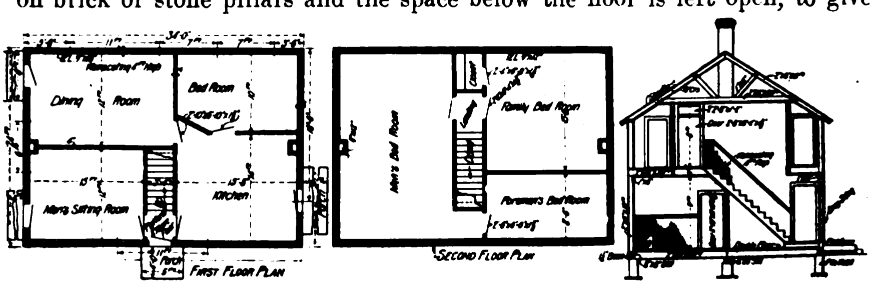

Fig. 354.—Section House, C., R. I. & P. Ry.

ventilation, being guarded at the edge of the building by several strands of barbed wire stretched from pillar to pillar, to prevent animals from getting under the building. The standard section house of the East Tennessee, Virginia & Georgia branch of the Southern Ry. is a one-story, three roomed, L-shaped building with a front and rear porch connected by a hallway through the center of the house, this feature being especially suitable for good ventilation. Many section houses throughout the South are provided with fireplaces in the two principal rooms, which arrangement conduces very much to comfort during chilly weather, in spring and fall, when it is not desirable to keep fires burning continuously throughout the day.

The standard section foreman's house of the Norfolk & Western R. R. is a cheap but neatly arranged one-story building of four rooms, and might be taken to fairly represent a typical southern section house. As shown in Fig. 352, there is a hall leading from the front porch to a sitting or living room in the rear, which also has a door opening to the outside. On either side of the hall there is a 13x15 ft. bed room, and in rear of the sitting room is the kitchen and dining room. In this part of the country it is not usual for the section foremen to board any of their men, and large section houses are not required. Ninety per cent of the section laborers are colored men, who provide a cooking stove, cots or bunks, buy their own sup-

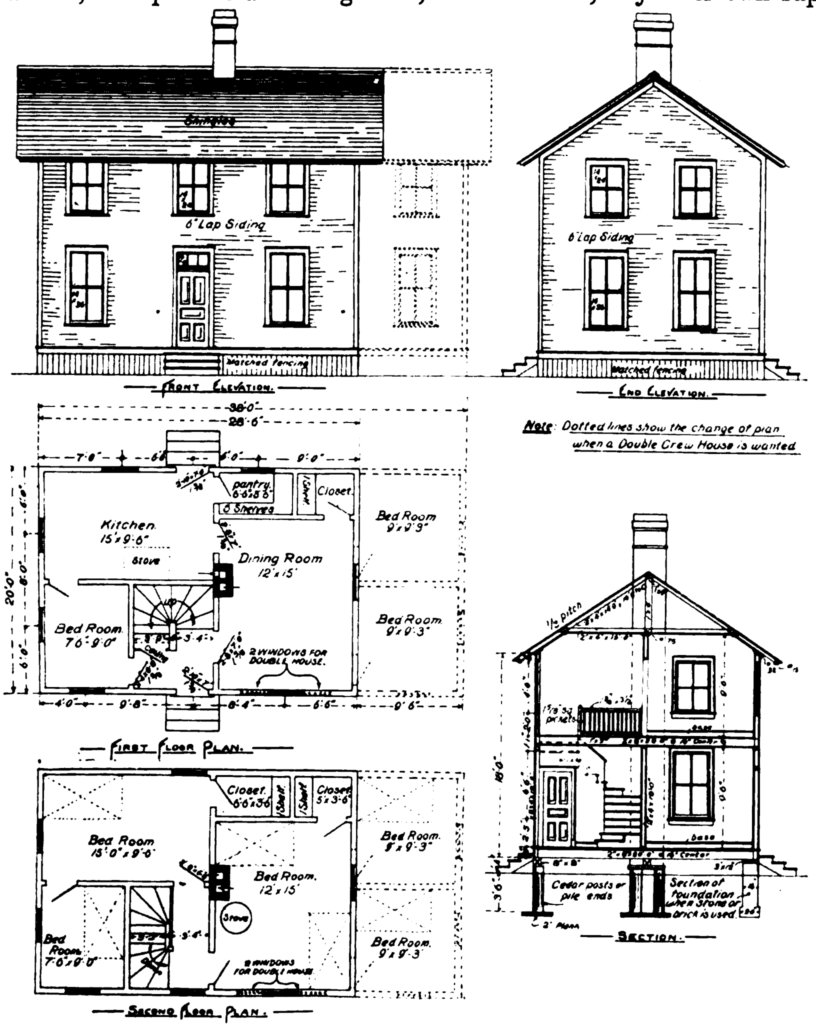

Fig. 355.—Standard Section House, C. M. & St. P. Ry.

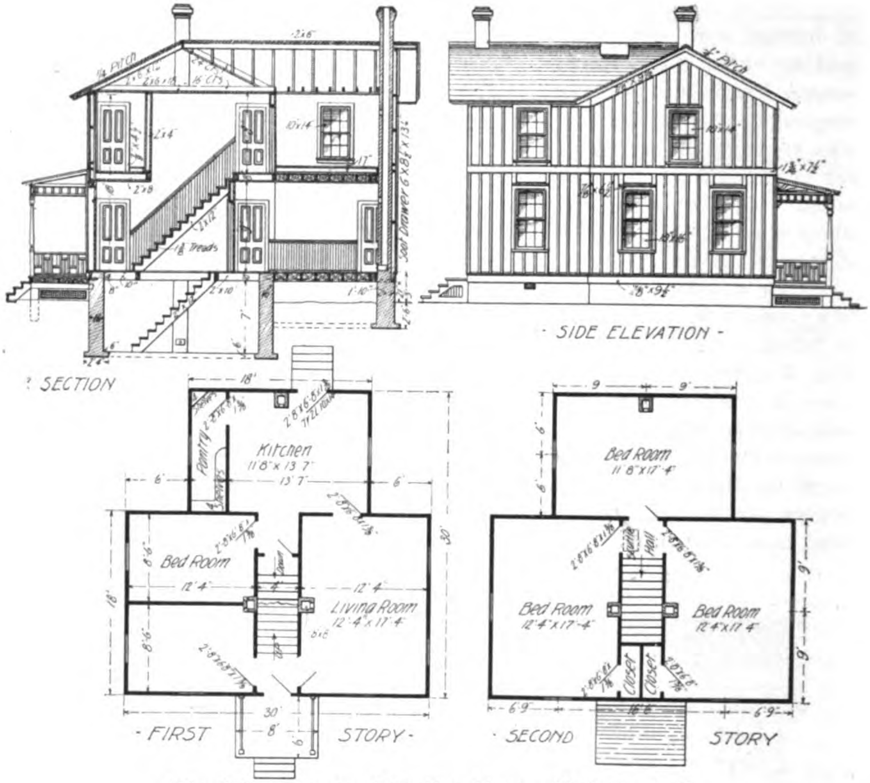

Fig. 356.—Standard Section House, Wabash R. R.

plies and do their own cooking. For their accommodation the railway company provides a one-room house 14x18 ft. in plan, known as the "standard house for section men." There are a door and window in the front side and two windows in the back side. A thimble and a brick chimney extend from the ceiling through the center of the double-pitched roof. To provide for large gangs temporarily employed old box cars are set off. Figure 353 shows the arrangement of a four-room, one-story section house of a western railway. There are three front rooms 12x15 ft. in size, with two front doors, and a kitchen, pantry and closet.

Coming to two-story buildings, Fig. 354 shows the arrangement of the six-room section house of the Nebraska district of the Chicago, Rock Island & Pacific Ry. A noticeable feature is the unusual number of outside doors. Considering the purpose of the rooms as shown, it would seem that a door should be provided between the dining room and men's sitting room, so as to avoid going through the kitchen.

The plans of the standard section house of the Chicago, Milwaukee & St. Paul Ry. are arranged with a view to alternative construction, to suit the size of the crew. For an ordinary or single crew the building has three rooms on first floor and three bed rooms on second floor. There is a convenient arrangement of closets, and a pantry, as shown in Fig. 355. The front door opens into a small hallway at the foot of the stairs leading to the upper floor, from which doors lead to a bed room on one side and the dining room on the other side. The dining room is 12x15 ft. in size and the kitchen 15 ft. x 9 ft. 6 ins. in size, thereby affording good opportunity to combine the kitchen and dining room in one, so as to reserve the large front room for a sitting room. Or the small bed room, which communicates with both the kitchen and hallway, would answer as a dining room for a small family. On the second floor the two family bed rooms communicate with each other and there is only a single door leading to the stairway. The kitchen auxiliaries, in the shape of pantry and shelves, are facilities not usually found in buildings of this kind. The building is 20 ft. x 28 ft. 6 ins., roofed with shingles and sheathed on the outside with 6-in. lap siding. The interior is ceiled. The building rests upon cedar posts or pile ends, or upon a brick or stone wall 16 ins. thick, as conditions determine. When resting upon posts the open space is closed in by matched fencing. The rooms are well lighted, by windows of good size for a building of this class, and in general the interior is conveniently arranged. When constructed for a double crew or for a large number of boarders, a 9½-ft. addition is built on one of the gable ends, thereby increasing the size of the building to 20x38 ft., as shown by the broken lines. This extra space, on both lower and upper floors, is divided into two rooms, each 9 ft. x 9 ft. 3 ins. in size, marked for bed rooms, in the illustration. It is readily seen that by leaving out the partition between these two rooms on the lower floor a room of good size, with three windows, is afforded for a sitting room or for any other desirable purpose. The position of the windows for either the single or the double arrangement is shown in the figure. This double arrangement affords on the upper floor four single bed rooms and one double bed room. The structure is designed with an idea to economize material, and it forms what might be taken as a very good basis for convenient additions, in various ways. Thus, for instance, if either of the longer sides of the building faced the south it might be provided with a porch of substantial dimensions; or to obtain additional room a lean-to or L or T-extension could be built on the rear side.

The standard section-house plans of the Wabash R. R. (Fig. 356) show a feature that is highly commendable, but not commonly found with railway buildings of this class, and that is a cellar. The house is also well arranged in other respects, there being a pantry and stairway to the cellar convenient to the kitchen, and a chimney in every room in the building. For plans of a large number of tool houses and section houses the reader is referred to an extensively illustrated work on railroad structures entitled "Buildings and Structures of American Railroads," by Walter G. Berg, chief engineer of the Lehigh Valley R. R.

The Hand Cars of the Pike's Peak Cog Road (See Index).

CHAPTER X.

WORK TRAINS.

140.—There is much track work which can be done most profitably with a train and crew, and much that cannot well be done in any other way. For various kinds of work a train of some kind is needed, at least a portion of the time, or at one or more intervals during the year, on every road or division; and in some cases it can be kept employed constantly. But whether the need of a work train be for little or much of the time, sooner or later such exigencies will arise as will make the demand for the train practically imperative, on any road where the reliability of the train service is of consequence. Such preparation should be made, therefore, that whenever the demand comes everything will be in readiness as soon as the crew can be made up. Compared with the ordinary expense for railroad equipment, the necessary cost of such preparation is small and it is a profitable investment in the end.

141. The Train.—The kind of cars which make up a work train depends, of course, upon the work the train is handling at the time; and as the different kinds of work usually handled by work trains and their crews are taken up in separate sections, the cars needed in each case, as well as those which must be kept in readiness with their equipments, are discussed in those sections. There are always required a locomotive, a caboose for the crew and workmen, and a flat car provided with a large tool chest or two. A locomotive too much worn for regular train service but which can be profitably used for awhile before going to the shops, will answer. Too often, though, the engine furnished the work train is one so badly out of repair that much time is lost in getting over the road; and the work is seriously hindered if it is unable to pull good-sized loads. It should preferably be a passenger engine of fair weight, so that passenger-train time can be made; and the train should be so equipped that, if necessary, it will be able to run as second section of a passenger train. In this connection, all cars used in work-train service should be equipped with air brakes; and cars having flat wheels and old cars too weak to carry heavy loads at high speed should not be used. In some cases—on level roads, for instance—an old locomotive too light for the increased train loads of the road is fitted up and used exclusively in work-train service. On roads where the grades are not heavy such an engine usually does quite well, and if it is too light to be of service at wrecks, a heavier one can be sent out on such occasions, for it sometimes becomes necessary to send two or three. A tender having a large capacity for fuel and water will contribute much toward the efficiency of a locomotive for work-train service. It sometimes happens that, owing to the interference of traffic trains, a necessary run for water is the cause of losing several hours' work. A switch rope should always be carried on the tender.

The caboose should be large—at least 40 ft. long inside. The inside should not be cut up by partitions, but the space should be in one compartment, and open. The seats are best arranged along the sides—generally chests with hinged covers, in which can be stored fuel, dinner pails, coupling links, etc. The seats should be provided with cushions of some sort, and a few arm-chairs will be found articles of much comfort to tired workmen when the caboose is crowded, and should be furnished, as far as there is room. There should be a heavy, flat-top heating stove anchored to the floor, at one side, at the middle of the car, a writing desk in one corner and a tank for drinking water in another corner. The windows should be large, so as to give good ventilation in hot weather. The doors at the ends should be large, and the platforms should also be large, covered overhead, and there should be a hand-brake on each. The steps and grab-irons should be large and conveniently placed. There should be a cellar or store box hanging to the middle of the car, underneath, and in it should be carried a 3-in. manila switch rope about 80 ft. long and two snatch blocks; two journal jacks and two heavy screw jacks; two ⅞-in. chains, each 16 ft. long; two rerailing frogs and two dollies. There need be no seats or windows aloft, as is necessary for a freight caboose, but hand-irons for getting to the roof should be provided at each end.

The flat car used as a tool car should always be coupled with the caboose; preferably ahead of it. A 2x8-in. plank should be hung along each side of this car at the proper hight to serve as a step, so that men may get aboard quickly and easily. Along the outer edge of the car floor a 2x2-in. scantling should be spiked or bolted fast to serve as a grab-piece for men getting on the car. On this car there should be two large tool boxes for holding picks and shovels, but both picks and shovels should not be thrown into the same box. They should also contain a few pinch bars, spike hammers, a claw bar, gage, track wrench and a dozen pairs of rail tongs.

Of course, the train may run on or hold main track only subject to the orders of the train dispatcher. Before starting out, full information should be given the dispatcher regarding the character of the work to be done, the limits within which it is to be done, the probable time required for doing it and where it is desired that the train shall go after getting through at any place. With this understanding the dispatcher may be able to make better arrangements than would be possible if he knew nothing about the plans for the train. Wherever it can be done without deranging the service too much, the work train should be allowed to hold main track until the arrival of freight or second-class trains in sight (always protecting itself by flagging), since it is frequently the case that when such trains are late much more time might be used by the work train, whereas, it would otherwise be lost while standing in some siding waiting for the arrival of the belated train. The case of a heavy grade against the freight train could be cited as an instance where this rule might have to be modified. It is a good plan to carry a velocipede or speeder on the flat (tool) car, as it can often be used to good advantage when it becomes desirable to "flag in" to some point. Work trains running "special" should whistle before entering every curve, so as to give hand cars a chance.

142. The Crew.—The crew required to handle the train is an engineer, fireman, at least one brakeman, and a conductor. While the brakeman is out flagging, the fireman should assist by opening switches. The conductor is sometimes dispensed with and the foreman of the working force is given charge of the running of the train, but since there is always need for two men to act as brakemen, and as the conductor usually takes the place of one of them, it is better to have him. To require too many duties of the foreman may hinder him in overseeing the working crew.

The foreman of the working force should be an active, decisive, coolheaded, intelligent man who understands all kinds of track work and who has previously been a laborer on a work train himself. He should be a more capable man than is necessarily required for the average section foreman, and his executive ability should be such that he can, at times, get intelligent laborers to hurry a little without offending them. He should be well acquainted with the rules and principles governing the running of trains, so that he can, in consultation with the conductor, lay out his work to best advantage. The man holding this position ought to be, or at any rate ought to be capable of being, the assistant roadmaster. It seldom works well to have the conductor act as foreman of the working force: first, because trainmen do not ordinarily take interest in track work, even if they have had previous experience in it; and, secondly, a trainman who is held responsible for one duty, such as the safe running of a train, and who does it well, is not so apt to feel responsible in a like degree for some other duty not usually intrusted to trainmen. He is, therefore, inclined to look upon the oversight of the work as a secondary matter, and feel that any slight negligence of it is not going to be charged against his record as conductor. It is, therefore, better to have the man in charge of the work responsible directly to the track department and to that department only.

The working force should comprise at least 20 laborers, and as many more as can be profitably employed at the particular work to be done. The cost to a railway company for a locomotive and fuel, and crew to run it, is about $25 per day, or about the wages of 20 laborers. There is no economy in sending out a work train without enough help to accomplish something proportionate to the entire cost. If the train is kept constantly at work it has its own crew, of course, but if it is used only a few days at a time inexperienced men picked up temporarily will not always make a satisfactory showing, and the scheme of sending out a work train at occasional intervals is sometimes called in question. When, however, it is considered that a competent work-train crew may oftentimes dispose of much section work, and to vastly better advantage than is possible for the regular section crews, it will sometimes pay to draw upon the section help for manning the work train temporarily, if it cannot be done in any other way. Under such circumstances the practice of calling a man from each section is a good one. These men will understand the work better from the start and accomplish a great deal more than green men hired upon the street. An increase of 10 or 20 cents per day in wages will usually be an inducement for them to cheerfully leave the section temporarily, especially with single men who have to pay board. Oftentimes a crew has been made up in this way where the management would not have consented to the hiring of a special crew. An opportune time to do this, providing the work is also seasonable, is about the usual time of laying off section hands, in the fall. Men sent from the sections to work with a train should each take a shovel and be responsible for its return when the user returns. Another plan, where the work train is intended only for temporary service, is to organize the crew with one of the floating gangs as a nucleus. In selecting a work-train crew, young or middle-aged men only should be sought, because climbing on and off cars is too hard work for old men, and, besides, to them, it is dangerous.

It should be the aim of the work-train foreman to keep the men employed as constantly as possible, and by all means to avoid working over hours. The men should not fall into the habit of thinking that because the train must run to a siding to clear the main track the company can afford to pay them for standing idle. The men get abundant rest while riding to and fro on trips that are really necessary. Any work which the foreman can see about him, for which he has tools, he should set his men to doing. Thus, for example, he may find opportunity to clean station grounds, or in summer time he can often steal a march on some section foreman by striking in and grubbing a half mile or more of grass in the track, while waiting for his train; or the men might work at ditching or policing. A half hour's waiting with a gang of 20 men is the loss of a day's labor paid for by the company.

143. Boarding Accommodations.—A question of importance in some situations is whether or not the crew of a work train should be boarded with the train. Unless the headquarters for the train are near the middle of the division it will frequently happen on single-track roads that much time will be lost running to and from work, and the hours of all connected with the train are much prolonged. This is so not altogether on account of the distance, but because of interference from the traffic trains, especially when scheduled trains happen to be late. On roads with long divisions, principally in the West, it is usually found to be a matter of much convenience to the company, and of comparatively little cost, to furnish facilities for board and lodging for the men, so that after the day's work the train may lie over at the nearest telegraph station.

Lodging in bunk cars should be furnished the men free of charge, and board at cost. It is rank injustice and little short of robbery to let the boarding of a work-train crew to contractors, or to allow the foreman or anyone else to run it at a profit. The same sentiments apply to the practice of running a commissary car to pay off the workmen in overalls and tobacco, at high price. Wherever it may be found necessary to supply the workmen with ordinary necessities of living it should be the business of the company to see that these things are furnished at cost. It is quite generally known that work-train foremen on some roads are, or have been, permitted to "make a little on the side" by boarding the workmen on their own account, the company fixing the price of board and collecting the same from the men's wages, while the foreman furnishes the board and, of course, decides upon the quality thereof. Looked at from an income standpoint, some transactions of this kind would easily lead one to believe that the chief business of the foreman was the keeping of boarders, while his duties as an overseer of labor and the monthly compensation therefor was the real matter "on the side." The most satisfactory method of boarding a work-train crew is on the club plan, each man paying his share of the cost. The company can well afford to furnish a car for the purpose of cooking and also pay the cost of cooking. The cost of provisions should then be borne equally among the whole crew, both the train crew and working force, the foreman and the cook—all who eat. There is no good reason why the cook should not be paid satisfactory wages and then share in the boarding expense, the same as the rest. Under such an arrangement some cooks would have reason to be less wasteful of the supplies which pass through their hands.

The cost of equipping a kitchen car, outside of the cost of the car itself, is small. A large, clean box car, preferably a new one, at least 34 ft. long on the inside, may be selected and end doors and four side windows should be put in. A large cooking range, well secured to the floor, should be placed in or near one corner. This end of the car should be fitted with cupboard and side table, and a water tank or reservoir having a capacity of at least four or five barrels should be provided and so arranged that it may be filled by hose or at water tanks. The reservoir is sometimes placed underneath the floor, taking its supply by hose from a water car or from the locomotive tender. The supply for the kitchen can be had through a pump at the sink. For a small crew the kitchen and dining facilities may be combined in one car, in which case an eating table, oilcloth-covered, may extend two-thirds the length of the car. This table will accommodate about

24 men at one sitting. If the working crew exceeds this number dining-car facilities ought to be provided in a separate car or cars. For this purpose ordinary box cars with a table running the whole length of the car, except for room to walk around the end of the table at each end door of the car, will answer; if there is only one dining car it should preferably be coupled in at the stove end of the kitchen car. By taking the dining table out of the kitchen car, one end of the latter is then available as a storage room for provisions, etc., for a large crew. Old baggage or combination cars remodeled to suit the service are much used for work-train dining cars.

One cook can prepare food for 25 men; and if the kitchen and dining facilities are combined in one car, and the men not permitted to rush in prematurely at meal time, he can set the table for that many and do the waiting. For a larger crew, especially if the victuals have to be carried into an adjoining car, he will need assistance in the cooking or in waiting on the tables. The dishes, plates, etc., should be of tin, and the cooking utensils of large capacity. There should be a small cleat along the edges of the table to keep dishes from being jarred off while the car is running, or when it gets bumped. A large cellar should be suspended underneath the car and provided with locks, for storing meats, vegetables, etc., and an ice box might also be arranged in it. There should be provided a half dozen wash basins, to be used outside, a pipe leading from the tank inside the car serving as a convenient water supply. Unless basins, soap and towels are provided in a convenient manner there are always some men who will neglect washing at meal time, much to the discomfort of those of more cleanly habits.

A supply of provisions sufficient to last several days should be bought wholesale, each time, so that the board will cost a minimum. Daily supplies of fresh meat and other perishables, as per the foreman's order, can, with but little trouble to the company, be sent by the regular trains. The foreman should see to the accounting for the same and to the distribution of the charges. Everybody should be treated alike—second table with the first, if meals have to be served in that way—and the foreman should not permit the trainmen to slip into the kitchen at odd spells to feast on delicacies or to get their meals by special order. The regular meals should be good enough for all.

The following bill of supplies is supposed to be a fair estimate of the needs of 25 working men for 7 days, giving a good variety—perhaps better than many would choose:

Flour	50 lbs.	Baking powder	1½ lbs.	Ginger	¼ lb.
Bread	175 lbs.	Steak and roast	125 lbs.	Pepper	1 lb.
Coffee	22 lbs.	Boiling meat	50 lbs.	Salt	9 lbs.
Tea	1¾ lbs.	Ham	38 lbs.	Baking soda	1 lb.
Crackers	25 lbs.	Bacon	18 lbs.	Mustard	2 bot.
Granulated sugar	40 lbs.	Salt pork	7 lbs.	Catsup	½ doz. bot.
Condensed milk	8 cans	Codfish	10 lbs.	Pickles	1½ gals.
Lard	20 lbs.	Beans	25 lbs.	Canned salmon	½ doz.
Butter	27 lbs.	Rice	8 lbs.	Can'd corned beef	1 doz.
Eggs	18 doz.	Oatmeal	8 lbs.	Dried peaches	8 lbs.
Potatoes	300 lbs.	Corn meal	15 lbs.	Dried apples	8 lbs.
Turnips	½ bush.	Tomatoes	12 cans.	Dried apricots	8 lbs.
Onions	¾ bush.	Corn	12 cans.	Prunes	10 lbs.
Cabbage	40 lbs.	Peas	6 cans.	Pie fruit	3½ gals.
Cheese	25 lbs.	Raisins	4 lbs.	Syrup	2 gals.
Vinegar	1 gal.	Nutmegs	1 doz.	Kerosene oil	2 gals.
Soap	20 cakes.	Cinnamon	1 pkg.		

Bread, of course, would not be furnished a week ahead, neither would fresh meat, in summer time. A half barrel (98 lbs.) of flour will make

175 lbs. or 175 loaves of bread. As pointed out in the chapter on track-laying, the baking for a large crew can be done by an extra cook working at night. Altogether, there is more meat in this bill than will be eaten by the number of men stated, but eggs, preserved and canned meats and fish will keep; and about this quantity should be on hand to fall back upon in case the regular supply of fresh meat should for any reason be delayed, as often happens. When fresh milk can be obtained it should be used in place of the condensed article, and 7 or 8 quarts per day will be required. In place of the dried fruits there might be substituted, in whole or in part, about 32 quarts of canned fruits. There are a few things included, such, for instance, as the cheese, onions, catsup, etc., which could be dispensed with, of course, and not materially affect the necessary supply. In summer time it is desirable to have ice, and an ice chest should be provided. A supply of 100 to 150 lbs. of ice on alternate days is sufficient for the kitchen purposes. The cooking should be regulated somewhat to the season and to the climate. For instance, during the hot months of summer or in a hot and dry desert country salt meats should be used sparingly, or only for the evening and Sunday meals; otherwise the men will be thirsty much of the time and drink too much water, causing them to become weak and incapacitated for work. In districts where the water is poor such food should be avoided as much as possible at all times.

When the work comes to an end the cook should clean the car thoroughly and put things in order. A few of such eatables as are not quickly perishable should be kept on hand, to be had in readiness in case this car should be needed at a wreck, a slide or in other emergency.

An ordinary box car fitted with a small stove and bunks serves well for sleeping quarters. While it is possible to arrange double berths in two rows the length of the car, so that a 34-ft. car can accommodate 40 men, in 20 berths (upper and lower) such an allotment of space is too close for comfort, as it does not give the men room enough outside the beds to sit or stand around. It is better to arrange eight double berths on one side and eight single berths on the other side, including upper and lower in each case, thus providing for 24 men, leaving a wider passageway between the berths and a large clear space between the two side doors. The latter space is necessary for stove room or for proper ventilation in hot weather; and it also permits access to the car from either side, the need for which alternates from one side to the other as the car is placed on different side-tracks, or to meet other conditions. There should be a side lamp attached to each side of the car (as in cabooses) on diagonally opposite sides of the large doors, some benches, and perhaps a small table. The fewer conveniences there are, the farther will the men straggle off nights and Sundays to find them in neighboring towns. For bedding the men usually furnish their own blankets, which, with some straw, are sufficient. The bunk car, if used permanently for such, should have four windows in the two sides, and there should be end doors, so that one may walk from car to car through the train while it is in motion. These changes cost but little and do not so alter the cars that they cannot readily be turned again to their former use. Old passenger coaches with the seats removed and fitted with berths are much used for work train sleeping cars. The caboose provides the train crew and foreman with desk room for necessary writing. The bunk and dining cars should be left on side-track near the work, for they need not necessarily be pulled about continually. A car-load of coal should be taken along, and a night watchman for the locomotive.

For large work-train crews employed with more or less regularity, specially designed double-deck boarding cars are used a good deal. The outfit of this style for the St. Paul & Duluth branch of the Northern Pacific Ry. consists of two cars with accommodations for about 60 men. Each car is 40 ft. 8 ins. long, 10 ft. wide, and 16 ft. 3 ins. high, from top of rail to running board. The head room at all points on the road is sufficient to admit the passage of a car of this size. One of the cars in each outfit is known as the kitchen car, the lower floor being equipped with a range, ice chest, hot-water tanks and other necessary appliances. Over the cooking range there is a large hood to carry the heat and steam up through the second story, and there is a removable extension pipe above the roof to improve the draft. One end of the lower floor in this car is partitioned off for a foreman's office and dining room, which is used also by the train crew. The upper story has sleeping quarters for the foreman, train crew, and the cook and his helpers, and the remainder of the space is used for storage purposes. In the other car the entire space on the lower floor is used for a dining room. Instead of the usual arrangement of a long table extending lengthwise the car, there are a number of short tables placed crosswise the car, the length being such as to leave a clear passageway along one side, for the waiters. The dining room will seat 56 men at one time. The tables and benches are movable, so that the space may be

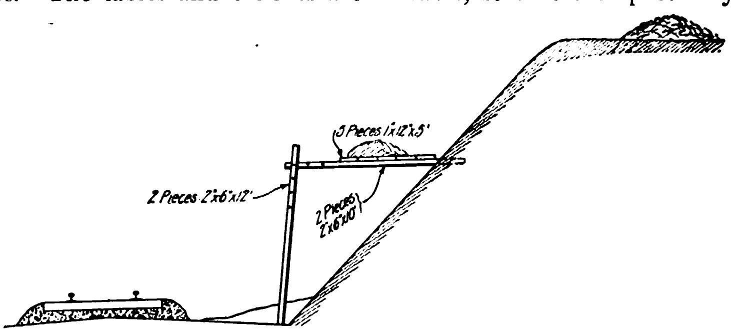

Fig. 357.—The Fort Ditching Scaffold, Southern Ry.

cleared to afford lounging room for the men at night and during stormy weather. The upper floor on this car is used entirely as sleeping quarters, and accommodations are provided for 48 men. The berths are double, upper and lower, with an aisle along the middle of the car. The car is well ventilated, there being a half window at the side of each berth. The upper story is entered by a stairway at each end of the car, but for emergency, as in case of fire, there are end doors convenient to the fixed ladders up the ends of the car. Owing to the unusual hight and large amount of surface presented to the wind, means are provided for attaching guy lines to the top corners of the car, to secure the car against uncomfortable swaying or danger of overturning when hard winds are blowing.

144. Ditching with the Train.—The task of cleaning out ditches in long, deep through cuts cannot be performed economically by the slow process of running the dirt or mud out on push cars; such is proper employment for the work train. Where the cuts are bad, ditches should be given a general cleaning out twice a year—in the spring, and again during the fall, before winter or the rainy season sets in. One advantage in handling the work with a train is that the material taken out of the ditches may then be used on fills which have shrunk away; and especially is such disposition of the material profitable if there be shrunken fills at the ends of bridges. Another advantage is that the means of transportation is of sufficient capacity to move large quantities of material, as when widening a cut that is too narrow. On many roads a sufficient quantity of material is taken from the ditches to maintain the fills to their proper width, and that such a balance may be maintained it is only necessary that some means of transporting the material be available. It frequently happens, also, that such material can be disposed of to good advantage in filling for a side-track about to be put in, or for a change of alignment somewhere in the main line, or to fill in trestle bridges. It is far better to dispose of the material in such ways, even if it must be carried some distance, than to run to a near-by siding to unload where the material is not needed, purely with the idea of utilizing time while waiting for trains to pass. On roads running through a hilly or uneven country it is usual to find fills on every section, where spare material may be deposited to good purpose.

The work of ditching should be thorough. Loose material should be cleaned from the faces of the cuts, and this can usually be scraped down while the work train is running to clear for the traffic trains. In summer time when the ground is dry and hard the picks may have to be used a good deal; hence a good supply of them should be carried along, so that a sufficient number may always be kept sharp. The most convenient way to carry picks while in use is to stick the handles downward through the stake pockets and let them hang at the side of the car. They are handy to get from this position, secure while the train is moving, and out of the way while unloading. If thrown upon the car they might get covered with material or be jarred off while the train is running. In some situations, as, for instance, where there is a good deal of ditching to be done in one place, particularly if the ground is wet, it is cheaper to use a plow than picks.

Flat cars used for moving dirt or gravel should have smooth floors. In unloading from cars which have floors cut up or so rough that there is not a good bottom for the shovel, much time is lost. Before loading the cars all spikes which may be projecting above the floor planks should be driven down. When loading material on cars during freezing weather, as must sometimes be done at slides or on other occasions, the material may be kept from freezing to the car, for several hours, by sprinkling the car floor with brine, or by scattering salt over it, just before loading. A water barrel and garden sprinkler furnish all the necessary equipment.

It frequently happens that in ditching cuts with work trains there are long delays waiting at sidings for the traffic trains to pass, and under ordinary methods of working it is not always possible to keep the men employed to advantage. Where the ground is firm it is permissible to deposit moderate quantities of ditch material on top of the banks, providing it is thrown well back from the top of the slope and does not interfere with the surface ditches. Wherever the material may be disposed of in this manner while the train is away, the ditching of the cut can be carried on without interruption. For getting material out of cuts that are too deep for casting at a single throw, Resident Engineer W. A. Fort, of the Southern Ry., has used a scaffold, of which he is the designer. As illustrated in Fig. 357, it consists of two 2x6-in. posts 12 ft. long, with two 2x6-in. horizontal pieces 10 ft. long running into the bank to support a platform of five 1x12-in. boards 5 ft. long, upon which material from the ditches is thrown in process of casting it out of the cut by stages. The posts and horizontal supports are bored at intervals to permit adjustment of the hight of the platform, and in a deep cut one scaffold may be placed above another. The device is obviously simple, and is readily carried about on a push car or work train. This scaffold was first furnished the section foremen, and was found to be of such value as a time saver when trains were late and the foreman was not allowed to use a flag to protect a push car, that the ditching trains were equipped with them. By placing one man on the scaffold and two in the ditch the dirt can be kept moving regardless of trains.

Ditching Machines.—Ordinary ditching is usually done by hand, but on some roads running through long stretches of swampy land or mellow soil machinery is brought into use. The Barnhart railroad ditcher consists of a light excavator or steam shovel mounted upon a timber frame, which is dragged along between the side stakes of ordinary flat cars in the same manner that an unloading plow is moved. The excavator rests directly upon a turntable which can be operated throughout a complete circle, and the handle of the dipper is long enough to permit the machine to excavate to the required depth below the track. The machine is supplied with a winding drum and wire rope tackle, which is stretched out over the cars ahead of the machine and anchored, thus enabling the machine to drag itself over the cars and travel away from the material which it excavates and loads upon the car behind. The radius of the boom is such that excavation can be made sufficiently wide to prepare the roadbed for a second track. This machine has been used on the Baltimore & Ohio, the Pittsburg & Western, the South Carolina and other southern railways.

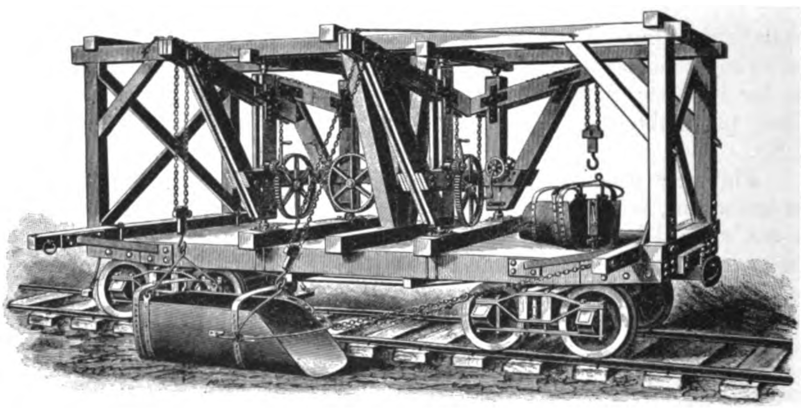

Fig. 358.—American Railway Ditching Car.

Another method of ditching by machinery is by the use of a car provided with side attachments which plow or scoop up the material by the movement of the car when coupled in with a work train or directly to a locomotive. The "American" railway ditching machine (Fig. 358) consists of a flat car upon which is constructed a heavy framework, strongly braced and provided with two cranes on either side. A car with low wheels, 20 ins. in diameter, is considered the best, although ordinary flat cars with 33-in. wheels will do the work. The ditching operations are performed by dragging a heavy scoop, of about 1½ cu. yds. capacity, at the side of the car. The scoop has 3 bails: one lifting vertically at the rear, another lifting vertically at the front end and another pulling horizontally at the front end, to which is attached a chain made fast to a projecting cross beam at one end of the car, for hauling the scoop. The scoop is suspended from the two cranes by means of chains attached to the vertical bails and wound up by winches on the car, so that the inclination of the scoop and the depth of scooping are regulated by the winches. The setting of the crane regulates the distance of the ditch from the track. By attaching a scoop to either side of the car, ditching operations may be carried on at both sides of the track simultaneously. The attachments are easily reversible, and can be worked either way without turning the car. In service the machine is roofed over, so as to enable the men to use it in stormy weather, at which time the condition of the ground is most favorable to the operation of the machine. The machine works best in muddy or wet earth, but can be used with good effect in dry earth which has been plowed. The material scooped up is held until the train is run to a fill or other point for dumping. The scoop is dumped by winding up on the winch which lifts the rear end. This type of machine has been used on the Minneapolis, St. Paul & Sault Ste. Marie, the Chicago, Milwaukee & St. Paul and other roads in the Northwest. A machine of simpler construction which has been used on the Chicago, Ft. Madison & Des Moines R. R., has a 12x12-in. beam 20 ft. long extending crosswise the car and supported upon braced posts, with winches for raising or lowering the scoops, which are suspended by ropes passing over pulleys at the extremities of the beam.

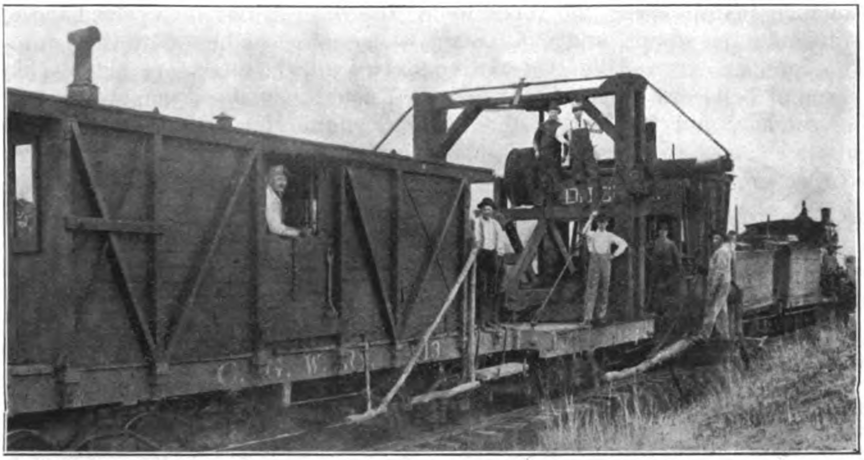

Fig. 359.—Ditching Train, Chicago Great Western Ry.

The Chicago, Great Western and the Kansas City Southern roads. have ditching cars with machinery operated by steam. In each case the working apparatus consists of a flat car with a housing at the forward end covering a boiler and engine which furnish the hoisting power; a hoisting shaft, with chains, mounted upon a strong frame which rests upon a turntable; and a scoop suspended from the hoisting shaft at either side of the car. The hoisting shaft projects past its supporting frame at either side, being of sufficient length to drop the scoop into the ditch at the desired distance from the track. When the car is in service the frame is revolved to stand crosswise the car (Fig. 359) and is held firmly in place by stay rods passing from the car decking to the top part of the frame. When out of service it is necessary to revolve the frame 90 deg., or to a position parallel with the car (Fig. 360), in order to clear for transit. The turntable upon which the frame rests is operated by the hoisting engine. The scoops of the Chicago Great Western ditcher are made of boiler plate and, on the average, each will hold a load of 1¾ cu. yds., the capacity depending somewhat upon the character of the material. The front or cutting edge of the bottom is reinforced with three teeth, after the manner of a steam-shovel dipper. The scoop is provided with a strong bail, and at the back side or closed end there is a strong socket into which is fitted a pole about 10 ft. long and 6 ins. in diameter. This pole serves as a means of tipping the scoop while it is taking its load, and is controlled by a rope attached to the end of the pole and passed through a pulley block suspended from the hoisting shaft. The scoop is hauled in the ditch by two chains, one attached to either side, to keep it straight with the ditch. The chains are attached to a stout cross beam which rests upon hangers suspended from the sills of the car. When the scoops are put into use this beam is pulled out to project over the ditch and is held by a stay rod attached to the front corner of the car.

The ditching train consists ,of a locomotive, followed by an extra tender, which serves the steam plant of the ditching car; behind the extra tender the ditching car is coupled in, and in rear of the ditching car there is a "tool car." All the cars are air-braked, and the tool car is provided with a conductor's valve for quick application. The tool car carries, besides other tools, a forge and blacksmithing outfit, for repairing chains, clevises, etc. The operating force (when working both sides) consists of six men, including a hoisting engineer, who does his own firing; two men manipulating the ropes to fill the scoops; two men who handle and dump the scoops, and a foreman, who is also conductor of the train. The foreman sits in the tool car and gives all the necessary signals by means of bell cords, there being one cord running to the locomotive, over the ditcher, and another to the hoisting engine for signaling when to raise and lower the scoops. Besides the ditching crew there are two flagmen, to protect the train.

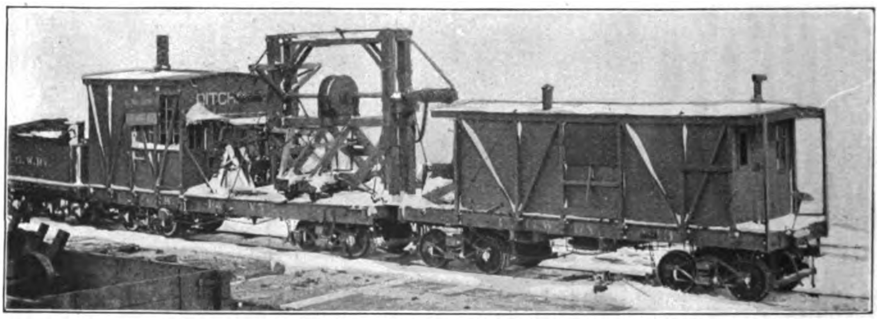

Fig. 360.—Chicago Great Western Ditcher Arranged for Transit.

The manipulation of the train and ditching apparatus is about as follows: As the train arrives at the ditch the scoops are quickly lowered, and as the train starts forward each scoop is tilted by the pole and rope arrangement, and as soon as it receives its load a man jumps down and sets a dog, which extends from the back side of the scoop to the middle of the bail and prevents the scoop from tilting and dropping its load. The scoop is then immediately hoisted and the train starts for the dump. On the way, while the train is in motion, the scoop is drawn up and the rear end is hitched to the loose end of the hoisting chain, which hangs from the shaft, being made fast to the spool of the winding shaft at about the middle (of the chain); and the two parts of the chain are wrapped several times around the spool, in opposite directions, so that the turning of the shaft unwinds one part of the chain while it winds up the other. As the dumping ground is reached the shaft is revolved as though to lower the scoop, thus unwinding the chain attached to the bail and winding up on the chain attached to the rear of the scoop. The scoop being thus hung up on its rear end, dumps itself. Meantime the train is quickly stopped and immediately starts back to the ditch, being kept continually in motion except when reversing direction and when stopping an instant for the men to set the dogs on the scoops. The train may run either way to dump, and, when ditching only one side, the off scoop is filled with stone. In usual practice the pulling beam and hoisting chains are set to excavate the ditches 14 ft. 8 ins. from inside to inside. The car is also used to slope down the bank where the material is dumped, there being for this purpose a moldboard connected with the pulling beam and maintained in upright position by brace pieces footing into shoes which slide on the ground, and by brace struts abutting against the car. When it is desired to pull dirt toward the track the sloper is held to its work by block and tackle attached to the car.

An average day's work with the machine, when within convenient distance of the dumping place, is 300 cu. yds. of material moved. Of course a great deal depends upon the amount of time lost from interference with the traffic trains. At one time while working on Sunday the ditching train made 91 trips, with 4 cu. yds. of material at each trip, the distance covered in a round trip being 700 ft. more than a mile. On this day the ditching train had to run to clear for six stock trains. On another occasion 656 cu. yds. of material was taken out in seven hours. For a number of years the machine was used from early spring to late in the fall.

Fig. 362.—Dumping the Scoops.

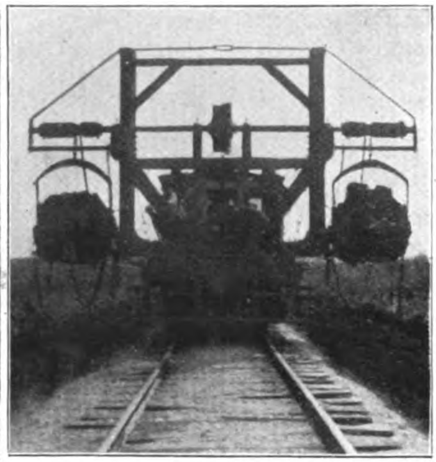

Fig. 361.—Loaded Scoops in Transit.

The ditching car of the Kansas City Southern Ry. is quite similar to the Chicago Great Western machine, on general lines, but essentially different in a number of the details of operation. The ditching machine and all the appurtenances necessary to its operation are carried on a single car, the hoisting engine taking steam from the locomotive. The hauling beam on each side is hinged, and when put into service is swung out at right angles and secured by a stay rod. As may be seen in Figs. 361 and 362, this ditcher has a small shaft below the main hoisting shaft, to which is attached a chain for the purpose of raising the inner side of the scoop, to give the ditch the proper slope for drainage. This lower shaft does not revolve, the tilting of the scoop being adjusted by lengthening or shortening the chain. While taking its load the scoop is steered and maintained in balance by means of a guiding pole 13½ ft. long. The scoop, which is 6 ft. long, 4½ ft. wide and 3 ft. deep, is hauled by two chains attached to its sides, at its front end, and to the pulling beam. The capacity of each scoop is 3 to 3½ cu. yds., and each reaches 14 ft. from the center of the track, or a distance of 28 ft. over all, for the machine.

The pulling beam is hinged to a side post at a point higher than the decking of the car, thus making it possible to swing the beam onto the car when it is not in use and save considerable time which would otherwise be occupied in lifting it and putting it in place.

This machine is used in cuttings where the amount of material is too small to be excavated at economical cost by a steam shovel. If the ground is hard it is first loosened up by hitching a heavy plow to the pulling beam and plowing several furrows through the cut. In excavating the material the scoops are hauled forward until filled and are then hoisted high enough to clear objects at the side of the track, and maintained in horizontal position, as shown in Fig. 361. The locomotive then runs to some near-by embankment or other point where filling material is in demand. The scoop is dumped by hooking to its rear end a chain wound upon the hoisting shaft in the reverse direction from that in which the chain is wound which supports the bail. When it is desired to dump the load the hoisting shaft is revolved to unwind the latter and wind up the former, thus tilting up the scoop and dumping the load, as shown in Fig. 362.

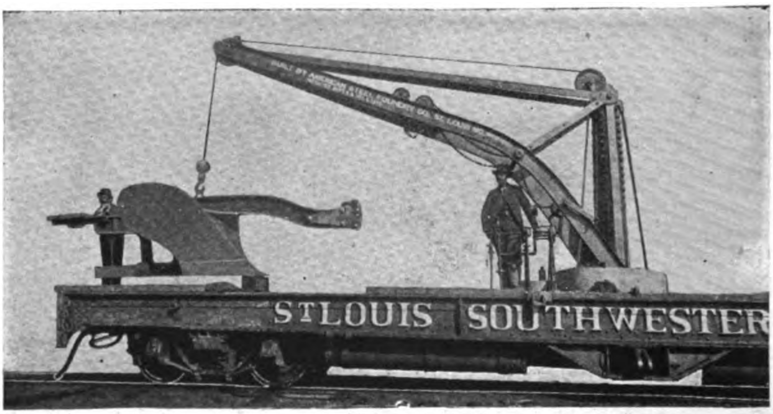

Fig. 363.—Doddridge Ditching Car.

The average amount of dirt handled with this machine during one season's work was a little more than 400 cu. yds. per day, carried an average distance of 1800 ft. This included material taken out of cuts containing rocks, stumps, etc., and from other places where considerable time was lost in removing obstacles that could not be handled by the scoop. At times as high as 900 cu. yds. of material was handled in one day. The cost of handling the dirt has ranged from 7.74 to 9 cents per cu. yd. This includes the cost of labor, train crew, use of locomotive, fuel, repairs to ditcher, and, in fact, all costs. The limit of economical haul, as determined from the experience with the machine on this road, was found to be about 4000 ft. The car and machinery were designed by Mr. F. Mertscheimer, superintendent of motive power. The plan drawings and dimensions in detail were published in the Railway and Engineering Review of Jan. 12, 1901.

The Doddridge ditching car, designed by Mr. W. B. Doddridge, while general manager of the Missouri Pacific Ry., and used quite extensively on the St. Louis Southwestern, the Texas Midland and the Minneapolis & St. Louis and other roads, is worked by compressed air supplied by the air brake system. The car itself is 50 ft. long and, with the exception of the decking, is constructed entirely of steel or iron. Both side and center sills are plate girders 18 ins. deep, strongly braced. The car has attachments for handling material in excavating ditches, building up and re-enforcing embankments, lowering track, raising track, altering grades and filling. All of these implements or tools are carried on the car and are composed of a plow, scraper, scoop and shoulder former. At the center of the car (Fig. 363) there is mounted a revolving crane 9 ft. high, having a reach of 14 ft. from the center of the car, capable of raising a load of 8000 lbs., and swinging through an entire circle. The crane is provided with two cylinders: one 12 ins. in diameter and 14 ft. 7 ins. stroke, for hoisting; and another 12 ins. in diameter and 9 ft. 5 ins. length of stroke, for swinging the crane. In addition to the crane cylinders there are four air cylinders near the four corners of the car, each 8 ins. in diameter and 5 ft. 4½ ins. long, for operating the plow guides. The air supply is stored in five cylindrical reservoirs, each 22 ins. in diameter and 10 ft. long, secured to the frame beneath the floor of the car.

In operation, the plow is generally used first. This is of cast steel, in one piece, except the moldboard, which is of heavy boiler plate, and weighs 2500 lbs. The plow is swung from its position on the car by the crane and is held to its work by four attachments. There is a draft cable attached to a heavy steel casting forming the end sill of the car, which has extensions at both sides of the car for this purpose. The depth at which the plow runs is regulated by the crane hoisting cable, and the plow is held at the desired distance from the car by a tubular strut attached to the front end of the beam, as shown in Fig. 364. The plow is maintained in a vertical position by a strut attached to the rear or upwardly deflecting extension of the beam, the strut being operated by the piston rod of an air cylinder. At the rear end of the beam of the plow there is a small platform upon which a rider may stand while the plow is in operation. The plow cuts a furrow 24 ins. wide and 30 ins. deep, if such depth is desired. It can be run as far out as 20 ft. from the center of the track and at an elevation of 10 ft. above to 16 ft. below the top of

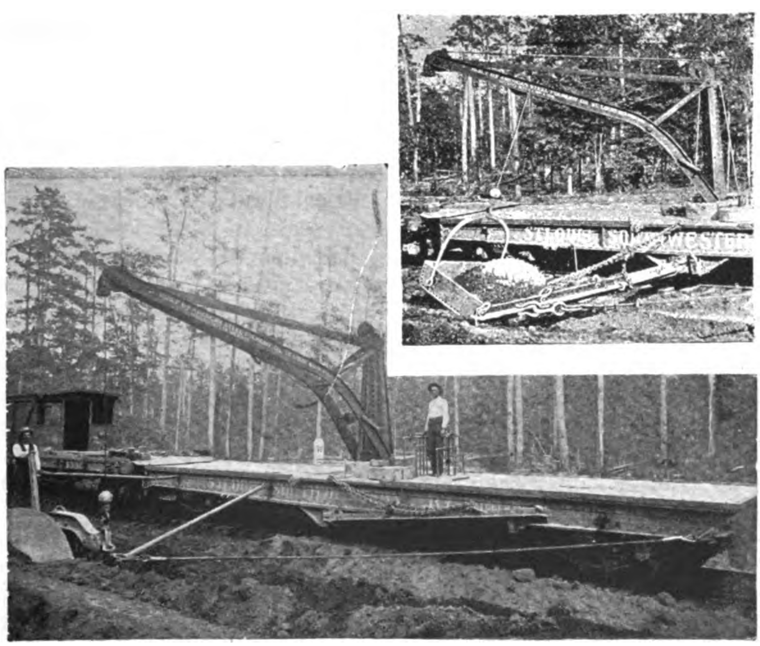

Fig. 364.—Doddridge Ditching Car, Plowing and Scraping.

rail. The tool next used after the ground has been furrowed up by the plow depends upon the character of the work to be accomplished. If it is desired to level down a strip of earth next the track the scraper is used; or if the embankment needs strengthening the scraper is used, being so attached as to carry the earth toward the track. The shoulder former is then hauled along to even off the surface of the roadway to a uniform contour. In ditching operations the scoop is used.

The scraper consists of a heavy moldboard, such as is used in ordinary road machines, and is braced at the back to horizontal trailing pieces which maintain it in a vertical position. It is attached to the end sill extension of the car by a draft cable and maintained at proper distance from the car by the swing beam or tubular distance bar. The nose or forward end of the scraper is attached to the swing beam by a short piece of chain and the amount of dirt scraped is controlled by the hoisting cable attached to the rear end of the scraper, which gives it the inclination. The scraper will bring material toward the track from a distance of 20 ft. from the center of the track, and will throw material either to or from the track, as may be desired. The shoulder former consists of a heavy scraper having a bottom edge shaped to the desired cross section and, as previously explained, is used for leveling material brought up by the scraper or dumped at the side of the track. It is attached to the side of the car by a pivot hinge, at one end, and to a draft cable at the other. It is re-enforced at the rear by several tubular struts bearing against the side of the car. The depth at which it works is regulated by the hoisting cable, attached to it at the top, at the middle of its length.

The operation of scooping is shown in Fig. 364. The scoop is 4 ft. wide, 8 ft. long and has a capacity of 3½ cu. yds. It is maintained at proper distance from the car by the swing beam, and the depth of ditch is regulated by the hoisting cable, which also is the means by which the scoop is dumped. It is hauled by a draft cable attached to the end sill extension of the car. It can be used at any point from the ends of the ties to 20 ft. from the center of the track. It comes into use in ditching or when, after plowing a cut, more material is turned up than is required to form the shoulder. The dirt taken up is carried to the end of the cut or to a fill, to be deposited. It is easily seen how the use of this tool could be readily adapted to the excavation of the summits of grades in lowering track.

All of the operations of this car are manipulated at a single point on the car by one operator, by means of cocks in pipe connection with the various cylinders of the car. The machinery is worked by one man who handles the air and two laborers who attend to the shifting and adjusting of the side attachments. When not in use as a track tool the car is stationed at a division point, and in emergencies is utilized as a wrecker, for which purpose it is readily adaptable, being quickly gotten into action simply by coupling on a locomotive to get the air connection. In wrecks where the lifting is not too heavy the car does rapid work. So extensive and effective have been the operations of this car in the swamp lands of Arkansas that farms and forests in some cases have been drained many miles back from the railroad.

145. Distributing Ties.—The details of the work of distributing ties for renewals vary considerably with different roads, according to conditions of supply, density of the regular traffic, ideas concerning economical methods, etc. Where the supply of ties can be bought in the district tributary to the road they are usually received at the stations or at side-tracks and loaded upon flat cars, to be distributed by the section men or by a work-train crew. If the ties are received at numerous points more or less uniformly located part of the crew can be employed at loading while the remainder are distributing. If, however, the ties have to be loaded some distance from the points where they are to be used it is a good plan to load a long train of cars at one time and side-track them at points convenient for the work of distribution. This arrangement saves much running to and fro over the road, for as fast as the ties are unloaded the empty cars can be set out and loaded cars picked up without running considerable distance. A similar method is to have the ties shipped to the stations and side-tracks in order, beginning at the end of the division nearest to the point of shipment and setting the cars out in lots according to the number of ties needed, and then begin the distribution with a work train and keep it steadily employed until all the ties are laid down. The distributing crew is sometimes an extra gang or work-train crew and sometimes it is made up of two or three section crews.

For rapid distribution the ties should be loaded on flat cars, crosswise the car, except two under courses at each end. These courses should be placed lengthwise the car, each course blocked under the outer end by a tie placed crosswise, so as to give it a pitch inward. These slanting courses act as guards to keep the ties placed crosswise from being jarred or rolled over the end of the car. If in these slanting courses the two thickest ties of each course are placed on the outside, they will be held in place by the weight from above and no stakes will be needed. Enough room should be reserved at the end of the car for the brake to be used. On some roads flat cars for use in distributing ties are specially fitted up with permanent end boards. Ties received from points beyond the particular line of railway are usually shipped in box or stock cars, and, if received at about the time they are required for distribution, are usually unloaded from these cars direct to the side of the roadbed. In long-distance shipments of ties over a single line of railway or system, it is also quite common practice to use box, stock, or gondola cars with high sides; this for two principal reasons: In the first place, the commercial shipments in cars of the kind named may be heavier in one direction than in the other, and to avoid hauling some of these cars back empty they are loaded with company material. Again, accidents have happened by ties working out on flat cars and striking switch stands, through truss bridges, the sides of tunnels and snow sheds; and even cars and engines standing on side-track or passing on another track have been struck by ties that stuck out from piles on flat cars.

The exact number of ties wanted for renewals in places can be known and the right number of new ties can be dropped off, just as well as not. Much useless handling and trucking of ties results from throwing them off by guess while distributing, for without some system of estimating or counting the number required and the number delivered there will usually be either too many or else not enough. Where ties are thrown off in excess of the requirements it is usually the case that many old ties which could profitably remain another year will be removed, simply to make room for all of the new ties. Some foremen seem to have the idea that new ties are necessarily the best medicine for rough track. On the other hand, if an insufficient number of ties are distributed in places, the deficiency must be made good by trucking, or else some old ties will remain in the track which ought to come out. The work of distributing ties should be conducted with such system that the required number may be had at all points. It will then not be necessary to redistribute the ties with a push car, and there can be no waste of timber. Just before the time for distributing comes, each foreman should carefully inspect the ties on his section and count the number needed for renewals between each two telegraph poles. This number should be marked with chalk on the pole which stands in the direction from which the train will come when distributing. The best plan is to take a short ladder and place the marking out of reach of mischievous persons. Then when the work train comes along it will be an easy matter to throw off the required number, almost in place. Another method that is sometimes followed is to drive a stake on the shoulder temporarily for each ten ties required.

When ties are delivered in box, stock or gondola cars a strong force is needed to unload them promptly—say 25 or 30 men. On the average it takes four men about 30 minutes to unload a box car holding 300 oak ties. If the ties are loaded on flat cars a few men can tumble them off rapidly, and 15 to 18 men are a sufficient force. The best way to control the number of ties put off when unloading from flat cars is to work the men in relays of a few men each. It is much easier to control the movements of a few men working rapidly than of a whole crew working at the ordinary gait. When unloading from flat cars four or five men besides one to tally are usually a sufficient force working at one time to do the unloading. The crew being small, the man keeping tally can easily stop the delivery of the ties from the cars as soon as the required number for the place has been thrown off, or by calling to individuals he can easily increase the number thrown off by a tie or two, if need be, after the signal has been given to stop unloading. Another way to stop the unloading as soon as the required number has been thrown off in a place is to designate each man in the gang by a number, and have it understood that each man whose number does not exceed the one sung out by the tally man is to throw off a tie. Suppose, for instance, there are 15 men in the gang and it is desired to unload 12 ties between two certain telegraph poles. The tally man would sing out "twelve," and each man up to and including No. 12 would throw off a tie. If, say, 22 ties were needed the tally man would cry out: "Once around and seven more," when every man in the gang would throw off a tie, and each man up to and including No. 7, one additional.

The train should not be run faster than 6 miles per hour; and on high fills quite slow, because in such places ties thrown too hard will roll to the bottom of the slope. The foreman of the section whereon the ties are being unloaded should invariably accompany the train to advise as to the number of ties wanted and the exact location of the same. It is also well to have the section crew, or part of it, follow the train on a hand car, to throw out any ties which may have fallen too close to the track. At narrow cuts it is a good plan to throw off the whole number in piles at each end of the cut, especially if the old ties are not to be taken out for some time, and the same is true for high, narrow embankments. Proper attention should be given to loading and throwing off the hardest ties for the curves, as heretofore pointed out. In distributing ties on curves observation should be taken of the side of the track from which the ties will have to be pulled in when making renewals, and the ties should be thrown off on that side, if there is room. Thus, for instance, it will frequently be found that in renewing ties on curves the ties must be pulled in from the outside of the curve.

The question of using way freight trains for tie distribution depends upon the traffic conditions. On roads where the local freight business is light it is found to be economical to send the ties out a few car-loads at a time with these trains, to be unloaded in place by the section men, who are previously notified to be on hand at the point where the ties are wanted. The delay to the train in waiting for the ties to be unloaded is necessarily considerable, and on roads where the local freight work is heavy the way trains are frequently or nearly always behind time, and the extra work of tie distribution is considered inexpedient. Such is also quite liable to be the decision where the ties are to be unloaded from box cars, or where a train-load of ties arrives and there is a demand for prompt release of the cars. Quite frequently part of the ties are distributed from way freight trains and part from work trains, on the same road. One situation under which such is the practice is where some of the ties are delivered at stations or sidings, the cars being set in for the section men to load, and afterward taken out by local freight to be unloaded by the same forces; ties delivered from outlying points, however, are handled by work train with a special gang. Where only one car-load or a few scattering car-loads are to be sent out it is convenient, of course, to use the local freight trains, in any case. Good authorities are occasionally quoted on both sides of this question, one view being that distribution from local freight trains is the cheapest way to handle ties, while, on the contrary, the experience of some other man is that the same method is expensive and unsatisfactory. The varying conditions of traffic above noted undoubtedly account for the difference. Mr. J. C. Rockhold, roadmaster with the San Francisco & San Joaquin Valley Ry. (Santa Fe system), has kindly favored me with a clear and comprehensive statement of practice under certain conditions which are quite extensively found. This statement, which covers a method of distribution not hitherto described, is published as § 200, Supplementary Notes.

As a general thing ties distributed from a work train are put off in better shape than from a way freight. The crews of the latter class of train, especially when late, are frequently inclined to rush the work too fast, either by urging the men or by moving the train too fast for the men to properly unload the ties. An ordinary result of such haste is that ties are thrown down embankments, into bridge openings, or are so sparsely distributed that much time is lost in carrying them to place when renewals are made. In distributing ties with a work train time is sometimes needlessly lost or wasted in attempting to do the work continuously. For purpose of illustration, suppose the train is proceeding from north to south and at a certain time must quit work and run six miles south to clear for a regular train. If another train is due at the point where the work stopped, in less than an hour, it is more advantageous to work back north from the passing siding after the first train has departed than to run back the six miles purposely to make the distribution continuous, for in the latter case the train will have but a few minutes to work before it must again run to clear, whereas if it starts in to work back from the siding the time otherwise consumed in running to and fro is employed in throwing off ties, and the gap can be closed up during some more favorable interval in the train schedule. For this reason it is usually more advantageous to select the passing points in the direction in which the work is progressing.

The best time to distribute ties is in the early spring, just before the time for renewing begins, and the counting of the old ties to be taken out should not be done until a few days before the new ones are distributed. Of course, on many roads it is necessary for the purchasing agent to have in the fall an estimate of the number of ties required the next spring for renewals, but an actual count in the fall comes so close upon the renewals made in the summer (when all unserviceable ties are supposed to have been removed) that it is but little if any better than a guess, because the probable condition of the ties six to eight months later is, after all, largely conjectural—the number counted may overrun or fall short of actual requirements the next spring; and it is an expensive mistake to distribute more ties than are actually needed. On old roads an estimate based upon the average renewals for a series of years is more rational than an actual count of the ties in the fall, and is sufficiently close for the purchasing agent. If a few ties are left over as the result of a liberal allowance on the general yearly average they will be all the better for the seasoning they get. Authorities on timber say that ties should be allowed to season at least a year before being put into the ground, but generally they are purchased green in the winter, distributed in the spring and put into the track in the spring and summer. There should, therefore, be no money lost if a few ties remain over for another year.

On roads where ties are handled by way freight it is quite customary to begin the distribution as early as January; this for the obvious reason that only a few car-loads can be distributed each day, and it is necessary to take a good deal of time in order to get over the division by spring. Again, on roads where ties are received from outlying sources of supply it is frequently the case that the distribution begins late in the fall, so as to release the cars promptly and avoid piling the ties up in the yards. It is doubtful whether anything is gained in either case. In the first place, ties should not be unloaded and left lying on the ground through the winter, as in this position they gather moisture from the ground, are covered with snow or lie in ditches or wet places and become water-soaked, so that the germs of decay are well induced before the tie sees any service at all. In order to obtain all the advantage possible from seasoning, the ties that are received during fall and winter should be carefully piled at points exposed to the winds and sun, but it costs no more to do this in the yards and along side-tracks and to load them up again on flat cars in the spring and deliver them right where they are wanted, than it does to pile them up all along the right of way and then carry them or truck them to place when the renewals are made. In the second place, the practice of piling up new ties along the right of way, to remain three to six months before they are used, is contrary to the principles of good policing. If the right of way is piled with new ties all winter and spring and with old ties all summer and perhaps most of the fall, there are but few months when it presents a clean or finished appearance. In the third place, as already explained, an accurate count of the ties to be renewed cannot be made until the time for renewing is close at hand, and then is the best time to make the distribution, unloading the ties right where they are wanted, and so soon before they are used that they need not be piled.

Where it is the practice to pile ties up after they have been distributed along the track they are usually piled loosely, sometimes cribbed, 10 to 20 in a place, near the track. In localities where timber is scarce railroad ties are in good demand for gate posts and for numerous other purposes, and on some roads it is necessary to watch the tie piles closely. In order to check up thefts of this kind it is the practice on some roads to place the same number of ties in all the piles, so that the foreman can tell if any have been taken. The loss is liable to be greatest from piles conveniently near the highway crossings. Certain remarks in the above relating to inspection and distribution of ties with reference to the seasons may not apply to some railways of the South and Southwest where the winters are mild or the ground does not freeze. Thus, on the St. Louis, Iron Mountain & Southern Ry., in southern Arkansas, it is the practice to inspect and renew ties twice each year—in the winter and again in the summer.

146. Handling Rails.—In the work of unloading rails, either at piles or when distributing for renewals, there are several methods in practice. The method of prying the rail over the edge of the car with bars and letting it slide off on skids is referred to in connection with track-laying. At points where a large number of rails are to be unloaded a derrick is sometimes erected, the rail being lifted from the car and swung around on the boom, to the pile or to a tram car. For unloading its 100-lb. rails the New York, New Haven & Hartford R. R. makes use of portable derricks which are attached to the side of the car. The derrick is constructed with a piece of rail for a mast and a piece of 1½-in. gas pipe for a boom. Two of these derricks are used with each car as it is unloaded, one being placed 4 ft. from each end of the car, on the side opposite that from which the rails are unloaded. There are two sliding clamps on the mast, one of which engages the top edge of the side board of the car and the other the lower edge of the side sill. With this device six men to the car unload the rails at the rate of about one each minute. There are two men who handle the rope tackle, two men on the car to attach the tongs and two men on the ground to release the load. When the car is unloaded two men can take up and transfer the derricks to another car in about two minutes. It is used both when unloading rails in piles and for distribution along the line, the car being moved a rail's length at a time in the latter case. The usual method of operation is to have two sets working simultaneously, unloading two cars at once. The average result during one season was upwards of 700 rails unloaded per day with 16 men, 20 men in one instance unloading 917 rails in a day, on main line under traffic.

In distributing rails for renewals it is here and there the practice on double-track roads to drop the rails onto the ballast between the tracks, two in a place. If the space between the tracks is evenly filled in, or if the ground is covered with snow of sufficient depth to serve as a cushion, and both ends of the rail are dropped simultaneously, such treatment is not liable to kink the rails; neither are they liable to be damaged if properly dropped on a well filled shoulder outside the tracks, as on single track, but the rails cannot in this way be kept even with the distance so well. A very common method is to haul the rails off the rear end of the car and lay them to place. As each car is unloaded it is cut off and left standing, so that other cars may be got at. Two men on the car, with light pinch bars, slide the rails onto dollies, one being placed on each side of the car at the rear end. By means of a rail hook and short piece of rope the men standing in the track grab the end of the rail in a bolt hole, pull it back, and, letting the end down, place it to the end of the rail just previously taken off, which is usually left on the ties, outside the track rail, or else on the shoulder near the ends of the ties. At a signal the car is then pulled ahead a rail's length and the other end of the rail is caught, as the car is pulled out from under it, and dropped in place outside the track rail. While the rail is being pulled back one of the men on the car should hold his bar in the frame of the dolly to keep the rail from running off the roller. With a dolly having a concave roller, however, it is not necessary to do this. Twenty men, divided into two gangs, can unload rails on both sides at the same time. Rails of 45 or 60 ft. length can best be pulled off the car by means of a chain, cable or rope, which is usually about 30 ft. long, with a hook in one end to attach to the rail, in a bolt hole, and a clamp or grab hook at the other end for attaching to the track rail, or for catching at the back of a tie. The rail is pulled off by moving ahead with the car, and drops onto the ties, in the track. No dollies or rollers are used on the car. The rails are easily thrown outside the track with pinch bars.

The practice of hauling rails off the cars with a drag rope anchored to the track is quite extensively employed for rails of 30 ft. length also, and it is not necessary that the rails should be let down with a gang of men. In order to break the fall a "platform car" or "tail gate" arrangement is quite commonly used. The former consists of an ordinary push car coupled on behind and carrying a large stick of timber or a few ties placed crosswise the car for the rail to drop on as it is pulled off the rear end of the train, thus letting the rail drop easily by stages. The tail gate consists of a panel of heavy plank, the top edge of which is attached to the sill of the car, the bottom edge trailing along on the rails, thereby forming an incline down which the end of the rail can slide gradually. For gondola cars two gates—one attached to the top edge of the car, with its foot resting upon the lower gate—might be a desirable arrangement. Another contrivance to break the fall is an iron yoke bolted to the coupler head at the rear of the car. This is crowned, so that when the end of the rail drops from the car it

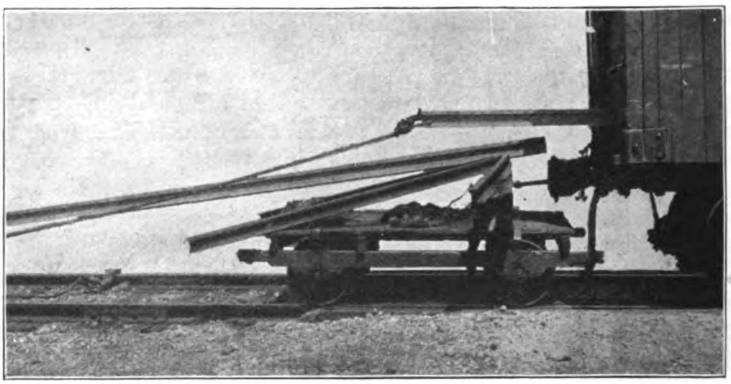

Fig. 365.—Unloading Rails With Drag Rope and Truck. C., M. & St. P. Ry.

will slide laterally off the yoke and fall clear of the track. It may be well to here explain that if one end of the rail rests upon the ground when it is dropped, the liability of injury is not nearly so great as it is when dropping the rail bodily, and rails as long as 45 ft. sag so low before the end drops upon the track that the rail cannot fall heavily, and on some roads no device is used to drop the rail by stages. It may be stated, however, that in general practice rails are handled with more care than formerly.

As for the details of the drag-rope method of unloading, the work is started by pulling back the first rail until its end stands even with a joint. The drag rope is then pulled back taut and anchored, and as the train pulls ahead this rail drops off end for end with the rail in the track. After that the clamp is applied to every track rail at a corresponding position relative to the joints; that is, if in pulling off the first rail the clamp is applied 10 ft. ahead of a joint in the track, then by applying the clamp in the same relative position in pulling off the succeeding rails, they will drop rail for rail with the ones in the track and just a rail length apart. By such a system of working, the rails are distributed in proper place and the extra work of carrying them ahead or back when they are set into place for coupling up in the track is avoided. In the case of short rails it is necessary to make allowance, which, however, is a matter of ready mental calculation. In usual practice two drag ropes are used, sometimes to unload on both sides of the track at the same time, and sometimes alternately on the same side of the track, so as to unload for one side without stopping the train, as explained further along. One of the roadmasters of the Chicago, Burlington & Quincy Ry. has used four drag ropes—two alternately for each side of the track.

On many roads the track department is seldom or never fortunate in receiving shipments of rails on flat cars. Especially is this the case in the West, where rails frequently come in box, stock or gondola cars. For unloading rails from box cars Mr. Edward Laas, with the Chicago, Milwaukee & St. Paul Ry., while roadmaster, put into practice a drag-rope method involving a number of interesting details. To prevent the rails from falling heavily upon the track a platform car is used at the rear of the train or car that is being unloaded, arranged with an incline to support the rails as they are dragged from the train and permit them to slide off easily onto the ballast shoulder at the ends of the ties, without the use of bars. This arrangement is illustrated in Figs. 365 and 366. Across the front end of a push car there is a timber, to the top of which is spiked a piece of rail about 9 ft. long, bent to a crown and bowed backward; and bolted to this at the middle there is a V-shaped piece of rail rearwardly inclined over the hind corners of the push car, forming wings which cause the rail to slide outward as the push car is hauled underneath it. On the rear end of the

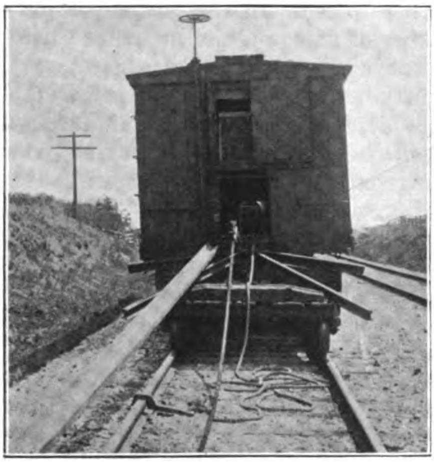

Fig. 366.—Unloading Rails With Drag Rope and Truck; End View.

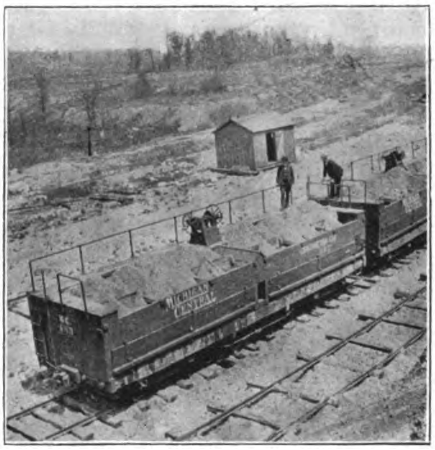

Fig. 367.—Torrey Ballast Cars Loaded, Michigan Central R. R.

push car, between these two wings, there is a piece of timber shod with an iron strap to prevent any possibility of the rail dropping between the wings. The coupling to the train is by means of a link in the rear coupler made fast to the cross beam. The whole arrangement is simple, cheaply gotten up and can be quickly lifted from the track and set aside. The Minneapolis, St. Paul & Sault Ste. Marie Ry. has used the same kind of an outfit.

In unloading rails two drag ropes, each 50 ft. long and 1¼ ins. in diameter, are employed alternately, and the train is moved slowly ahead without stopping. In order to accomplish this continual movement the rails for one side of the track only are unloaded at one time, those for the opposite side being unloaded during another trip. For handling the rails in this manner there is a gang of 11 men, three in the car and eight outside. Two of the men in the car stand in the rear end, on either side of the rear door, with a pair of tongs, to swing the ends of the rails into the opening. The third man stands at the front end of the car and handles a short bar to free the end of any rail which gets caught between other rails in the pile, in order that the rear end of the same, outside the box car, may be swung out of the track. Outside of the car, there is a man standing on the front end of the unloading truck to reach into the door to apply the hook. On each rope there are two men, one to pass the end of the rope up to the man who hooks it to the rail and another who carries and anchors the clamp. Besides the foregoing there are two men who seize the rail and push it outside the track when it is about half way out of the car, or when about to overbalance, and another man who carries a bar and walks behind to make sure that all of the rails are clear of the track after dropping upon the ballast. Occasionally one end of a rail may slide off the shoulder and cause the other end to stick up and obstruct the track. By this method 700 to 750 rails are unloaded per day, including the time lost in getting out of the way of the traffic trains.

If the rails are delivered on flat cars without sideboards they may be picked off the car and lowered to place by a crew standing on the ground. The proper way to take the rail from the car is to place a stake in one of the corner pockets and swing the end of the rail from the other end of the car so that men can get hold of it; this can be done by one man on the car working with a bar. The rail is then grasped by the whole crew, pulled from behind the stake, and let down to place. In this manner of unloading it is customary to run a long string of flats opposite the point where the rails are needed and have two unloading gangs walk from car to car and unload the rails. These gangs may work on opposite sides of the train; or they may work on the same side, beginning in the middle and working toward the ends of the train on one side, when they begin again at the ends and work toward each other on the other side, repeating the operation at each stop of the train. Of course, one gang can unload by this method to good advantage, or if it is desired to hurry the work four gangs—two on each side of the train—can be set to work. It should be noted that when unloading by this method calculation should be made for backing the train a sufficient distance to allow for the spaces between the cars. By observing the necessary distance, the train may be backed two or three times while the men are progressing the length of the train, so that the rails laid down will just about reach over the ground covered. This distance can be gaged by the engineer, allowing so many rail lengths for the idle space. In placing the rails on the ground it is always desirable, of course, to lay them as near as may be to the point where they will be used in the track, and hence it saves a good deal of labor if the rails are unloaded both sides of the track, instead of unloading both rails on the same side.

Dependence upon physical exertion for handling heavy material used in track maintenance has been gradually giving way to more rapid and more economical methods of work. One of the most toilsome operations in track work, when done by hand, is that of unloading rails and stringing them out along the roadbed for renewals, and this fact accounts for the many devices for and methods of unloading rails without direct lifting or lowering to place by hand labor. Aside from the contrivances already named there are several arrangements for lowering rails to the ground by means of side attachments to the car. The Byers rail unloader, which has been used on the Pennsylvania R. R., consists of three brackets with hooks of graduated length to attach to the stake pockets of flat cars or to hang over the sides of gondola cars. These brackets carry rollers, and when hung in place form an incline from front to rear. Upon being placed upon the rollers the rail runs back, and when the train moves ahead the rail drops to the ground and is set to place by a gang of men. In a similar way a trough-shaped or channel-shaped chute is sometimes used, being hung at the side of the car. The rail slides back until the lower end strikes the ground, and as the train pulls ahead the upper end of the rail is let down gradually as the chute is dragged from under it. For unloading rails from gondola cars a pair of skids are also sometimes used. The skids are hooked over the top edge of the side of the car, one pair at each side, so as to unload on both sides of the track. The rails are lifted and placed upon the skids by a gang of men in the car, and each rail slides down the skids under control of ropes in the hands of two men. Each rope is provided with a hook to attach to the end of the rail and is passed around a pulley at the top end of the skid. Each time the car is moved ahead the men pick up the bottom ends of the skids and carry them along. (See also § 211.)

Loading Rails.—The quickest and easiest way to load up old rails by hand is to get men enough to raise the rail at arm's length, high over the head, step up close to the car and throw it on broadside. It is dangerous for inexperienced men to attempt this method without careful instruction, but as soon as they get confidence in themselves, so that all will act together, there is no danger. The rail should be grabbed by the head and raised up by word. A good word to raise and throw by is: "Up—high—yo—heave!" It can be done in that many distinct movements. In order to pitch the rail to the farther side of the car the word should be given with greater force than when throwing to the near side. In all heaving and throwing by word, there being much of it done in railroad work, men should practice lifting heavily or lightly according as the word is given more or less loudly. The foreman should always be sure that every man fully understands what is to be done when the word is given; and he should explain that each man should act as though, independently of the others, he were throwing a piece of the rail equal in length to his share, according to the number of men who have hold of it. If a flat car is loaded with rails to be sent some distance it should be provided with end boards of heavy plank, and four stakes on each side.

The foregoing method of lifting and throwing rails applies to the work of loading upon flat cars or flat cars with low side boards. In times of busy traffic, however, it is frequently the case that flat cars are not available, and consequently gondola cars, or even box cars, must sometimes be used for this purpose. The work of loading rails into gondola or box cars by hand is a tedious operation, as they must be shoved through the end of the car. The usual method is to lift the rails and shove them over a dolly placed at the end of the car, but it saves a good deal of high lifting and hard labor to have a "loading truck" or "platform car" carrying a dolly at the proper hight to form an incline rollway onto the car. An arrangement of this kind is shown in Fig. 368. A push car is coupled to the rear gondola or box car by means of a stick of timber, and upon this push car there is a dolly blocked to proper hight for shoving the rails upon the car. A gang of men large enough to lift the rail then pick it up, shove it forward on the dolly until it reaches the end of the gondola, where men with tongs grab the rail and pull it forward. In order to handle the rails easily and quickly by this method, about 22 or 24 men are required.

An ingenious machine which dispenses with the services of a large gang of men in the heavy work of rail loading is in use on the Chicago, Milwaukee & St. Paul Ry., being designed by Mr. Edward Laas while roadmaster on the Chicago & Council Bluffs division. This machine is operated by compressed air supplied by the air brake system of the cars. It consists of a derrick operated by an air hoist, mounted upon a push car or truck 7 ft. wide and 10 ft. long, with a tool box on one end to carry such tools as are needed for the convenience of the work and to counterbalance the derrick while it is being moved. The derrick mast is a piece of 3-in. gas pipe screwed into a plate on one end of the truck and held by stays running to the four corners. The foot of the boom swivels on a pin set in the plate which supports the mast. The boom is 23½ ft. long and consists of two 2½-in. gas pipes trussed vertically with rods passing over the ends of wooden blocks, and braced laterally by rods running over iron struts set against the aforesaid wooden blocks. The hoisting cylinder is 8 ins. in diam. and 6 ft. long, on the inside. The piston rod carries a 17-in sheave wheel on a cross head guided by small wheels running on the two pipes of the boom. Hoisting is done by means of a two-part ⅝-in. wire cable made fast at the end of the boom and passed around the piston sheave wheel so that for a full travel of the piston the cable lifts 12 ft. The pulley at the end of the boom is 17 ins. in diam. In rear of the mast there is a storage reservoir 3 ft. high and 2 ft. in diam. which is placed in connection with the air brake

Fig. 368.—Loading Rails Over a "Platform" Truck.

pipe of the cars by disconnecting the hose between two cars and coupling on in the ordinary manner. This reservoir has a capacity sufficient to lift two rails after the air from the train has been cut off. The hoisting cylinder is operated by means of an air cock. The end of the boom stands 19 ft. above top of rail, and when rails are being lifted the end of the derrick truck opposite from the derrick is held down to the car by means of two adjustable hook clamps attached to a beam running crosswise the truck and set to catch the under sides of the side sills of the car. The derrick is designed to lift a load of 1500 lbs. In handling rails the derrick truck is run to one end of a flat or gondola car (Fig. 369) and clamped in position for loading upon the adjoining car. As each car is loaded the machine is pulled back one car length, small gang planks being used to bridge the opening between the cars. The machine can be pushed over the cars by five men, but in usual practice it is pulled by cutting the train one or two cars back of the machine and attaching a rope to the last car coupled with the locomotive. One important advantage in the use of the machine is that it may be operated to load a whole train of empty cars without the necessity of shifting.

In loading rails six men are required, and the usual practice is to pick up the section gang where the rails are to be loaded. In the distribution of this force there is one man at the air cock (usually the foreman), two on the ground to attend to the lifting tongs and to prevent the rail from swinging; and three on the car, one of whom handles the lifting hooks and the other two swing the rail to place while the man handling the air lowers the derrick cable. While the work of loading is in progress the boom is stayed to one side of the gondola or flat car so it will not swing too far out. When a rail is lifted the boom is swung by merely swinging on the rail. After some experience it was found that the most convenient device for attaching to the rail was a single pair of tongs at the middle. As a matter of record this machine has loaded 65 rails in 30 minutes. The cost of labor in loading 608 rails, or 18,240 lineal feet, of 75-lb. rail, on one occasion when the work was interrupted by running to sidings to clear for trains, was $8.75, or less than 1½ cents per rail.

When laying new steel on double track it is the practice on this road to throw the old rails into the space between the tracks, so that with this machine the rails can be loaded with the work train standing on either track. When loading the rails into box cars they are first lifted onto a flat or gondola car and then run into the end of the box car on a series of dollies placed at an incline. As is obvious from the illustration, the machine can be used just as conveniently in unloading rails as in loading them. Machines built to a later design have the wheels inside of the side sills of

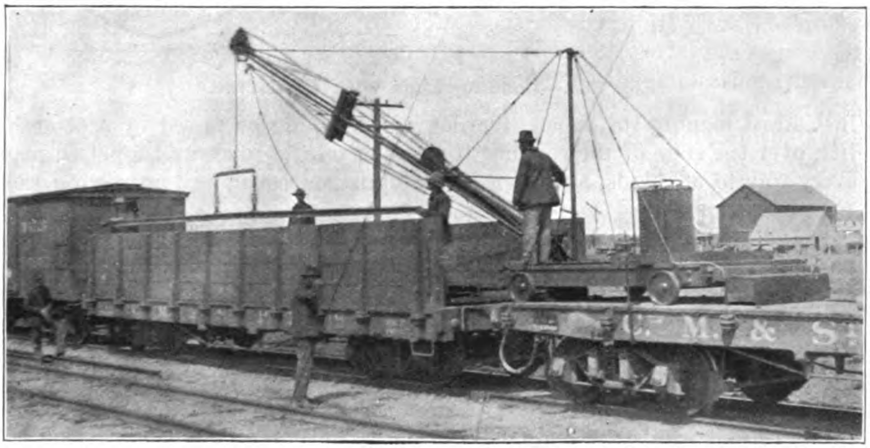

Fig. 369.—Loading Rails With a Laas Derrick, C., M. & St. P. Ry.

the truck, where they are out of the way and cannot catch the side of a gondola car when being hauled over the train. The "American" rail loader is a similar machine, and is described in § 218 Supplementary Notes.

147. Loading Logs.—On roads where logs are handled as traffic it sometimes becomes necessary to reload logs which have rolled off the cars; and on any road running through forests large trees will occasionally fall across or into the cuts and have to be removed. One way of handling trees is to roll them into the track, drag them out of the cut with the work train, and then roll them down the embankment, if there be one near. If the logs or trees must be loaded onto cars, however, it may as well be done in the cut, at the first handling, or once for all. For lifting the logs the derrick or wrecking car can be used, of course, but with this means only one car can be loaded before it becomes necessary to switch the cars in order to get an empty car next the derrick. A convenient method quite frequently resorted to is the use of a parbuckle, the hauling being done by the engine or train. The arrangement is quite simple and is shown in Fig. 370. The car to be loaded is placed opposite the log and the brake set. A rope is then passed around the log, near one end, one part (A) of which is passed over the car floor and, after being looped around the rail under the far side of the car, is made fast to the snatch block C. The other part (B) is passed through the snatch block and is pulled on by the locomotive, the part A remaining stationary. Two sets of ropes and snatch blocks being arranged as shown—one set near each end of the log—both are pulled on at the same time, so that both ends of the log come up evenly. On the car the log should be rolled onto skids, so that the ropes can be easily taken from under it. It is better to use a $\frac{3}{4}$ or $\frac{7}{8}$-in. wire rope than a hemp rope, as a hemp rope would be rapidly worn out in being drawn over the edge of the car. A chain might be used for anchoring the snatch block to the rail,

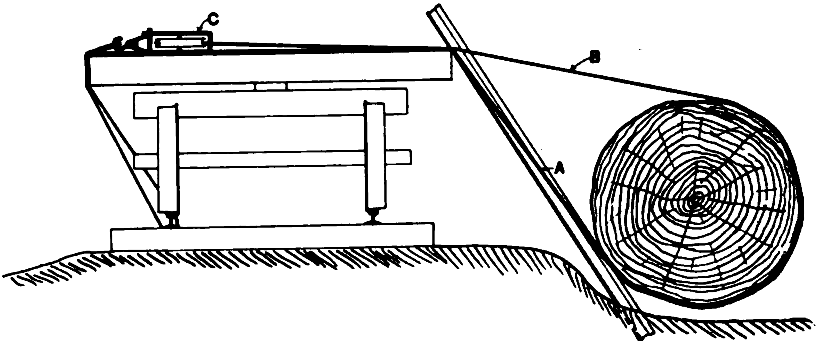

Fig. 370.—Loading Logs with Parbuckle.

instead of looping the rope. The log can be slung or raised by a straight lift, over the edge of the car, but it is easier on the ropes and a better plan every way to use skids, as shown in the figure, pieces of rail answering well for such purpose.

148. Handling Ballast and Filling Material.—Most railway companies which have the opportunity avail themselves of a bank of gravel on or somewhere near the line, as a source of ballast supply. When running a spur into a gravel bank it should, if possible, be made long enough to extend past the bank. If the loading is to be done by steam shovel the "tail track" should be at least as long as the train of cars which the engine is expected to handle in the pit. The practice of taking out gravel in piecemeal sections spoils the bank for the most convenient methods of loading. The end which swings into the bank cannot easily be kept even with the rest as the work progresses inward, and a nasty curve results which sooner or later brings things to a halt. In order to get more gravel the track must then be thrown back, over the ground on which it has advanced, and extended past the pit so made; and thus the work goes on at continual inconvenience and disadvantage. It is a better plan to use more rails when the track is first laid, as then the track will not have to be moved so frequently and, having room to shift cars, the face of the whole bank can be worked away evenly. It usually happens that by the time a railway company gets through with a gravel bank the amount of material taken out has proved to be several times the first estimate. In case the track cannot be run past the whole length of the bank, the far end of the spur can be kept even with the rest by shortening it a rail's length at each move inward; or by running up the far end and taking out the bank to a less depth there to compensate for the extra amount of material which must be moved at the end of the last car. In loading gravel or filling material it is sometimes desirable to make a cut straight into the face of a bank and extend it for some distance by loading one car at a time at the head end of the track. One way to keep the track even with the work without frequently laying short pieces of rail is to use extension rails bottom up. Each extension rail is laid outside the last rail that is coupled in the ordinary manner, with the base of the former overlying the head of the latter. This arrangement brings the upturned bases of the extension rails to gage, and in line with the gage sides of the rails laid in permanent style; and as the excavation advances they are merely shoved ahead while a car is being switched. After the pit has been extended a rail length the end rails are laid workwise and inverted extension rails are placed temporarily as before. Sketch B, Fig. 370A, shows the arrangement, the extension rails being shown in solid section. To make the rails secure against overturning, a switch rod of suitable length might be put on at the end, but such is not generally used.

In order to keep gravel ballast free from loam it is usually necessary to strip the top soil from the bank. It is sometimes considered that in deep cutting the mixture of top soil is so slight as to be negligible, but if the gravel is otherwise clean and the soil overlying it of appreciable depth, and particularly if there is a sod, it will generally pay to strip it. Stripping is usually done by teams and scrapers. Strippings makes good material for filling on the slopes of embankments where it is desired to get seeding started, and one way to dispose of it at a gravel pit is to scrape it to the front side and load it up for that purpose when making the first cut through. It is also good material for placing under track that is being lifted in stages, as in raising grade through a sag, or in track elevation. Railway companies, when loading gravel on private property, are sometimes obliged to enter into a contract to replace the soil on the land after excavating the gravel to a stipulated depth. One way in which this is done is to scrape the soil to the edge of the bank and cast it to the foot of the slope each time a cutting is made through the bank, or as often as each two or three cuttings are made, thus moving the material in strips of a width corresponding to convenient scraping distance. The soil thrown down the

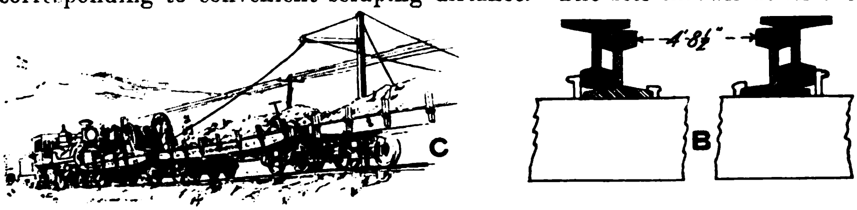

Fig. 370 A.

slope is then spread over the bottom of the pit, usually with teams and scrapers. If the pit is narrow the soil may be scraped into a long heap, either to the front side or to the back side, or half in each direction, before the excavation of the ballast is started, and then spread over the bottom of the pit after all the work of excavation is completed. Another plan that is sometimes followed is to haul in loam on cars from the outside, and unload it behind the steam shovel or loading gang as each cutting is made, the empty cars being loaded with gravel on the return trip. It is sometimes quite convenient to do this, the material being available where work is in progress at widening cuts through loam or in making original cuttings for a changed location.

When loading gravel by hand it is well to put about 2 ins. of elevation in the rail farthest from the bank. This inclination in the track will tilt the flats toward the bank and very much facilitate the work of loading. By loading a little from the side farthest from the bank, or by handling the material over on the car, 15 cu. yds. of gravel can be put on a 33x9-ft. flat without side boards, and it will ride the car a good distance without spilling off to any extent; with side boards 12 ins. high the load can be made 20 cu. yds. By going deeper than the bottoms of the ties at each move, the hight of the bank may be continually increased, thus necessitating less frequent moving; and also it continually leaves behind a quantity available for finishing out the far side of the car. It is best to load the cars to their full capacity, if it can be done conveniently, as under such a plan fewer cars are required to move the material and, as a matter of course, there is less shifting to be done. If the gravel is thrown upon the cars carelessly, with no view to getting loads of good size, or if clear space is reserved at each end of the car for standing room, 10 or 11 cu. yds. will be about the average load. Since the track must be moved frequently, little attention need be paid to the manner of its support. Bring the ties approximately to an even bearing by throwing gravel or blocks of wood under them and let it go at that, without much regard to surface. Much time spent on such track is time thrown away. Ordinary judgment will suggest to the foreman when the track is safe enough for slow-moving cars or the locomotive.

In ordinary gravel, 20 cu. yds. is a fair amount for one man to load on a flat car by hand, in a day of 10 hours. Shoveling gravel becomes more tedious than tiresome, and most men, as time goes on, will fail to keep up the gait which they started out with during the first few days, especially if too many get together at loading the same car. Men paid by the car-load, however, will gradually increase the amount loaded per day and are not so apt to complain about the work being hard. Loose gravel, if fine, seldom needs picking down. For the sake of a change men sometimes get into the foolish habit of climbing up the bank and picking it down from the top. The more the bank is picked away at the top the more gradual becomes the slope, of course, and therefore the greater the necessity for using the pick at the bottom or foot of slope. Picking, if done at all, should be done at the bottom, as fast as the loose material is shoveled away. The weight of the material above will then bring down the top, of itself. Large, round stones found in a gravel pit are generally disposed of easiest by burying. Dig a pit as close to the boulder as possible, roll it in and cover it over.

During winter time, when the ground is frozen and section men cannot do much on the track, in place of laying off part of each section crew for the time being, it will pay to make up a work-train crew (if there be no regular one), by calling one man or more from each section, and with it to spend a week or so hauling out cinders along the road. The cinder piles at water stations and other places can in this way be cleaned up and the material utilized to advantage by being spread over the shoulder, outside the tie ends, to a depth of 2 or 3 ins. Money spent in this way will be more than refunded by the decreased cost for grubbing weeds, which will result from the use of the cinders during the following summer; and then there are usually many places where the shoulder needs strengthening. If by keeping the winter forces at work as steadily as possible the results can be made to show substantially by way of decreased labor expense during the following summer, the policy is certainly a wise one to follow.

Steam Shovel Work.—Sometimes a question arises as to the advisability of using a steam shovel for loading gravel. There are circumstances and conditions under which a steam shovel is, of course, a very economical means for loading gravel, and there are others when hand labor will load cheaper than the machine. First, the question must be settled as to whether the quantity of material to be handled will warrant the outlay for a steam shovel; next, whether, under the conditions, the steam shovel can compete with hand labor. A steam shovel in gravel is worked to best advantage where the bank is high, as then its progress is not so frequently interrupted in moving ahead. There should also be ample ground beyond the pit for the tail track, so that a string of cars may extend past the machine when it is working at any point along the bank, else the time taken up in switching will delay the work to a great extent. Under favorable conditions a steam shovel with a 1½ or 2-yd. dipper will load about 125 flat cars per day, or 1100 to 1200 cu. yds. In many cases this record has been far exceeded, machines with 3 or 3½-yd. dippers loading more than 2000 cu. yds., but the average machine under average conditions will not keep it up day after day. There are certain conditions, as where the bank is short or shallow, or the work train service is much interrupted by the traffic trains, so that time is lost waiting for empties, where it is not safe to put the average day's work higher than 700 or 800 cu. yds. The expense of running a steam shovel per day is not usually less than $25, including cost of wear and tear, fuel, men to operate it, and pitmen. There is required, or, at any rate, usually employed, in addition a locomotive with its engineer, fireman, brakeman and conductor, in constant attendance, making the cost to the company of running the machine not less than $50 per day, or the wages of about 40 laborers. Now, in fair gravel, 40 laborers can load 800 cu. yds. per day, and no locomotive will be needed. The locomotive which hauls the gravel away can do the necessary shifting of cars, whereas to get the gravel away from the machine requires two—a matter of importance for a small road to consider. An occasional breakdown or delay of some kind to the machine is bound to occur, while with a force of laborers there is no breakdown, and the right kind of foreman will see that there is no delay. It is thus seen that, to compete with hand labor, the machine must work under favorable conditions. In material which would require much picking, if loaded by hand, the advantage is more likely with the machine in any case.

The expense of operating a steam shovel, together with a locomotive working with it in a pit, is itemized below. The amounts of fuel used, prices for the same and for labor of the various kinds are averages of figures obtained from similar work on several roads. One night watchman is supposed to take care of both locomotive and steam shovel. Six pitmen are allowed for leveling off the surface and laying track ahead of the machine, handling the jacks, picking and poling down the slope and other miscellaneous work. A steam shovel in a high bank might get along with four men for this work, but in shallow cutting as many as eight are sometimes required. No allowance is made for foremanship, as the cost would be the same for either hand or machine loading, and therefore this item is not needed for the comparison. The cost also of throwing over the loading track would be taken the same in either case, although there is always more tinkering with tracks where a steam shovel is used than where the loading is done by hand. Allowance is made for a conductor and brakeman in the pit. In ordinary work two men will be needed to do switching in the pit, in order to keep the machine loading as constantly as possible. The conductor is thus supposed to do a brakeman's work, his work in the capacity of conductor being light. He should endeavor to so arrange his cars that switching may be done while the machine is being moved ahead. The locomotive used in the pit should be supplied with air or steam driver brakes, to facilitate close movement and rapid handling of the cars while they are being loaded by the machine.

Daily Expense of Locomotive in Pit.

Use of Locomotive	$ 8.00
Coal, 2 tons @$2.25	4.50
Oil, 14 cents; waste, 5 cts.	.19
Water, 50 cts.; Kindling, 20 cts.	.70
Half watchman	.88
Ordinary repairs	.55
Engineer's wages	3.75
Fireman's wages	2.25
Conductor's wages	3.25
Brakeman's wages	1.75
Total	$25.82

Daily Expense of Operating Steam Shovel.

The work of loading dirt can usually be done cheapest with the steam shovel, as in such work the shoveling is more difficult than in ordinary gravel, and the machine can outstrip hand labor more easily than it can in gravel. In widening cuts, where the cars are loaded on main track, the advantages in favor of the machine are apparent. In such case a locomotive is required with hand labor, the same as with the machine; and while the train must be away to give track rights or to unload, the loss from the machine standing idle would be less than that for a large crew of laborers. And then, too, the machine can generally utilize at least part of such time in moving ahead. In widening out cuts for double track the machine can reach the main track from the far side of the excavation, whereas hand shovelers could not cast the material over the whole distance.

A steam shovel works upon a short piece of track laid in sections 4 to 10 ft. long. It is advanced by taking up sections in the rear, carrying ahead, and laying them down at the front. Lengths of 6 ft. are most commonly used, the rails being held to gage by tie bars and spliced with short splices with one or two bolts or keys in each. Another arrangement commonly in service is to have the sections of rails spiked to 6x12-in. stringers which rest upon ties or blocking at the joints. The track is held to gage by tie rods hooked into eye-bolts in the sides of the stringers, and the sections are joined end to end by tie rods across the joints, hooking into eye-bolts in the sides of the stringers, so that it is not necessary to splice the rails which rest upon the stringers. Another form of shovel track has joint ties with wrought iron chairs bolted or spiked fast. The rail sections fit into these chairs and carry the shovel without splices or tie bars.

In working a steam shovel in a bank considerably higher than the reach of the dipper it is desirable to have the material slide down to the shovel gradually. In a gravel pit the working of the machine, with perhaps a little extra labor at picking or poling the face of the bank, is usually all that is necessary to bring the material within convenient reach of the dipper as fast as it is needed. In a high bank of hard earth, however, the material will frequently stand to a vertical face until undermined by the shovel and then suddenly cave off in large masses, burying the shovel or jeopardizing the lives of the pitmen. Where trouble of this kind is liable to occur it is common practice to loosen the bank or "shoot it down" with explosives, in advance of the shovel. In doing this holes are bored, say a rod apart and to a depth and at a distance back from the edge of the bank depending upon conditions, and loaded with blasting powder after exploding a stick of dynamite in the bottom of the hole to spring it to larger cavity. In some cases one hole is fired at a time just in advance of the shovel, the latter backing off far enough to escape the falling bank; and sometimes a number of holes are fired simultaneously, bringing down a long stretch of bank in rear of the shovel to be handled when it backs up for a new cut.

In order to economize in cost of engine service, a team of horses is frequently used to spot the cars at the shovel. The heavy shifting is attended to by the road engine that hauls away the material, and if the grades in the pit are easy the plan works fairly well. In providing loading tracks for steam shovels there are two general arrangements. The ordinary plan is to have only a single track through the pit, and after the shovel reaches the end of its cut this track must be thrown over to the bank before the shovel can be run back and begin another cut. Where the cut is a long one this throwing of the track takes a good deal of time, frequently a half day for a gang of a dozen men. In order to avoid delay to the loading this work is sometimes done in the night. By what is known as the "double-track" plan, a track is laid in behind the shovel as fast as the latter advances, and as soon as the shovel reaches the end of a cut it may immediately be run back to begin another cut, the only delay being to connect the new loading track with the main siding where the shovel starts in again. In one instance where this arrangement was in practice on the Canada Atlantic Ry. a shovel was moved back 1300 ft. and put to work again in 27 minutes from the time she ran out of the cut. The material for laying the track which follows up the shovel is obtained by taking up the old loading track for the previous cut and carrying it across piece by piece. This is done by the pit crew, which usually has more or less time to spare, and thus the laborious work of throwing track is avoided without extra help or delay to the work of loading. This plan of working requires sufficient material for a double track the length of the pit. In some instances a switch is put in at the starting end, so that the track behind the shovel can be used to hold the tank car, where it can be available while the shovel is working. This arrangement is something of a convenience, for the usual plan is to push the water transport and fuel supply cars back on the tail track, or couple them behind the string of empties to be loaded, and then spot them opposite the shovel or the shovel tender when the engine pulls out to switch the loads, so that water and coal can be taken while the train is away. It is also usual to attend to taking on coal and water during the noon hour and at night. Where the steam shovel is working lower than the loading track, as when cutting down summits on main track, the coal can be run over on a chute. Plenty of track room in a gravel pit is a useful provision, as with a good supply of empty cars on hand the steam shovel can keep going regardless of delays to the road train or trains that are hauling the material.

Dredging Gravel Ballast.—In order to obtain suitable gravel for ballast within reasonable hauling distance, railway companies sometimes find it necessary to resort to unusual methods of excavation. Good deposits of gravel are sometimes found on low-lying land or in the beds of streams, so that the material is available only by taking it from under water, by dredging methods. The Choctaw, Oklahoma & Gulf R. R. is a road whereon such a condition prevails. Gravel banks, as they are ordinarily found, do not exist, but along the Memphis division of the road a supply of good material has been taken from the beds of streams, many of which are apparently dry about two thirds of the time. In times past the company has contracted for the loading of this gravel by teams, over traps, for 12½ cents per cu. yd. This cost was exclusive of trap material and the labor account for ditching. Delays incident to rain storms, floods, etc., were troublesome, and in addition there was a great deal of annoyance arising from the cutting down of the team force on account of sore hoofs. and from the large amount of skeletonizing of the track in advance of delivery of the gravel, owing to the impracticability of keeping the supply properly regulated to the demand.

As these difficulties made it desirable to devise some method of machine loading adapted to the conditions, the matter was taken in hand by Mr. John H. Harris, general superintendent, who concluded to try the method of dredge working, whereby the machine could be floated and cut its own channel along a siding used for a loading track. An ordinary Bucyrus steam shovel with a 1½-yd. dipper was placed upon a barge 50 ft. long, 20 ft. wide and drawing 27 ins. of water, constructed of old stringers taken from bridges rebuilt, and was launched into a "hole" or pond excavated for the purpose, the scene of operations here described being the bed of Crow creek, between Madison and Forest City, Ark. The steam shovel was run aboard on a track spiked to the deck of the barge. There was a spud at each corner of the barge to steady the outfit and hold it to its work, and the only change made in the steam shovel was the lengthening of the dipper arm to enable it to reach a distance of 24 ft. from track center, thus giving the barge considerable latitude of movement in its channel. The position of the shovel on the barge (Fig. 371) was regulated by means of stay chains on either side, snubbed to posts upon the barge, and in addition to these chains there were permanent beams securely bolted across the rails at the ends of the barge as a safeguard against dropping the shovel overboard. The shovel was capable of working to a depth of 10 ft. under the water. In moving ahead from one working position to the next the barge was shoved against the gravel slope ahead, this being done in two or three minutes, by two men, who

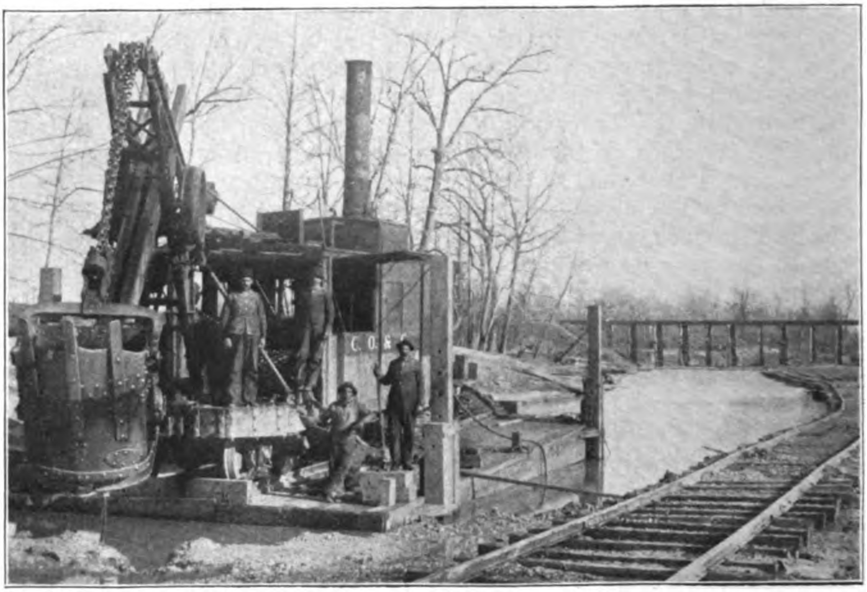

Fig. 371.—Loading Gravel Ballast with a Floating Steam Shovel, C.,O. & G. R. R.

would lift the spuds and push the barge ahead with poles, after which the spuds would be dropped and the shovel moved ahead on the barge to its working position. When the shovel had worked out all the material within reach of any certain position it would be moved back a few feet on the barge, lifting the bow and causing the barge to float at both ends. The barge would be then backed off a few feet and held to position on pinned spuds while the shovel cleared out the channel. The barge as it appeared in the figure was working up stream, the fall of which is at the rate of about $\frac{3}{4}$ of one per cent. The plan of work was to proceed as far up stream as the point where the shovel could no longer reach the top of the cars, after being blocked up on its trucks to gain something more in hight. If it was desired to go farther, the water would be raised by damming the channel behind the barge and then the work would proceed as before. The gravel obtained in this way was of excellent quality, being free from mud or clay, and as the dipper was lifted through the water the excess of sand was washed out, the quantity remaining being usually less than 5 per cent. When plenty of empty cars were on hand the gravel was loaded for $1\frac{1}{4}$ cents per cu. yd.

The Baltimore & Ohio Southwestern R. R. has employed an ordinary dipper dredge for loading gravel ballast. At a point on the Wabash river, in Illinois, four miles from Vincennes, Ind., a gravel ridge 12 to 16 ft. high on a low prairie had been taken off with a steam shovel to the water line. It was then found that below the water there was a deep deposit of gravel suitable for ballasting purposes, and to save buying more land

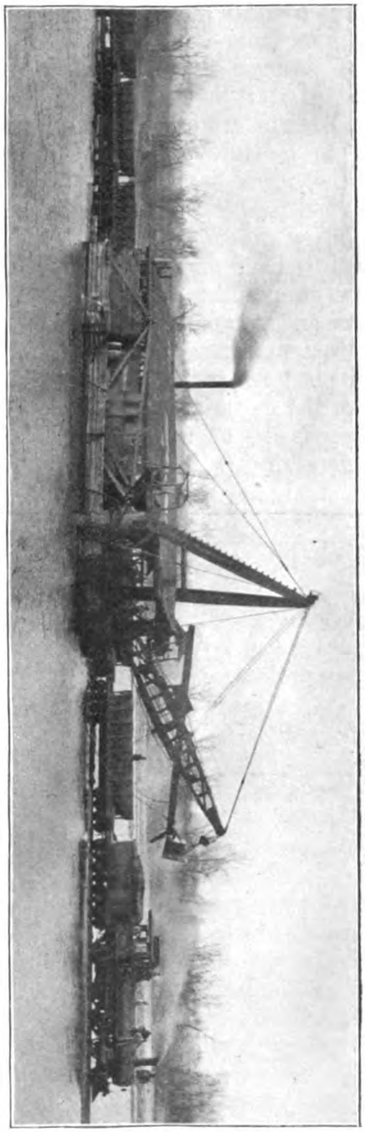

Fig. 372.—Loading Gravel Ballast with a Dredger, Baltimore & Ohio Southwestern R. R.

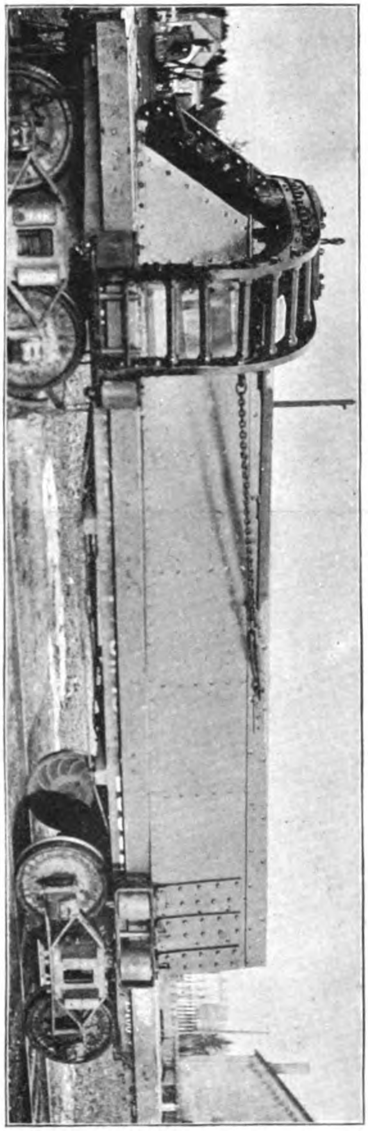

Fig. 373.—Warner Unloading Plow, Northern Pacific Ry.

it was decided to put in a dredge and take out a deeper cut. Accordingly a $2\frac{1}{2}$-yd. Marion dipper dredge was put in and gravel was excavated to an average depth of 24 ft. below water line. Figure 372 shows the dredge in operation. The cars hauling away the material were Rodger ballast cars of 80,000 lbs. capacity. At the time the photograph was taken the whole region was overflowed to a depth of about 18 ins., and in order to lay the track high and dry, and throw it over on dry ground when the dredge reached the end of the cut, the dredge deposited gravel enough on the far side of the track to raise the roadbed above the water. As the ground had been formerly worked over by a steam shovel the gravel taken up by the dredge was free from soil.

Loading Gravel in Moderate Quantities.—In loading gravel for ballast renewals, or for any purpose where the quantity of material needed during each season is comparatively small, there frequently arises some question regarding the economy of working a steam shovel. The operation of a steam shovel requires an extra engine and crew to haul the ballast away from the pit, for distribution along the line, since the quantity which a steam shovel will load each day is rather more than can be disposed of if it is intended to economize in cost of hauling by using the local freight trains. In employing a steam shovel it is therefore necessary to go into the work somewhat extensively while the work lasts. On the other hand, where hand labor is employed the cost of loading is a considerable figure. Nevertheless, where it becomes desirable to forego the heavy expense of a steam shovel and work trains the plan of loading gravel by hand and distributing it by local freight trains is very commonly found in practice. One method of loading at medium expense is with teams and scrapers, dumping into cars through traps. This method is followed on a number of roads. The arrangement for the purpose consists of a platform or staging built over the track, with an opening through which the material can be dropped into the cars. The construction sometimes consists of a temporary bridge over the loading track or siding, the bridge stringers being laid upon cribbings of ties which serve for the

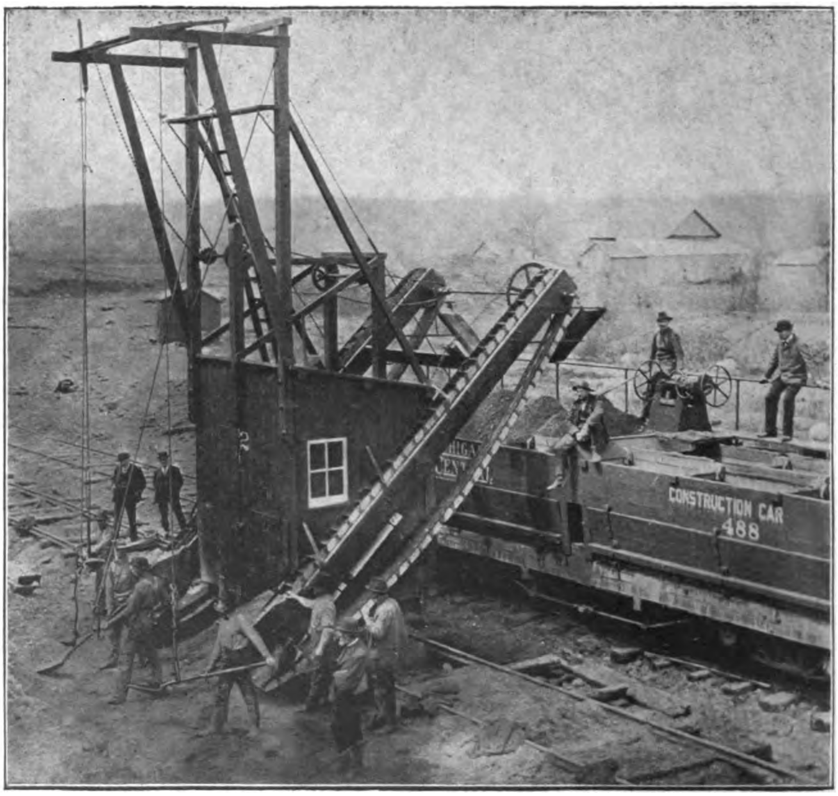

Fig. 374.—Torrey Ballast Loader, Michigan Central R. R.

abutments. As the temporary use of the material in this way does not injure it for other purposes (except for the wear to the floor planking), the expense for the lumber is only a trifle. The most favorable location for traps is where they can be built over a side-track along the foot of a hill or bank, or along side hill, as then the material can be scraped into the cars without elevating it. The cost of loading gravel in this manner is 8 cents, more or less, per cubic yard, depending upon the lay of the ground, the distance the material must be hauled, the quantity that can be loaded before it becomes necessary to move the traps, etc. In one instance where the average haul of the scrapers was 175 ft. and the average distance traveled per round trip over the traps 600 ft., the average quantity of material handled per team was 50 cu. yds. per day, making the cost of loading 7 cents per cu. yd. Most of the scrapers were of the wheel type, only a few being drag scrapers.

A method of team work similar in some respects to the foregoing was at one time practiced by the Calumet Improvement Co., at Plainfield, Ill., and in some other places, for loading gondola cars. The material was excavated by teams and scrapers and conveyed to the gondola cars by an endless belt driven by a portable or stationary engine. The belt was composed of steel plates and was made to pass under a low platform onto which the gravel was hauled and dumped upon the belt. The other end of the belt was elevated, so that the material was dropped into the cars as they were hauled along under it or let down an incline by gravity. The teams were driven around in a circle, so that several could be worked within a close radius. In this way the material was handled quite rapidly and cheaply, so it is stated, but no figures are at hand. One of the principal objections of this method of loading was the fact that it failed to mix the gravel properly. As the scrapers were necessarily worked on the upper surface continually, the gravel was taken off in layers, or practically as it lay in the strata in their natural positions, so that some cars were loaded with the fine material and others with material from the coarser layers. In loading gravel by hand or by steam shovel the material is taken from or near the bottom of slope, so that, as the gravel from the various layers rolls down the slope, all sizes become quite thoroughly mixed, which is the condition most suitable for the purposes of ballast.

An interesting scheme for loading gravel is a combination of machine work and hand labor devised by the late Chief Engineer A. Torrey, of the Michigan Central R. R. In general terms it may be stated that the arrangement enables the loading of smaller quantities of material than would be handled by a steam shovel working to its capacity, and at a cost for loading which approximates that of steam shovel work. The loading outfit (Fig. 374) consists of an elevator or loading car, which occupies a track at the foot of the gravel bank and conveys the gravel to the ballast car standing upon a track 12 ft. distant from the first, center to center. The material is conveyed from hoppers into which it is deposited by shovels of large size, handled by the men with the assistance of power to lift the loaded shovel to a level with the hopper. The loading car is 9 ft. long, 8 ft. wide, and is housed over. The source of power is an upright gasoline engine of 5 horse power. At each end of this car there is a rubber belt conveyor running over 20-in. pulleys. The belt is 10 ins. wide and carries buckets 3 ins. deep, 3 ins. wide, 9 ins. long across the belt and set 9 ins. apart on the belt, being formed of steel plates riveted to the belt, with overlapping plates at the sides, so that no openings are formed as the belt turns around the pulleys. The belt has a velocity of 180 ft. per minute. The hoppers are 10 ft. 4 ins. apart between centers and 3 ft. above the ties, and they extend 3 ft. beyond the rail. Attached to the upper part of the elevator car there is an overhanging frame carrying a horizontal shaft 24 ft. above the track and 4 ft. beyond a perpendicular line through either hopper, or 7 ft. beyond the rail. On each end of this shaft there is a double crank, or pair of oppositely-extending crank arms, from which are suspended two ropes, to the bottom end of each of which there is attached a scoop shovel, with a long handle, the scoop being the size of an ordinary grain scoop, holding 2½ to 3 times as much material as an ordinary track shovel. The rope is attached to the scoop about 1 ft. from the blade, and adjustment in the length of the rope is obtained by a strap and buckle, which forms the means of attachment. Each crank is 18 ins. long, from center, which gives a 3-ft. stroke to the rope which lifts the scoop. The modus operandi of a single scoop is as follows: The length of the rope to which the scoop is attached is so adjusted that while the crank is passing under the center the scoop is lowered to about the level of the bottoms of the ties, and is then thrust into the bank of gravel, by the man holding the handle. As the shaft revolves it lifts the scoop to the hight of the hopper, the shoveler meantime swinging it to position over the hopper, into which the scoop is emptied by revolving the handle and overturning it. As the crank descends the scoop is again lowered to receive another load. At the other end of the same crank the rope attached manipulates another scoop in the same manner, the two scoops being worked 180 degrees apart in phase, one scoop being at the lowest point of suspension, or at the point where it receives its load, as the other scoop reaches the highest point of suspension, at which time its load is being delivered to the hopper. Both scoops suspended from the same crank are unloaded into the same hopper. At the other end of the revolving shaft the same evolutions occur, there being two suspended scoops lifted and lowered alternately as the crank revolves. The cranks on the two ends of the revolving shaft are set 90 degrees apart, or at right angles, as the shafts of a locomotive, the idea in this arrangement being to balance the work on the engine, since if the cranks were set together there would be two loaded scoops to be lifted simultaneously while the other two scoops would be empty. The reach of the scoops into the bank is 10 ft. from the hopper, at the level of the bottoms of the ties.

The revolving shaft to which the suspended scoops are attached makes 10 revolutions per minute, so that each shoveler delivers to the hopper 10 times each minute, the gait being set by the machine. The speed of the shaft, however, can be regulated at will. The ordinary rate at which a shoveler will load gravel onto a flat car, from the ground level, is about eleven shovelfuls per minute. Working in this manner a crew of six men and a foreman, including four shovelers and two men to pole down the bank, have loaded 300 to 350 cu. yds. of gravel per day of ten hours, when cars were available for continuous work. The engine burns five pints of gasoline per hour, costing about 12½ cents per gallon. The elevator belts and engine have a capacity for carrying about three times the amount of material here mentioned. The gravel cars are run to position opposite the loading machine by gravity, half of the car, or the space from the middle to either end, being loaded in one position of the car. The gravel is first permitted to drop into the car direct from the two conveyors, until the two ends of the half section of the car become filled, when incline troughs (See figure) are set to direct the material from both conveyors into the intervening space, thus loading the half section evenly over its whole length. The foreman attends to setting these incline troughs, for trimming out the load, and to shifting the cars to position in front of the machine. The loading machine is easily pushed by the shoveling crew from point to point as the bank within reach of the same becomes shoveled away. Machines of this design are used on the Duluth, South Shore & Atlantic, the Mississippi River & Bonne Terre and other roads besides the Michigan Central. An average result of a season's work (117 working days) with one of these machines in a pit at Oxford, Mich., on the Michigan Central R. R., was 240 cu. yds. of gravel loaded per day, at a cost of 5.2 cents per yard. This cost covered the expense of supplies for and repairs to the elevator, and all labor, including that for moving the tracks, the full pay of men during wet weather, when they could not work all of the time, and for time lost in standing idle waiting for cars.

Hauling Away.—The cost of hauling material from the pit is the most uncertain and the most difficult of estimation of any of the expense items connected with the work of handling material for ballasting or for filling in embankments or for other purposes. It depends somewhat upon the distance moved, but more largely upon track rights and the number of cars which can be taken out per train load, which latter, of course, depends upon the grades. The quantity of material carried per car-load is also a factor not to be overlooked, as are also any unusual difficulties in the unloading. Allowing 30 cents per day for the use of flat cars each, and 8 cents per train mile for depreciation of track, the cost of hauling material in trains of 15 cars or more, with loads averaging 8 cu. yds. per car, a distance up to 10 miles, may be taken at somewhere between 4 and 5 cents per cubic yard. Of course this estimate must be looked at in a most general way, for delay to work trains by interference from traffic, the manner of unloading, etc., all affect it. The expense for the locomotive, cars, and crew goes on just about the same whether the train is waiting or running. The average cost of hauling large quantities of gravel ballast on one of the railway systems running west from Chicago has been 0.35 cent per cu. yd. per mile. This average covers material hauled all distances up to 50 miles, on flat cars with side boards, holding 15 to 18 cu. yds. per car. The average cost of unloading with plow and cable has been 0.84 cent per cu. yd.

On roads where train movements are frequent it requires a good deal of head work to dodge the traffic trains and dispose of the material promptly and to good advantage. In this connection it is important that there should be proper switching room at the pit, else delay to the road train hauling away the material may cause the shutting down of the steam shovel or loading force. In some cases where the time for completing an important piece of work has been limited, it has been found advantageous to run the steam shovel and the work trains both night and day, in this way supplying material for a large working force during day time. If the work of hauling gravel or other material from the same pit is to continue for some time and no permanently established station is near by, it may pay to establish a temporary telegraph station at the pit, in order to facilitate the movement of the work trains.

At pits from which large quantities of material are to be taken, and particularly where more than one work train is engaged in hauling the loaded cars away, extra sidings of good length, for the use of the road work trains, are usually paying investments. They facilitate the movements of the work trains in keeping out of the way of the traffic trains without occupying the pit loading track. The use of the latter for passing purposes might in cases necessitate shutting down the shovel meanwhile. In hauling to some point where a large quantity of filling material is required, as at a long, high trestle to be filled in or large embankment to be constructed, certain economies can be put into practice which would be sources of useless expense when hauling material in small quantities to any one point. One of these is a passing siding at the trestle or embankment. This arrangement gives the work train two places for passing the traffic trains, and where the distance from pit to fill is considerable, or the traffic congested, the arrangement is sometimes a means of saving costly delays.

Cars and Unloading Plows.—In § 36, Chapter IV, in connection with the subject of ballasting new track, there are descriptions and illustrations of several kinds of center and side-dumping ballast cars. In work-train service on old track the largest practice is to unload material—either ballast or filling—from the side, and hence flat cars with plow and cable, and side-dumping cars are in largest use. An unloading plow is a heavy framework

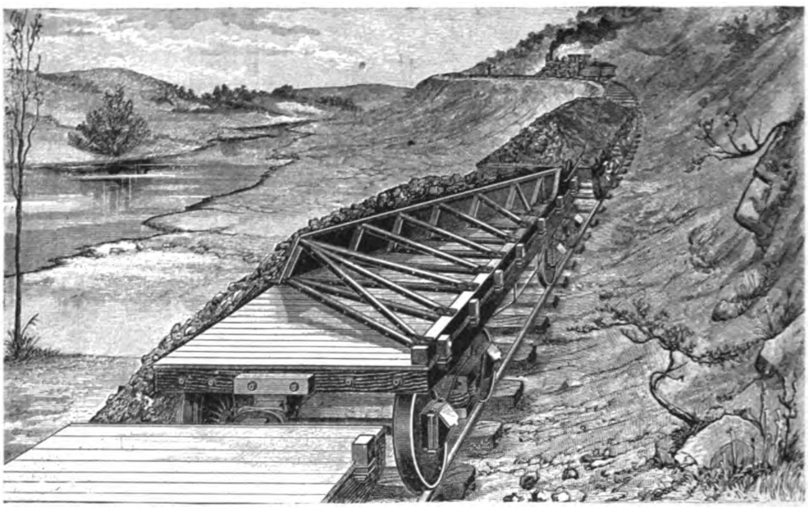

Fig. 375.—Barnhart Side Unloading Plow.

as wide as the cars, faced with a boiler-plate moldboard. The Barnhart side unloading plow, used in unloading filling material or ballast for double track and sidings, is shown in Fig. 375. Formerly the plow was guided by a timber guard bolted at one edge of the car floor and shod at the ends with beveled cast iron tips, to prevent the plow catching when passing from car to car; but as such an arrangement required some modification of the car and discommoded very much the work of unloading by hand at occasional intervals when such became necessary, such plows are now made to be guided by side stakes only. The old arrangement for guiding a plow unloading to both sides of the track was a timber guard bolted along the middle line of the car, but this arrangement also has been replaced by devices which do not require a modification of the car floor. Either type can be used on ordinary flat cars simply by taking the brake shafts from the ends of the cars and placing them at the sides thereof, and placing short stakes in the side pockets. On some roads (the Michigan Central being one) the brake shafts of flat cars used in the work train service are jointed at a socket below the level of the car floor. While the plow is being drawn over the cars the top part of the shaft is lifted out of the socket and hung on a side stake. The Barnhart center unloading plow is shown as Fig. 376. The plow is preceded by two runners or guides which bear against the side stakes and are united by an arched frame which straddles the load. The nose of the plow is hinged to the arched frame, which serves to hold it in the middle of the car. At the rear of the plow, on both sides of the car, there are trailing runners to hold the plow steady. The cable for hauling the plow is attached to the plow direct, at the nose. There is a weighted lever fulcrumed over the arch, which tends to lift the point of the plow and prevent it from scraping the car floor too hard when running in light material. The weight is adjustable and is set according to the nature of the material handled. Thus, for instance, when plowing off gravel, sand or light loam the weight is placed at the end of the lever, so as to reduce the bearing of the plow at the point and throw the weight onto the runners; but in sticky clay or soggy material, where the tendency of the plow is to lift from the car and ride the load, the weight is slipped toward the fulcrum as far as possible, so that the point of the plow may bear on the car with its full weight. In extreme cases additional weights have to be added; and this is true as to both of the extreme positions of the weight, it sometimes being necessary to place a few stones on a platform laid on the braces of the plow framing, in order to hold it down and properly clear away the material on the car. It is also customary for a man to ride the plow when difficulties of this kind are being encountered, to watch the action of the nose and lift the lever if the plow starts to ride the load. Figure 377 shows a man attending to this duty. Owing to the heavy friction against the side stakes, side plows are harder to pull than center plows.

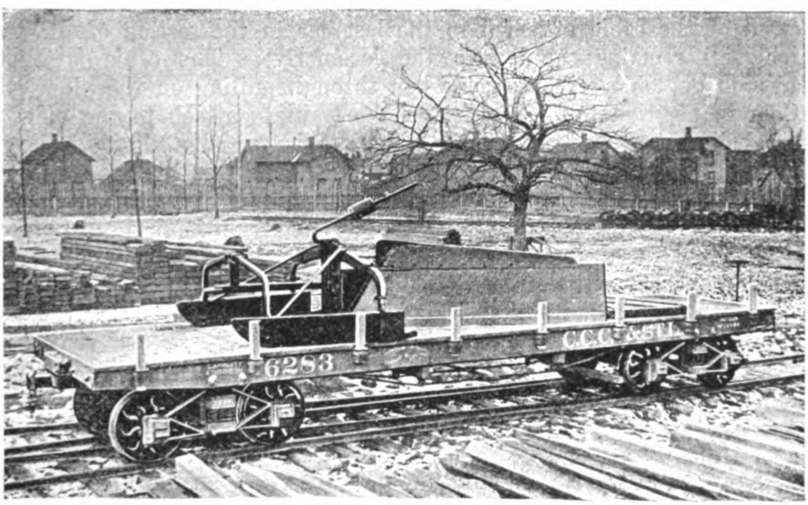

Fig. 376.—Barnhart Center Unloading Plow.

An unloading plow used on the Northern Pacific Ry., designed by Mr. H. H. Warner, master mechanic, is guided by a yoke which overreaches the sides of the car and bears against the side sills by rollers, there being no side stakes or guard timbers. This plow has a wide range of adjustment, it being possible to set it to unload all of the material at one side, half on each side, or to unload unequal parts of the material at the two sides of the car. It is illustrated in Fig. 373. The nose of the plow is adjustably attached to the guide yoke, and the spread of the latter can be adjusted to the width of the car. The rear of the plow is guided by two rollers journaled at each side, as shown, these also being adjustable to the width of the car. The guide rollers are spaced widely enough apart to straddle the opening between the cars—that is, as each pair of rollers passes the opening between the cars, the roller in the advance reaches the side of the car ahead before the following roller leaves the car behind. The plow is adapted to ordinary flat cars by placing filling blocks between the stake pockets to give an even bearing for the rollers. Cars detailed for special and continuous service in ballasting work, or for hauling material of any kind, are provided with a metallic plate attached to the side sills, as is the case with the car shown in the figure. The back ends of the moldboards project over the sides of the car, making it possible to clear the deck completely. The clevis at the point of the plow, to which the hauling cable is attached, can be moved up or down in suitable holes to adjust the draft of the plow to suit the character of the material handled. One trouble frequently experienced with unloading plows used in handling coarse material on cars with side stakes is that large stones or snags get fouled between the stakes and the plow, breaking off the stakes or wrenching off the pockets. Cakes of hardpan are particularly troublesome in this respect. It is obvious that with the Warner plow no such difficulty can arise. It is said that the plow is pulled over the cars with less than the usual amount of friction attending the operation of plows guarded by center timber or side stakes.

In usual practice the unloading plow is hauled by a locomotive, attaching to it with a 1¼ or 1½-in. wire cable reaching over the entire train to the plow on the rear car. In case the train should be longer than the cable, the train can be parted at a suitable distance from the plow and the end of the cable attached to the last car in the section of the train which still remains coupled to the locomotive. The cable is usually thrown to one side of the track when through pulling on the plow, as it is then in position to be thrown on the train to attach to the plow for hauling off the next train load. This is a better plan than to leave it lying on the empties to be covered up when the cars are loaded, for it requires considerable power to haul it through the material. Whenever it becomes necessary to load the cable, it is easier to haul the cars alongside of it and throw it on than to have the men drag it endwise over the cars. The plow is usually left on the last car to which it is hauled in unloading the train, and switched each time to the far end of the train from the locomotive. If it is desired to unload all the material in one place, as at a washout, a sink hole or at some particular point in filling in a trestle, the plow is headed from the locomotive and the cars are then unloaded by anchoring the cable to the rail at the far end and pulling the train from under the plow. In unloading by plow around a curve, the cable may be kept along the line of the cars by snatch blocks held by chains secured to the stake pockets or, better, to the track rail underneath.

By the method of hauling the plow with a locomotive it is necessary that all the material loaded upon a car be unloaded in one place, or in a distance corresponding to the length of the car. In unloading filling material or in unloading ballast for the first time along new track, where all the material is needed, this method may do quite well, providing the locomotive is heavy enough to pull the plow; but when it comes to unloading ballast the second time in one place, or wherever a smaller quantity than a full car-load is needed each car length, this plan of work is somewhat inconvenient. In some instances where the material is desired in small quantities the cars are unloaded by hand, and in other instances the cars are loaded below their capacity, in order that the plow may be used, but either plan increases the expense of handling the material. By the use of a machine with a winding drum, known as the Lidgerwood "unloader," the objections met with in pulling the plow with a locomotive are not found. This device consists of a heavy hoisting engine set up on a flat car, taking steam either by flexible pipe connection with the locomotive or from a boiler carried on the car. On some roads the outfit is called a "mill car." With this device the movement of the plow is independent of the movement of the train or of the locomotive, so that it can be hauled over the cars while they are in motion, making it possible to distribute material along the track in any desired quantities, regulated by the speed of both train and plow. If desirable to skip a place, it is only necessary to stop the winding drum until the train moves to the point where material is needed again. By hauling the plow in the same direction that the train is moving the material may be distributed in smaller quantity than the loading, and by hauling the train and plow in opposite directions simultaneously the load may be deposited along a stretch of track shorter than the length of the train; if the two are moved in opposite directions at the same speed the material will all be discharged in one place, as is sometimes desirable at a washout or in filling in a trestle. Thus, where this device is used the cars may be loaded without regard to the quantity of material that it is desired to unload per unit length of track. As an illustration of this principle, a certain railway, in handling material for reballasting, uses cars with high side boards, loaded to full capacity, and by means of a Lidgerwood unloader the gravel is deposited along a stretch of track three times as long as the train.

There are also other advantages. The plow can be pulled at a steadier speed than when hauled by a locomotive, and no brakes need be set when unloading the train at a standstill; but when hauling with a locomotive, brakes must be set to keep the cars from being started as the plow is hauled over them. The machine also has greater hauling capacity than locomotives of ordinary weight, which are sometimes unable to plow off heavy material, like sticky clay, if the cars are loaded to their capacity. In heavy pulling the locomotive is sometimes unable to start the plow without backing up and jerking on the cable, and such performances frequently result in broken cables. For this reason it is sometimes the practice to use two locomotives, in order to get sufficient pulling force to haul the plow steadily and avoid broken cables and the troublesome delays incident thereto. The capacity for hauling the plow may also limit the train-load or the number of car-loads handled in each train, for the longer the train the harder the cable pulls. In general practice it is considered that 20 car-loads are all that it is economical to handle at one time when pulling the plow with a locomotive, but with an unloading machine the plow can be pulled through as many car-loads as the locomotive can haul—35 or 40 or more cars, if the grades are not too steep. When the pulling is done with a Lidgerwood machine a man usually rides the plow and gives hand signals to the engineer of the winding engine which enable the latter to regulate the speed in accordance with the conditions of the unloading.

The cable may be unwound by making the end of it fast to a post or some other anchorage at the side of the track and then pulling ahead with the train. When drawn out in this manner it must afterward be thrown upon the cars. In order to drop the cable upon the cars as it is unwound it is usually the practice to set up a "stretcher boom" over the siding on which the loaded train stops to await orders. This is a simple and cheap device consisting of a stout pole or mast set at the side of the track, to support a horizontal arm or "boom" extending over the track at a hight sufficient to clear all cars. As shown in Sketch C, Fig. 370A, the mast is guyed, and the boom is stayed to the top of the mast and guyed to withstand the pull of the unloading cable. After hooking the cable to the boom the train is pulled slowly ahead, the cable unwinding and dropping on the center of the loaded cars. When the plow car reaches the "stretcher" the train is stopped and the cable is hooked to the plow. Another way to arrange for unwinding the cable is to drive a pile on each side of the track. When it is desired to draw out the cable a chain is stretched between these piles to clear the track about 14 ft. The cable is then hooked to the chain and as the train pulls ahead it drops upon the center of the loaded cars. Still another arrangement that has been used is an A-frame erected on each side of the track, using old bridge timber. As constructed on the Atchison, Topeka & Santa Fe Ry., this device consists of vertical posts footing between a pair of long switch ties laid to project from both sides of the track, with leaning posts to brace the vertical ones in the direction in which the cable is to be pulled out. To anchor the cable for unwinding, a chain is stretched between the A-frames

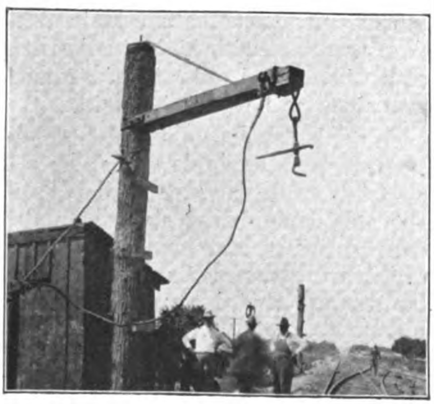

Fig. 376 A.—Cable Stretcher, G. T. W. Ry. Fig. 376 B.—Apron for Trestle Filling.

and the cable is hooked to it. When the work is completed these upright frames and track sills are taken down and out, and if needed elsewhere are set up again. A cable-stretching device that has been used on the Grand Trunk Western Ry. consists of a pile and swinging arm (Fig. 376A), the top of the pile standing 15 ft. and the arm 9 ft., above the rail. The cable to be pulled out is attached to a hook with a tripping arrangement which the brakeman (who rides the car on which the plow is carried) strikes with a stick as he passes underneath it, causing the cable to let go without stopping the train. The stretcher post or pile is driven to lean slightly away from the track, and the guy for the stretcher arm is clamped to the cable which guys the post, as shown. As the cable lets go, the spring in the guys, due to the sudden release from tension, pulls the arm back, causing it to automatically swing around clear of the track.

In order to reduce the cost of hauling material to a low figure, especially when hauling a long distance, it is necessary to send the cars out well loaded, and in this connection 25 to 30 cu. yds. should be considered only ordinary car-loads. There is no economy in handling cars loaded to only half or two thirds of their capacity. Not more than 8 or 9 cu.

yds. of gravel can be placed upon a 33x9-ft. flat car by steam-shovel loading, without boarding up the sides, for the reason that in dropping from the dipper the material sprawls out over the car; and consequently more cars are required for handling the same amount of material than is the case where it is loaded by hand, and the dead weight load runs up rapidly. Side boards at least 12 ins. high are now commonly used in loading flat cars, and in order to have them always with the car they are sometimes attached to the side sills with pieces of chain just long enough to permit them to drop down and hang about 18 ins. from the ground while the car is being unloaded. To facilitate handling these planks, a hand hole may be cut under the top edge near each end.

To increase the loading of flat cars beyond the capacity with side boards, it is now extensively the practice to side them up with outswinging doors hinged at the top and locked in position by catches at the bottom. Such is known as the Haskell & Barker type of construction. The plow being the same width as the cars inside, the doors are swung open by the crowding of the material against them, and the car is completely cleaned. To prevent material from dropping upon the track an apron of

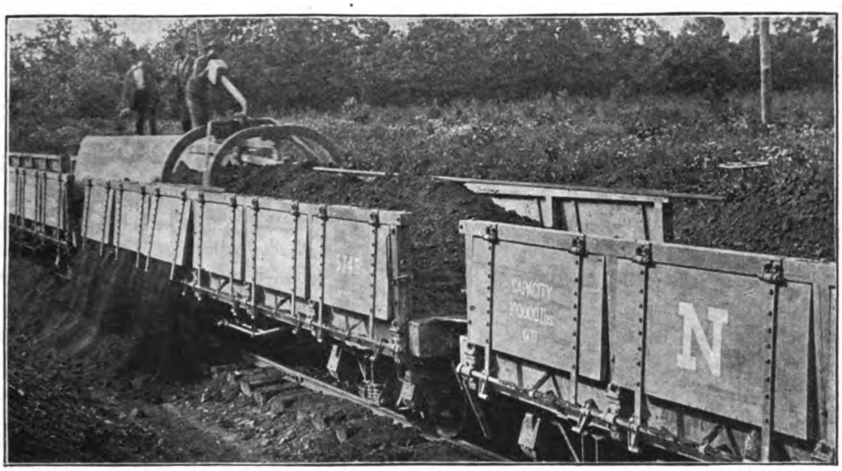

Fig. 377.—Haskell & Barker Cars, Norfolk & Western Ry.

boiler plate is hinged at one end of each car, so as to overlap the space at the coupling. A typical car of this class is the standard ballast car of the Wisconsin Central Ry. The car, which is 40 ft. long over end sills, is made by side-staking a flat car and mortising a 5x6-in. top plate over the side stakes, which are spaced 6 ft. 3¾ ins. center to center. The side doors are 2 ft. 8 ins. high, from the floor to the under side of the plate, and the top plate is 6 ft. 8 ins. high above top of rail. The side doors are hinged to the top plate with strap hinges which extend below the door and rest against the face of the side sill. Running along each side of the car there is a shaft with locking dogs which engage the bottom ends of the straps. This shaft is operated by a lever at one end of the car. There are no end boards, and at each end of the car there is a hinged apron plate of $^3/_{16}$-in. iron, which is folded across to cover the gap between the cars. The cars are unloaded by plow and cable. After turning the shaft to unlock the straps holding the side doors in place, the plow is hauled along and the pressure of the ballast forces open the doors, which return to the closed position after the plow has passed. These cars have a capacity of 100,000 lbs. and in ordinary service are loaded with about 32 cu. yds. of gravel. When the cars are not used in work-train service they are fitted with portable ends and converted into 40-ft. gondola cars for the regular freight service, for handling coal, lumber, etc. The Norfolk & Western cars shown in Fig. 377 are of similar construction. The center unloading plow seen in this picture is the Marion "Class 10" pattern for heavy duty. By heaping cars of this type they may be loaded with 40 to 45 cu. yds. of material. In making extensive grade reductions on the Kansas City Southern Ry. at one time, cars of this kind were used with remarkable effect. By loading the cars to the heaped capacity stated the average cost of hauling (average distance not stated) and unloading for a period of five months was only 1.36 cents per cubic yard. When material is to be plowed from cars with swinging sides the catches are sometimes knocked loose by two men with spike mauls stationed on either side of the train as it is moved slowly past. As the doors are released considerable material falls from the cars, and in filling trestles it is desirable that this material should drop into the embankment. One arrangement which provides for this is a platform built on each side of the track on and near the end of the trestle, on which are stationed the men for knocking loose the catches on the side boards, so that all the earth which escapes from the cars as the doors are released will drop into the fill.

When ballast or filling dirt is carried a long distance the economy of hauling and unloading is decidedly with the plow and cable method or with side-dumping cars of large capacity. The Goodwin car (Figs. 44 and 45) is of the latter class, and has been used to considerable extent under the conditions stated. The average cost of unloading with plow and cable, including labor of handling the cable and use of equipment, is about ½ cent per cubic yard. For handling filling material on short haul, careening or tilting side-dump cars are usually more economical than flat cars unloaded with plow and cable pulled by a locomotive. This comparison may be found to hold true in hauling up to three miles, and, under some conditions, perhaps, up to five miles. The facts regarding a test of the relative serviceability of tilting side-dump cars and flat cars unloaded with plow and cable, made in connection with extensive grade-reduction work on the Chicago, Burlington & Quincy Ry., at Galva, Ill., are as follows: The material was a heavy loam, loaded by steam shovel with a dipper capacity of 1¾ cu. yds. The side-dump cars used were of the tilting type, capacity 5 cu. yds., three dippers per car-load, the pit measurement averaging 3.87 cu. yds. per car. The hauling distance from pit to fill was ¼ mile to 2 miles, and two trains, hauled by switching engines, were worked continuously day and night. The work consisted in elevating 9000 ft. of double-track main-line road a maximum of 17 ft., requiring 193,000 cu. yds. of filling material. The tracks were raised with the filling, one at a time, in lifts of 3 to 4 ft. It thus happened that much of the time the material dumped did not slide clear of the track. As soon as the bank would begin to widen from the ends of the ties, the dirt dumped from the cars would be plowed out over the slope with a spreader car, which left a shoulder level with top of rail for a distance 6 ft. out. With the dumping ground in this condition a considerable portion of the load would remain in the tilted car, making it necessary to adopt the practice of dumping half the train and then pulling ahead to let the dirt slide out of the cars, when the latter would be righted and the other half dumped in the same manner. Such were the conditions during a good deal of the time of handling upwards of 5000 train-loads. The average time consumed in dumping trains of 16 side-dump cars was 1½ minutes, and the average time required to dump the cars and get them back into position—that is, from the time the train stopped to unload until it was ready to return to the pit—was 6 minutes. The other plan tried was with trains of 10 flat cars each, with an extra locomotive to assist in hauling the side unloading plow and cable. When working on this plan it was found that about 6 minutes were consumed each trip in stretching out the cable and getting ready to haul the plow, besides considerable delay occasioned in setting brakes to hold the cars at a standstill. The average time consumed in unloading the flat cars by this method was 20 minutes, thus deciding the competition in favor of the side-dump car, without question. The dump-car trains could handle the same quantity of material as the flat-car trains in much less time and at less cost, even when the expense of the extra locomotive used to haul the plow was not considered. The reason for using the extra locomotive was to enable the power to pull the plow steadily and avoid breaking the cable, which frequently occurred from jerking when only one locomotive was used.

In constructing new road tilting side-dump cars are very extensively used, as they can be readily transported ahead of the track-laying, and, on short haul, can be worked to good advantage by horses. For such service they are usually built for narrow-gage track (2 or 3 ft.) and are of small capacity—1 to 3 cu. yds. In widening out embankments for a second track, where the material is taken from an adjacent cut, this type of car is quite convenient and extensively used, being sometimes pulled by horses, and sometimes by light locomotives, in trains of considerable length. An interesting track arrangement sometimes employed in such places until the embankment becomes well widened out, is to use one main-track rail for one side of the tram track, the outside tram rail being laid as a third rail at gage distance from the outside of the main rail. Where the tram track diverges to clear main track a switch point is laid against the main rail. When cars are run out to dump it is of course necessary to send out flags or manipulate distant signals.

The body of the usual form of tilting side-dump car is either hinged to a center longitudinal beam of the truck or is supported by transverse rockers which bear upon tracks suspended from the truck on hanger irons at each end. In a few instances dump cars of this type have been operated automatically by an air cylinder and piston under one side of the car body. In the case of the Thatcher automatic dump cars, used on the Canadian Pacific Ry., the air was taken from, and the operation of the car was controlled from, the locomotive through a line of hose pipe independent of the brake system. These cars were designed for dumping material from trestles, so that it would be unnecessary for men to be upon the structure while the cars were being dumped. Many attempts to operate tilting dump cars by compressed air have not, however, proved successful, and the usual method of dumping such cars has been to push the body over by hand or by prying under the rockers with bars; or to have the load overbalance, so that the body would tilt by gravity upon releasing the stay chain or prop. Owing to the character of the body supports and to the method of dumping, the capacity of such cars is necessarily limited to a small quantity—usually 3 to 5 cu. yds., or perhaps 7 cu. yds. in a few instances. For this reason they are not an economical car to use in a long haul. Neither are they suitable for unloading ballast, because on an embankment of ordinary width the material leaves the tilted car with a momentum sufficient to carry a portion of it over the shoulder and waste it down the slope. On many roads there is a good demand, however, for a side-dumping ballast car which will drop all of its load near the track, as will now be explained.

On roads where the local freight trains are not hard worked it is economical of maintenance-of-way expense to have these trains distribute the moderate quantities of material usually needed for ballast replenishment; and if the cars in which it is sent can be rapidly unloaded, a great deal of ballast can be handled in this way without seriously delaying the trains. Again, there are roads, particularly some systems with poorly constructed branch lines, where only a meager supply of ballast has been provided, or where, perhaps, the track is largely or entirely ballasted with dirt. In such cases considerable quantities of gravel or cinders may be in demand, here and there, for raising the track out of sags or for ballasting stretches of track on a plan of gradual improvement. Such work may be, and commonly is, undertaken by the regular section crews, and if the ballast can be distributed by the local freight trains the saving in expense which would otherwise be incurred for extra train service is important. In order to give entire satisfaction when handled in the local freight service, ballast cars must be designed to suit several requirements besides quick action in dumping the load. Some side-dump cars deposit the ballast too far from the track, and in the case of a narrow shoulder much of the ballast, as already stated, is lost by sliding down the embankment. Again, other cars deposit the ballast so close to the track that it obstructs the rail and must be shoveled away, at some expense for labor, not to speak of the inconvenience and the time lost to the section forces in being obliged to be on hand every time ballast is to be unloaded. Another requirement is that the cars shall be of large capacity, so that a considerable quantity of material may be handled without unduly increasing the length of the train; and still there should be such flexibility in the arrangement for unloading that the material may be discharged in quantities commensurable to the work. One respect in which some side-dumping cars of large capacity fail to meet this requirement, although quite suitable for the service in other ways, is that the whole load must be let go in one place once the doors are opened.

To cite an example of a road which has in practice a well regulated system of ballast distribution by local freight trains, reference may be made to the Michigan Central R. R. This system and the plans of cars specially designed to meet the requirements were studied out by the late Mr. A. Torrey, chief engineer, whose method of loading gravel has already been described. The plan of work is such that after the gravel is loaded upon the cars no extra expense other than that which accrues in operating the regular trains is involved in transporting the gravel and unloading it at the exact points where it is needed along the track; and the delays to the regular trains in handling this material are inconsiderable. The system was intended mainly for the branch lines of the road. The ballast cars were designed with particular reference to facility of unloading, so as to dispense with an extra crew for this purpose. The cars are 34 ft. long and the carrying capacity is 80,000 lbs. The floor of the car slopes each way from the center, at a pitch of 3 in 4. The car is divided transversely across the middle into two compartments, and each compartment is divided lengthwise into three sections, the middle section containing about half the material in each compartment. The material in each section is retained or released by doors extending the whole length of the compartment. The doors for the middle section in each compartment close against the sloping floor of the car about midway between the peak and the outer edges, and are hinged from 5½x5½-in. longitudinal timbers. The doors of the outer sections are hinged from 4½x5½-in. timbers built into the sides of the car. The sides of the car are tied together in two places in each compartment by 3½x5½-in. timbers. Each set of doors is locked by a winding shaft running the length of the car—all the inner doors by one shaft and all the outer doors by another. Each shaft carries a grooved wheel which is locked by means of a friction block set by a hand wheel and screw. The chains connecting the locking wheels and shafts with the main winding shafts running the length of the car pass through an open space 12 ins. wide separating the two compartments of the car. The doors are released by the pressure of the load as soon as the friction block is withdrawn from the grooved wheel. By the means described half of the load can be dumped at one time by releasing the outside doors, while the other half may be retained by holding the inside doors in the locked position. The car stands 8 ft. 4 ins. high above the rail, and across each end and along one side there is a foot board and hand railing. The hand wheels for locking the doors are arranged at the middle of the car, to one side, on a small stand, as shown in Figs. 367 and 374. The normal capacity of the car loaded to the top timbers from which the doors are suspended, is 20 cu. yds., or 22 cu. yds. when heaped; but by placing side boards on the car the load may be increased to 26 cu. yds. There are pockets to hold planks when it is desired to heap the load. When not

Fig. 378.—Half Unloaded. Torrey Ballast Car. Fig. 379.—Empty.

in use these side boards or planks are carried in an open space under the floor, access to the same being had through a door in each end of the car. Figure 367 is a view showing the general appearance of the car when loaded. The hight of the cars has been restricted to the limit of convenient loading by steam shovel, so that they can be utilized in any equipment for general ballasting work.

The transporting of the gravel and the work of unloading it at points along the track where it is needed, as indicated by stakes set by the section foremen, is done by the local freight trains with their regular crews. As each train of this class going in the direction in which the gravel is needed arrives at the pit it takes what loaded cars happen to be on hand and, stopping at the point where material is needed, the outer doors are released and half of the load slides down into heaps at the ends of the ties on either side of the track. The train is then pulled ahead the length of the several gravel cars, when the inner doors are let go and the remainder of the gravel is unloaded. The releasing of the doors is but the work of a moment, as the brakemen have only to run from car to car and give each hand wheel a turn. The whole operation of unloading a long string of these gravel cars, depositing half of the load at each stop and pulling up in the meantime, requires but a few minutes. Figure 378 is a view showing some of these cars coupled in with a local freight train, taken just after the outer doors had been released and half of each load deposited. Figure 379 is another view showing the same cars after they had been pulled ahead and the inner doors released. The outer doors swing inward after the gravel slides out and require no attention on the part of the train crew after the material has been unloaded, as the cars are returned to the pit with the doors unlocked. As the train proceeds the empty cars are set out at the first side-track and returned to the pit by the next local freight train going that way. By dumping half the load in a place enough gravel can be placed to raise the track 8 ins. The quantity of gravel to be unloaded at any particular point, to meet the conditions there obtaining, may be suited to the requirements by regulating the quantity loaded. For this purpose load lines for 16 and 20 cu. yds. are marked on the car. The stakes set by the foremen to indicate where ballast is needed have arms or pointers showing in which direction from the stake the ballast is to be dumped. A valuable feature of the work is that the material is deposited close to the track but not near enough to obstruct the rail, so that no attention to the unloading is required of the section men.

The Pratt side-dumping cars of the New York, New Haven & Hartford R. R., which have one swing door above another, for unloading half the material at one time, are described in connection with the work of ballasting new track (§ 36, Chap. IV). In the same place some account is also given of the method of unloading ballast between the rails from hopper-bottom gondola coal cars. This plan is sometimes followed also on old track, where the line is being reballasted or the ballast replenished, such being the case on the Norfolk & Western Ry. The practice there is to remove the old ballast filling as low as the bottoms of the ties and throw it out to widen the shoulders. The hopper doors are opened in one car at a time, and just far enough to let out the desired quantity of gravel, which is struck off level with top of rail by skidding a tie ahead of the wheels of the rear truck. If a large quantity of material is to be leveled down and spread out over the rails in this manner, two ties are used—one on top of the other. To prevent the wheels from mounting the tie that is being shoved before them, as they are liable to do in case the tie should strike a lump or other obstruction, the brake on these wheels should be set up tight.

Filling Trestles.—Improved earth-handling appliances, such as steam shovels, material cars and unloading plows of large capacity, have so cheapened the cost of handling dirt that trestle filling has become a widely established method of constructing railway embankments. When new roads are being constructed it is frequently the plan to build temporary trestles out of timber conveniently at hand, in order to quickly open the road for traffic and begin earning money, while these trestles are being filled in with steam shovels and work trains at much less cost than it could have been done by contract from borrow pits or adjacent cuts at the time the roadbed was being graded. It is also a policy, now widely adopted, to fill in all the old wooden trestles of moderate hight as fast as they require renewing. In support of this plan there are many considerations, such as the relative cost of track and bridge maintenance, danger from fire, accidents liable to happen in cases of derailment, etc. Investigations of the comparative cost of embankment filling and wooden trestle construction have shown that, under usual conditions of timber supply and traffic movement, trestles as high as 22 to 25 ft. can be filled as cheaply as they can be rebuilt, considering first cost only; and that, taking the cost of periodical rebuilding and the various items of bridge inspection and bridge maintenance into consideration, it is an economical proposition to fill trestles up to 50 ft. in hight, providing unusual difficulties are not encountered in maintaining a waterway. Local conditions, such as cost of timber and cost of handling earth, as influenced by interference with work-train service by the traffic trains, might change these figures one way or the other, but for general practice they are regarded as typical limits unless the situation is attended with exceptional conditions.

Before the work of filling a trestle is started there are two important matters requiring investigation. One of these is the area of the waterway to be left in the embankment. This question, which has a bearing on the size and design of the culvert or of the bridge construction, in case an open waterway is decided upon, is treated with some fulness under the subject "Culverts," § 5, Chap. I. The other matter, the importance of which increases with the hight of the trestle, is the character of the bottom. It is well understood, of course, that the surface is sometimes unable to support a high fill. In order to properly understand the conditions it is therefore necessary to examine the under formation. This may be done by digging pits or driving piles, at different points. Almost any kind of surface except solid rock will settle at least a little under a high fill, but excessive settlement may badly break up or wreck any culvert that is not placed on a solid foundation. Some experience is necessary to prompt the judgment in matters of this kind. The remedy for a soft or unstable bottom is to start the culvert on a pile and concrete foundation. Some attention should also be paid to the character of the material dumped. Clay is treacherous and should not be placed in any part of an embankment. Whenever it meets with water it assumes a slippery condition, and is frequently the cause of sliding embankments. Material ditched from cuts should be rejected for filling purposes if it possesses the characteristics of clay, but mud or other wet material is not necessarily objectionable.

In filling trestles it is the practice to a considerable extent to put in the base of the embankment with teams. The local conditions, such as the opportunity to use grading machines or to open borrow pits within economical distance for hauling in scrapers, may be such that a good deal of team work can be done to advantage. It may also be necessary to construct ditches for draining the ground or to change the course of a stream, and in such work teams would usually be employed and the excavated material hauled into the base of the fill. The bulk of trestle filling is, however, usually done with trains, using cars that are unloaded from the side—either flat cars with plow and cable or tilting side-dump cars.

In dumping material from high trestles considerable damage is frequently done to the bents and bracing in being struck by large stones or heavy lumps of material falling from the cars. In order to prevent trestle posts or piles from being knocked or crowded out of position while filling is being done, struts of old timber are sometimes fastened between the ends of these members, underneath the caps; and in trestle bents of two or more decks struts are placed between the posts both underneath and on top of the inter-caps. In filling very high trestles such reinforcement is not sufficient protection, and in order to avoid damage or accident in such cases it is sometimes the practice to construct an apron of heavy plank or timbers sloping outward from the top of the trestle, so as to deflect the material and cause it to drop far enough out to clear the bracing and batter posts. The apron also drops the material nearer the foot of slope, so that there is less sliding of the material in building up the embankment and less material to move in case the practice is followed of leveling down the dirt as fast as it is dumped. Figure 376B shows an apron for trestle filling in use on a structure about 100 ft. high, on the Southern Pacific Lines in Oregon. The apron was built to slope from the ends of the bridge ties and was supported upon stringers placed upon the caps of the trestle bents and on braces footing against the batter posts of the bents at the level of the bottom of the top deck. The timber used consisted of old stringers of odd sizes. The apron was taken up when the fill reached the lower edge. Owing to the cost of erecting these aprons and removing them when the embankment approaches completion, this company has abandoned the use of them on structures lower than 60 ft. in hight. In such cases it is the practice to merely strengthen the girt timbers temporarily by using old trestle stringers. In the experience with trestle filling on this road it has been observed that the girt timbers are the members which suffer most from the material dumped. Aprons are sometimes made as a screen, with plank set edgewise, to let the fine material drop through but to intercept large masses and throw them clear of the trestle bents.

In building some remarkably high embankments on the Boone cut-off of the Chicago & Northwestern Ry., between Boone and Ogden, Ia., portable aprons were used to protect the temporary trestles erected for the purpose of construction. As, however, the arrangement is applicable to old trestles as well, a description of these aprons and their operation is not out of place here. The general scheme, which was adopted with a view to spread the material over the entire width between the slope stakes as it was unloaded, was to dump it from two lines of trestle 80 ft. apart constructed across the ravine. On each side of each trestle, 10 ft. below the top, a bench or shoulder was built to support a track which carried the portable apron or chute. Half of this apron, in width, was a good deal longer than the other part, and the two parts were separated by a vertical partition. Material dumped into the longer side was dropped out near the slope stakes, while that dumped into the short side fell closer to the trestle. As the material accumulated in a place the apron would be moved along. In this way the embankment was built up by dumping the material in two parallel ridges each side each trestle, or eight ridges in all.

For temporarily supporting the track over culverts built under trestles that are to be filled in, the Atchison, Topeka & Santa Fe Ry. has made extensive use of a pair of through girders 80 ft. long. After the culvert is completed the embankment is filled in, either with wheeled scrapers or by dumping from a work train, and as soon as the track can be supported on the grade the girders are picked up by a derrick car and shipped away for use at some other point.

In filling trestles it is usual to permit the material to drop and form its own slope as the embankment is built up. Embankments built in this manner, however, are loose and will settle about 10 per cent in hight, and when thus made they are usually permitted to settle for a year or longer before the trestle floor and stringers are pulled. In this way a good deal of expense is entailed keeping the track in surface. As the embankment is formed in sloping layers it frequently happens that troublesome slides will occur, for which reasons some engineers think that it pays to level down the material as it is dumped from the cars. If such is done with teams and scrapers the embankment becomes solidly compacted and will not settle appreciably after the work is completed. It also prevents damage to the trestle and distortion of the track alignment during the progress of the filling. Where the material is dumped and allowed to take care of itself, braces are liable to be broken by the weight of the earth and trestles are frequently pushed out of line by unequal pressure of earth against the bents or unequal settlement of different parts of the embankment. A trouble that is frequently experienced is that the batter piles of pile bents and batter posts of framed bents are crowded toward the center of the bridge, causing them to drop away from the cap and leave it supported only on the plumb posts. At a high trestle the fill should be built up more or less uniformly from end to end. If the filling takes place from one end or is made too fast in one place, the pressure of the earth against the bents is liable to strain the structure longitudinally. In filling over culverts the material should be deposited directly on top or simultaneously from both sides, avoiding a slope against one side only, as unequal pressure which then exists is liable to shove the culvert or crowd in the walls. The sliding of material is sometimes caused by plowing large masses of earth down the slope, as with a side leveler, about the time the embankment is being finished out. The slipping of an embankment may also occur where loose material has been deposited on ground which slopes transversely to the track. A way of preventing this is to cut trenches parallel with the track before the filling is started.

One road whereon conditions of the foregoing description have been carefully investigated for a number of years is the Nashville, Chattanooga & St. Louis Ry. On the Paducah & Memphis division of this road a number of high trestles have been filled in at various times, and numerous interesting details of the practice of doing the work and of the behavior of the material in the embankments have been described in papers presented before the Engineering Association of the South, by Mr. I. O. Walker, assistant engineer with the road. On this road it is the practice to level down the material with teams and drag scrapers as fast as it is unloaded from the trestle. In spreading the earth the fill is kept a few feet higher in the center, so that the loaded teams can pull down hill. The outer edge of the fill is also carried about a foot higher than the adjacent material, so that in case of rain the water will soak into the fill and not wash down the slope. The fill is checked occasionally to see that the slope is being carried up correctly, and practically no trimming is done. The outer row of scraper loads is dumped about 1 ft. inside the slope line, as it is found that when the next row is dumped the teams will tramp the first row out to the slope line, thus finally getting the earth where it is required and packing it solid. The cost of spreading earth in this manner for trestles under 30 ft. in hight is about 2 cents per cu. yd. and for trestles 50 ft. in hight the cost is about 2.8 cents per cu. yd., wet weather increasing the cost in either case. When trestles have been filled in this manner the embankment is so solid that the ties and stringers are pulled within 10 to 60 days after the filling is complete.

On this road high fills receive careful attention for a year or two after completion. If holes are washed in the slopes by rain they are promptly filled with good earth, and new embankments are protected by planting Bermuda grass all over the slopes. This is done by setting tufts of grass in rows 2 ft. apart each way. In order to get the grass to take root quickly the richest earth dumped from the trains is scraped out to the slopes, and sometimes stable manure is mixed into the layers at the outside of the fill. Fertilized in this manner it usually occurs that a continuous sod will be formed all over the slopes within a year.

In filling high trestles it will frequently occur that the trestle will settle as the embankment rises, owing to the settling of the original surface from the pressure of the fill, and if the fill settles unevenly it may crowd the bents over and pull the track out of line. When such work is being done it is therefore necessary that the track should be closely watched and maintained in fair surface and line. Surfacing may be done by shimming up the stringers, but the easiest way to reline the track is to draw the spikes and set the rails over. In order to have ready access to the caps and stringers it is a good plan not to fill higher than the caps until just before the ties and stringers are to be pulled. If access to the caps is obstructed by a mass of frozen earth the difficulty and expense of reaching them when it becomes necessary to block up are considerable. It is sometimes the practice to fill in the embankment to the level of the bottoms of the ties but leaving sufficient open space at each bent to expose the cap.

When trestles are filled the usual practice is to permit the floor system to remain until the embankment has become well settled, which may take a year or longer. When finally the track is put upon the grade it is necessary to "pull" the stringers, level down the roadbed and ballast and surface the track. The easiest way to remove the stringers is to first take up the rails and ties. The work of lifting out the stringers with track jacks and bars is a "tough job," and on some roads it is done with a derrick car, using a pair of heavy tongs to grapple the timbers, so that but little or no digging is required. Such is the practice on the Nashville, Chattanooga & St. Louis Ry., where a steam derrick car with a 24-ft. boom is used to lift the stringers and swing them out of the way, the rails and ties being removed from 60-ft. sections at a time. On this road the cost of pulling long trestles has sometimes been as low as 12 cents per foot, the cost being highest for the short trestles. In one instance the cost of pulling 1144 ft. of trestle top and replacing and surfacing the track was $506, or 44.2 cents per foot.

Filling Trestles by Hydraulic Methods.—The economical and very extensive operations of moving earth in hydraulic mining suggested the application of the same process to railway trestle filling, and on the Northern Pacific and Canadian Pacific roads a large number of high wooden structures have been filled in this way. The process, commonly known as sluicing, consists in loosening the material—gravel, earth or loose rock—from the bank with a powerful hydraulic jet and conveying it to the site of the trestle in sluice boxes or flumes. The water is obtained by diverting mountain streams at a sufficiently high level to produce the pressure required for such purposes. The flow to the monitor is through strong iron pipe, the head sometimes being upwards of 200 ft. The monitor is provided with nozzles 3 to 6 ins. in diameter, according to the head and the character of the material. For breaking up masses of material the small-size nozzles are most effective, while for flushing the sluices the increased volume of water required is furnished by the larger ones. By directing the jet against the face of the hillside the earth or gravel is broken up by the force of the discharge and brought down in the flow to the sluiceway. The sluice box or flume, which is sometimes 3 ft. wide and 3 ft. deep, is laid to a steep grade—10 to 25 per cent—so that heavy material, including boulders as large as 18 ins. in diameter, is readily carried with the current. To protect the flume from scour the bottom is paved with wood blocks or laid with old rails. The distribution of the material at the place of deposit is controlled by shifting the end of the flume from time to time and by deflecting the current to desired points on the fill.

As the material drops upon the fill it is carried in rivulets toward the slope, and as the water drains away the solid material is left behind.

To prevent washing where the water runs strong on the fill, boards are sometimes set down to break the force of the current and catch the material, and are then pulled up as the embankment rises. To deflect the current to desired points short pieces of plank with braces at the back are used. To protect the edges of the newly-made bank from washing down, hay, straw, marsh grass or brush is used as a binder. To confine the filling to proper limits and to form the slope to the established angle (usually about 38 deg.) old ties or logs are laid at the edge in rows, to form tiers on the slope. One advantage in binding the layers of material with hay or straw is that the seeds will germinate and soon grow a sod. The retaining logs are sometimes selected from wood that will take root and sprout, and thus in a short time bind the surface mass firmly together. The levee at the outside of the fill is carried up and maintained several inches to a foot higher than the interior, so as to form a pool and cause the water to drop its sediment before escaping.

Filling by the sluicing process has been done at the rate of 500 to 1500 cu. yds. of embankment built per day, using one nozzle. The quantity and the cost would, of course, be expected to vary with the character of the material, the water supply and other local conditions. The labor required is five to nine men with each nozzle, including one expert to handle the nozzle, two or more men with hooks to keep the sluices clear and two to six men to take care of the material on the embankment. The cost of the work has been 5 to 8 cents per cu. yd. The average cost of several million cu. yds. of hydraulic filling for the Northern Pacific Ry. was about 6 cents per cu. yd. In one instance where the sluiced material was conveyed a distance of ½ mile from borrow pit to fill the cost was 5 cents per cu. yd., including all charges. The average cost of moving 377,000 cu. yds. in filling eight trestles was 4.79 cents per cu. yd., of which 3.85 cents was the cost for sluicing and building side levees and 0.66 cent the cost for lumber and labor in building flumes. The remainder (0.28 cent) was for tools, levee material, superintendence and engineering. In one case where the water was pumped the cost of filling 42,250 cu. yds. averaged 13½ cents per cu. yd. In filling a trestle at North Bend, in the Frazer river canyon, on the Canadian Pacific Ry., the embankment built was 231 ft. in extreme hight and contained 148,000 cu. yds. The material in the pit consisted of 50 per cent cemented gravel, 30 per cent loose gravel and 20 per cent large boulders which had to be removed by a derrick. The cost for all charges, including explosives to blast the cemented gravel, averaged 7.24 cents per yard. Of this 3.44 cents was for the plant. The working force consisted of eight men, all common laborers except the pipeman. At a similar fill of 66,000 cu. yds. the total cost was 7½ cents per yard, of which 3.2 cents was for the plant and 1.78 cents the actual cost for sluicing. The embankments formed by this process are said to be very compact, insomuch that the foundations of masonry abutments and piers can be laid in the same. After completion no settlement of the material is noticeable. Aside from being cheap, the process has the further advantage that it does not require work trains or in any way interfere with the traffic of the road.

Hydraulic dredging is another process that has been employed, in cases, to fill in trestles or "make land" for railways. The opportunity to handle the material in this way has usually been in connection with harbor work. In hydraulic dredging the sand and other material at the bottom is taken up with the water by a revolving cutter and forced through a line of pipe extending from the dredging boat to the place of deposit. This pipe is supported at intervals upon scows or light pile bents. As the spoil falls from the end of the pipe line the water drains off, leaving the entrained solid matter behind. An interesting piece of work of this kind was the filling of 12,600 ft. of trestle of the South Pacific Coast Ry., extending from the mouth of Oakland harbor to the Alameda pier, in the Bay of San Francisco. This trestle, which ran parallel with the government channel into Oakland harbor, at a distance of 250 ft., was 8½ ft. high at the shore and 20 ft. high at the pier, the track being 7 ft. above mean high water and 11 ft. above mean low water. In dredging out this channel the spoil was used to fill in the whole space between the south line of the channel and the far side of the railway trestle. To retain the embankment and protect it from the waves, rock revetments were built along the boundary lines. Before the dredging began sheet piling was driven along the south side of the trestle, behind which the rock was eventually deposited, partly from barges and partly by dumping from cars on the trestle. The rock and dredgings were put in as nearly as possible at the same time, so as to keep the pressure of the dredgings on the inner side and the rock on the outer side about equal, to prevent the bulkhead giving way. At the track side of the embankment the top of fill was made level with the top of ties, but at the channel side it was made 1 ft. below the top of the training wall, which was 7 ft. below the level of the top of tie on the trestle. Thus the top of the fill has a gradual slope from the track to the channel. At the west end the embankment gradually widens from 250 ft., at a point 2100 ft. from the bay end of the trestle, to 525 ft. at the end of the embankment. This road is part of the suburban system of the Southern Pacific Co. terminating in Oakland, Cal. The dredging was done by The New York Dredging Co.

149. Wrecking.—At least some part of the work of clearing up wrecks falls to the track department, while on some roads the entire work of clearing the line for traffic and picking up the wreckage is placed in charge of the roadmaster or other track officer. In the organization of wrecking crews the most common practice seems to favor the plan of selecting the nucleus of the crew from men working around division headquarters, such as machinists and repair men from the locomotive and car shops, car inspectors, roundhouse employees and trackmen working in the yards. These men are within easy call during working hours, and their places of residence are known at the train dispatcher's office, so that at night or when off duty, they may be quickly called into service by messenger. Men who work at repairing rolling stock are familiar with the use of jacks, ropes and tackle and, having experience in placing crippled cars in running order, are usually given charge of the derrick car and jacks. The balance of the crew is usually made up of work-train hands or section men picked up by the wrecking train on its way to the scene of the wreck. As outlined thus far the organization may be considered applicable to railways generally, the respect in which custom varies with different roads being in the matter of supervision. As bosses, big and little, are nearly always on hand in good numbers at a wreck, there is never any lack of authority, and it is therefore important that an understanding be had as to who shall have the direction of affairs. Two systems are recognized: one in which the roadmaster takes charge and handles the bulk of the work with the track forces, the men from the shops then being employed as experts at stripping locomotives and looking more particularly to getting the rolling stock into running condition, so far as may be. By the other system the mechanical department is placed in authority, the master mechanic or one of his assistants being placed in charge as wreckmaster. In any case the track forces must look after placing the track in repair and all the "dirty" work, such as the handling of freight, lugging blocking, heavy tools and tackle, sinking dead men, etc. It would hardly be possible to clear away a bad wreck in good season without the aid of the track department.

The plan of placing the track department in full charge of the wrecking operations is perhaps more usually the case on roads where a work train is constantly employed. Under this arrangement the foreman of the work train usually takes charge until the roadmaster arrives. The work-train crew is more at home out on the road in all kinds of weather than are machinists and other workmen from the shops, and work-train crews of the old class soon become expert at handling heavy masses. Some of the work-train crews employed these days, however, would make but little headway at picking up wrecks—not even with the aid of a half dozen interpreters. The work of wrecking should never be incumbered by a confusion of tongues. Such labor can dig sewers and shovel ballast, but it cannot handle a wreck to any advantage. This much said in a general way, it may be well to mention various plans of organization for clearing wrecks, as carried out on a few of the principal roads of the country.

On the Southern Pacific road each division is provided with an outfit consisting of a derrick car, two tool cars and one camp or cooking car. This outfit is held at division headquarters in charge of the master car repairer, who has charge of handling all wrecks. The master mechanic also accompanies the outfit train when it becomes necessary to handle a wrecked engine. This outfit, with 10 or 12 men from the shops, is run special to the wreck as soon as it is reported, and additional force is picked up from the section gangs. There is also a telegraph outfit which is taken along and cut in, if the wreck is a bad one. It is frequently the case that two outfits are sent to one wreck; that is, should a serious wreck (one requiring some hours to clear) occur as much as 100 miles west of El Paso, one wrecking outfit is dispatched from Tucson and another from El Paso (312 miles east of Tucson), one outfit working at each end of the wreck.

On the Nebraska division of the Union Pacific R. R. there is, on the main line, one complete wrecking outfit stationed at Council Bluffs and a smaller one at North Platte. The outfit at Council Bluffs is equipped for the heaviest kind of work and has a regular force of one foreman and one assistant. When the outfit is idle it is taken care of by these two men; when in service, the extra force necessary is drawn from the shops and section gangs. Usually the same shop and track men are selected, on account of their familiarity with the work of handling wrecks. In extraordinary cases a large number of men are drawn, usually from the track forces. The outfit at North Platte is for lighter work and its working force generally consists of a few men taken from the shop at North Platte and from track men collected at the scene of the wreck. On the Wyoming division of the road there is a steam derrick car kept in readiness at the middle of the division, to facilitate getting it to any point quickly, and arrangements are made whereby an experienced wrecker is always with it. One man is sent along to look after tools, and three car repairers and six handy men accompany the car regularly. Extra men are drawn from the section crews. At district terminals there are hand derrick cars, with a regular force of car repairers who go out whenever it becomes necessary to pick up a pair of trucks or a small wreck. By a system of signals for calling out the men it is the aim to get started within 30 minutes after the wreck is reported.

On the Great Northern Ry. there is at most division points a regularly organized force consisting of a car foreman and several car repairers or rough carpenters—men who are handy with jacks and other tools—who are called upon for wrecking service. The balance of the force is drawn from the track. On the East Iowa division of the Chicago, Burlington & Quincy Ry. the wrecking crew is composed of round-house men and laborers. If the wreck is of considerable magnitude any force of men additional, track men, bridge men or other available help, is called upon. After the track is clear a force is selected to work with the wrecking outfit at picking up the wrecked cars. On the Atchison, Topeka & Santa Fe Ry. the wrecking crews work at track repairs at the division points where the wrecking cars are located. The number of men sent out is determined by the seriousness of the wreck and the damage done. If an engine is wrecked a machinist and helper from the shops are sent, but usually the car repairers, with their foreman, constitute the skilled labor of the crew. The roadmaster always goes to the wrecks and generally takes charge, unless the trainmaster or superintendent is present. On the Illinois Central R. R. the regularly organized wrecking crew consists of a foreman and six men, who take charge of the wrecking outfit. All of these men are employed in the car department at district terminals. Where engines are damaged and it is necessary to strip them a machinist is sent. The six regular men are used as follows: one man on the deck of the derrick car, one to each guy, one giving signals, one to make hitches and one attending to the line. The six men are used first in preparing each portion of the wreckage for the derrick, such as disconnecting brake rigging, taking out trucks, etc. In addition to this force a sufficient number of track laborers, with their foremen, are called to the place of the accident to transfer freight and assist the crew employed on the derrick car, the number of men so furnished depending upon the condition of the wreck.

Of roads entering Chicago the one best equipped for handling wrecks is probably the Chicago & Western Indiana R. R. This company has two large steam wrecking cars, one of 35 tons' capacity (Fig. 396) and the other of 45 tons (Fig. 395), and this outfit is available for any road entering the city of Chicago, whenever the wreck interferes with the traffic of the C. & W. I. road. These derrick cars in cold weather are fired up both night and day, in order to keep them from freezing and have them ready at a moment's notice; and locomotives with steam up are at all times available. The wrecking crew is composed principally of car repairers, the car foreman being foreman of the wrecking outfit. In day time the wrecking outfit can be got ready to move on 10 minutes' notice, but at night a somewhat longer time is consumed in calling the crew and getting it together. Besides the car repairmen noted there are two machinists—one running the engine and the other working the crane—who go with this wrecking outfit. As a matter of record, this crew in one year picked up 66 locomotives and 523 cars. Most of these wrecks interfered with the traffic on the C. & W. I. tracks, but whether the wrecks occur to the company's own trains or to foreign trains the outfit is sent immediately to the wreck to pick it up, and the bill for the work is sent the company responsible for the damage.

On the Allegheny division of the Erie R. R. the wrecking crew is organized from the shop forces under a wreckmaster. These men are generally engaged in doing labor around the shops, such as loading and unloading materials, handling scrap, etc., but with them are sent a sufficient number of skilled men from the repair yard. This force at the terminals is organized into gangs of four men each. When a derailment occurs the shop is immediately notified and advised as to about how many men are necessary. Callers are immediately given slips on which are shown the date, name of caller, time he receives the slip and the names of the men to be called, who live in the vicinity of the shops. This slip the caller returns to the shop with a record of the time each man was called. This system gives better satisfaction than the old way of calling the wrecking gang by whistle or bell, as the location of the men about the shops is known during daytime and they are expected to be at their homes at night. At the same time the shop is notified the yardmaster is notified, who calls the first crew ready to run the wrecking train. It is not found necessary to hold a crew (train crew) specially assigned to the wrecking train in readiness, as the time consumed in getting the wrecking train out of either terminal of this division averages only about 40 minutes, which includes the time required in securing orders, etc. A track force in sufficient number to repair the track and do the rough work of wrecking is notified and picked up en route. In every case of derailment where the wrecking crew is ordered the track supervisor on whose subdivision the derailment occurs goes on the train; also the division roadmaster, who looks after the general disposition of the track forces, and attends to the care of the merchandise, etc. The trainmaster also accompanies the wrecking train to attend to and care for the matters of transportation in connection with the derailed train and to order the movement of traffic at the wreck. The wreckmaster has entire charge of the wrecking forces and the clearing of the road, but the roadmaster and trainmaster, in their respective departments, are supposed to give him advice and assistance. The trainmaster is in authority and represents the superintendent in case he is not at the wreck.

On the Lehigh Valley R. R. the wrecking crews are made up of shop men in charge of one of the car shop foremen. On the Western division of the Fitchburg R. R. the wrecking operations are under the direction of the roadmaster, who mans the force from the work-train crew. In case an engine is in the wreck the machine shop is called upon for machinists to accompany the crew. On the Atlantic Coast Line the shops are drawn upon for forces to handle the derrick and jacks. A representative of the track department accompanies the train and furnishes any additional labor that may be necessary. On the Pennsylvania R. R. wrecks are handled by the division work trains, the work-train foreman or supervisor being in charge of all the details of the wrecking operations. On the New York, New Haven & Hartford R. R. the wrecking crew ordinarily consists of 15 or 18 men taken from the locomotive and car shops, the foreman being one of the erecting foremen in the locomotive machine shops. This crew is increased, when necessary, by details from the regular track force, to do the rough work. The train, including a steam derrick car, a car loaded with trucks, a car loaded with blocking, tool car and locomotive, is always kept in readiness on a side-track. One of the spare engines from the roundhouse is run out to the train and stands on side-track instead of in the house until it goes out on its next run, when its place on side-track is taken by another locomotive. The engine number is always known by the dispatcher, which arrangement avoids delay in getting the train orders ready, and during working hours the train is frequently off within two or three minutes after receipt of the notice of a wreck. Steam is kept up in the boiler of the derrick car, the fire being looked after by the roundhouse men. The signals for calling the men to the train are given by air whistle in the shops and by a large bell rung by compressed air in the roundhouse, both being operated by the telegraph operator in the master mechanic's office. When these signals are sounded throughout the works the members of the crew are supposed to drop everything and make for the train on the run. The total cost of maintaining the equipment in readiness to start is $3.15 per day. This estimate does not include a charge for the locomotive, because one is selected which would ordinarily stand in the house, so that no locomotive is kept out of service on this account. The system of keeping a locomotive standing coupled to the train with steam up is also in practice on other roads.

Wrecking Tools.—The first thing to look to by way of preparation for such sudden emergencies as train wrecks is a sufficient supply of efficient tools. The list of tools needed is a long one. They may not all be serviceable at any one time, but will always be appreciated when they are needed. It is altogether probable that no road, or but few roads, at the most, would use a selection of tools as large as that in the following list. The intention is to present a list that includes typical selections of the various kinds of tools, most, if not all, of which are in use on a considerable number of roads. In the line of jacks the usual selection is four 30-ton and two 20-ton hydraulic jacks, both crown and toe lift; two 8-in., two 12-in., four 18-in and four 24-in. screw jacks; a pair of Pearson jacks. Hydraulic jacks of 10 or 15 tons' capacity are frequently included, but four 10-ton ratchet track jacks may be substituted for the light lifting.

In looking over the wrecking outfits of half a dozen different roads picked at random it is seldom that the ropes of corresponding diameter will be found of the same length, or even approximately so. Rope 3-ins. in diameter is the largest in general service, one or more pieces of good length being usually furnished for heavy pulling through snatch blocks, although rope of this size is sometimes carried in pieces as long as 600 ft. or longer for block and tackle work. For heavy block and tackle work 2½-in. rope is generally standard, being used in lengths of 800 to 1500 ft. For lighter work of this kind 2-in., 1¾-in. and 1½-in. ropes are used, all three sizes being frequently found in the same outfit. For hand lines 1-in. rope is preferable to 1¼-in. or ¾-in. sizes, for general service, although all these sizes are sometimes found in the same outfit. Switch ropes of 5 ins. diameter are sometimes carried, but wire rope of equivalent strength is to be preferred. The following might be taken as a fairly representative equipment of wrecking ropes, specifications usually calling for No. 1 manila: One piece of 3-in. rope 300 ft. long, with one double and one triple pulley block and three snatch blocks; two pieces of 3-in. rope, one 80 ft. and one 125 ft. long; one piece of 2½-in. rope 1200 ft. long, with one triple and one quadruple pulley block and three snatch blocks; one piece of 2½-in. rope 500 ft. long, with one double and one triple pulley block; one piece of 1¾-in. rope 500 ft. long and another piece 300 ft. long, with two double and two triple pulley blocks and three snatch blocks; one piece of 1-in. rope 500 ft. long, one piece 300 ft. long, one piece 175 ft. long and one piece 100 ft. long, with two double and two triple pulley blocks and three snatch blocks; one piece of ¾-in. rope 500 ft. long, with two single blocks and one snatch block, to be cut into lengths as needed. Four-strand rope is more evenly round than 3-strand and is preferable for use in tackle blocks. For convenience of reeving the long ropes in blocks, both ends of the same should be free, and tapered and marled, but ropes larger than 1-in. diameter and as short as 100 ft. or less may have one end spliced to a link and the other end to a hook. This arrangement is preferable to splicing on a link at both ends, as the hook can be attached to a link if the latter is needed at both ends. Iron blocks are preferable to wooden ones and, to reduce the weight of the large blocks as far as possible without sacrificing strength, they should have shackles instead of hooks.

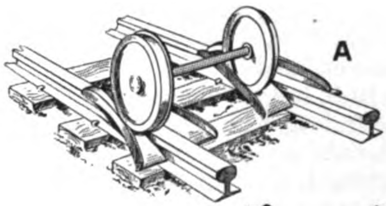
The rope list would also include about three slings of 2½-in. rope, each 12 ft. long; 4 slings of 1¾-in. rope, two 6 ft. long and two 12 ft. long; 4 slings of 1-in. rope, two 6 ft. long and two 12 ft. long; 4 slings of 1¼-in. wire rope, each 16 ft. long; four pieces of 1-in. steel wire guy line, each 175 ft. long; one 1¼-in. steel hoisting cable for switch rope, 125 ft. long, having one end spliced to a link and the other end to 10 ft. of 1-in. crane chain with hook on one end and ring on the other. The wire ropes should be spliced around a thimble at each end. There should also be a steel wire switch rope 30 ft. long, one 50 ft. long and another 80 ft. long, the ends of each spliced to hook and link. The manila switch rope will be needed where a snatch block has to be used and the steel wire ropes for straight pulling. Steel wire rope weighs only about half as much as hemp rope of equal strength, and as it does not absorb water and get soggy like hemp rope, it is better for use in wet weather.

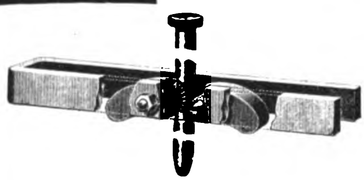
In chains there should be four best charcoal iron 1-in. crane chains, each 20 ft. long and having a 1¾-in. iron ring of 4 ins. clear diameter, on one end, and a hook on the other end; one ⅞-in. car chain 40 ft. long and six 16 ft. long, with hooks and rings; six ¾-in. log chains, each 16 ft. long, and two 10 ft. long, each having a 1½-in. iron ring of 4 ins. clear diameter, on one end and hook on the other end; six ⅝-in chains each 16 ft. long, and two 10 ft. long, with hooks and rings; one 1¼-in. chain 24 ft. long and another 16 ft. long, with ring and hook of suitable size. For hoisting purposes chain with links not to exceed ¾ in. diam. are preferable. Then what is lacking in strength of chain from links of small size can be made up by increasing the number of parts in the tackle. Hooks to hitch to the links of a chain are made diamond shape in section, with jaws open just enough to admit the link edgewise. A double hook of this kind is convenient for temporarily joining pieces of chain or for splicing broken chain. There should be clevises for all the chains; a supply of cold shuts for quickly mending broken chain, and some bulge links, part having a link attached and part without; two L-hooks for catching hold of car sills; four double or S-hooks, made of 2-in. iron, and two of 3-in. iron; six links 18 ins. to 30 ins. in length made of 1½-in. iron; four pairs of rerailing frogs; four wrecking inclines; four iron dollies, with rollers 6 ins. in diameter; eight steel rollers, each 4 ins. diameter, 15 ins. long.

Excepting hand car, push car, brush hooks, rake, grass and brush scythes and snaths, and wheelbarrows, there should be a full set of track tools, as per list given for a section crew in § 116, Chap. IX, increased by about 12 pinch bars, 3 axes, 18 shovels, 2 claw bars, 12 track chisels, 2 track wrenches, 4 spike hammers, 1 cross-cut saw, one 16-lb sledge, 6 picks, 3 peavies, 3 cant hooks, 2 kegs of track spikes, some angle bars and track bolts, 2 red and 4 white lanterns and a portable rail saw. There should be a chest of carpenter's tools commonly used in rough work, such as hand and rip saws, hammer, square, brace and full set of bits; one 2-in., one 1½-in. and one 1-in. hand auger; drawing knife, hatchet, mallet and chisel; keg of 60d wire spikes; lot of 40d, 20d, 10d, 8d and 6d wire nails.

There should be a set of machinist's hand tools, including a good assortment of monkey wrenches—say two each of 6, 8, 12, 18 and 24 ins.; also one large, one medium and one small-sized pipe wrench, and an alligator pipe wrench. There should be a set of blacksmith's hand tools, anvil, portable hand forge and fuel and a 6-in. vise. The forge and anvil can be set up on the ground beside the tool car, or on a flat car at the end of it. They are found to be very useful sometimes. There should also be included a drill press, a set of taps and dies, a few bars of round iron of different sizes, a strip of ⅜-in. iron plate and a good assortment of files. The drill press should be kept set up against a post attached to the side of the car, inside. It can easily be taken down and lag-bolted to a post or telegraph pole or other object outside the car, if there is not room to use it within.

There should be a sack of linemen's tools, including climbers; a portable telegraph set, mounted in some convenient manner; 200 ft. of flexible insulated wire; 2 coils of No. 6 galvanized iron wire; a tent and poles for telegraph office; a small "A" tent with poles, to use for a water closet, if the locality of the wreck requires it; and a railroad velocipede. And then there should be a set of car repairer's tools, with a supply of center pins, center plates, side bearings, journal bearings, a few drawheads, couplers and three-link couplings, and some extra air brake hose; a wheel gage; a quantity of ordinary sizes of bolts, short and long; a quantity of waste and car oil, packing hook and knife; a barrel of kerosene oil; one 2-gal. can of signal oil; one 2-gal. can of machine oil, and a few oilers; and perhaps several other articles which a car inspector might think necessary to have in such an emergency.





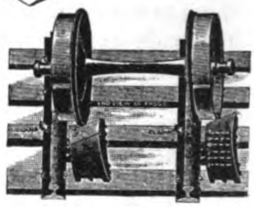


Fig. 380.—Buckeye Torch. **Fig. 381.** **Fig. 382.—Tilden Frog.**

There should be 24 oiled suits for the men to use in case of rain; and hip rubber boots for wading in water—say 6 pairs of No. 8 and 6 pairs of No. 10. A flat-bottom boat is also very useful sometimes at wrecks, and might be taken along. On some roads two or three dozen umbrellas are carried in the tool car for use in transferring passengers around a wreck in wet weather. For use in extinguishing fire there should be two empty oil barrels, 40 strong galvanized water buckets, a few lengths of 2-in. hose, with couplings and nozzle. For use in handling freight there should be 100 jute grain sacks, 20 grain baskets; a half dozen tarpaulins, 24x30 ft., for protecting freight from rain; a dozen hay-bale hooks and six pairs of ice tongs.

For work at night there should be about 20 hand torches and two pot torches. The way to place torches at desirable points around a wreck is to drive stakes into the ground and fix the torches on the stakes. Oil-spray lights, like the Wells or Buckeye portable torches, are commonly used in wrecking work at night. These torches (Fig. 380) consist of a tank, a hand pressure pump attached thereto, and a burner standing about 6 ft. high on the end of a pipe which enters the tank. The No. 3 torch has an 18x24-in. tank, holding 15 gals. of oil besides the necessary air space. The weight when empty is 110 lbs. and when full, 245 lbs. This size burns 1 gal. of kerosene per hour and produces a light of 2000 candle power. The pressure is pumped at intervals of three or four hours. The burner is first heated by burning a little oil in the pan underneath, and the light is produced by passing the oil through this heated burner, where it becomes vaporized and issues in a white, smokeless flame 30 ins. long, which is not affected by wind or rain. Two or three of these lights are usually carried in each wrecking outfit. Old locomotive headlights are also serviceable for night work at wrecks. They are used to best advantage if placed some distance away and set so as to throw the light on parts of the wreck from different directions, so that the men engaged will not have to work in their own shadow. A bonfire may also be used to good advantage for light, especially on a side hill, and in cold weather it is needed for limbering up the men's fingers, benumbed by cold. The wreckage will oftentimes supply the fuel. For lighting purposes at wrecks some roads keep on hand three or four car-loads of cord wood or rubbish cut up into cord-wood length. The lighting power of a bonfire which does not burn up quickly enough may be "assisted" by throwing on some rosin. The Pennsylvania R. R. has a car fitted up with a boiler, engine and 10-light dynamo, with a crew of four linemen to string wires and set lights for use at wrecks. The lights (arc lights) are suspended from tripods placed here and there about the wreck, and mounted on top of the car there is a search light. On a road like this, where there are four tracks on the main line, there are facilities for holding such a car at a wreck which cannot be had on single and double-track roads. It would be practicable, however, to carry a set of storage batteries ready charged for lighting purposes. These might be arranged under the derrick car or on the tool car.

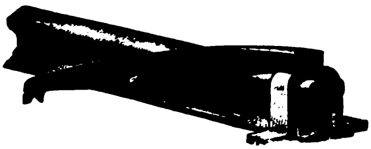

Fig. 383.—Wrecking Frog.

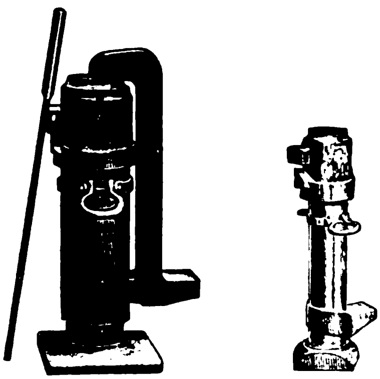

Fig. 384.—Toe-Lifting Jacks.

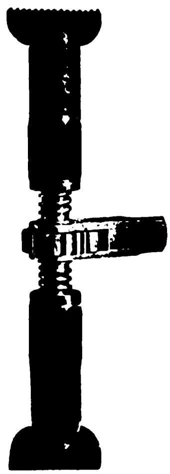

Fig. 385.—Pearson Jack.

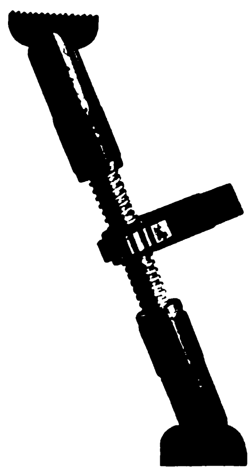

Fig. 386.

Toe lifting with hydraulic jacks, for applying the lifting force near the ground, is accomplished by either of two different arrangements, as shown on the Watson-Stillman jacks in Fig. 384. The jack shown at the right of the figure has a stationary claw cast solid with the lifting cylinder. The jack shown at the left has an independent claw, detachable from the jack, so that it need not be used when there is no toe lifting to be done. Hydraulic jacks of 20 tons' capacity weigh 200 to 225 lbs. and 30-ton jacks weigh 280 to 300 lbs. In wrecking it is frequently a matter of convenience to set jacks canting, so as to lift and carry at the same time. Ordinary jacks are not well adapted for this sort of work, since when the jack tilts over the bearing comes entirely upon one side of the base and is liable to crack or break it. The Pearson jack, shown as Figs.385 and 386, is made expressly for this kind of work. The jack is composed of five principal pieces, the central one of which is a screw, either provided with a ratchet or formed into a hexagonal nut at the middle, with holes for bars. The screw turns within threaded pieces of hollow cast iron, which are provided with swiveling foot and head, forming the bearing parts or shoes. The outer portions of the shoes are serrated for the purpose of obtaining a good hold upon blocking and car timbers. The 25-ton jack of this type weighs 85 lbs. This jack is a convenient device for placing derailed cars upon the track. Two jacks are used under the end of the car, the general arrangement being to set both jacks to lean in the direction in which the car is to be moved. If the derailed car is near the rails it is hoisted until the treads of the wheels inside the track and the flanges of the wheels outside the track just clear the rails. The truck will then adjust itself to the rails, the flanges of the wheels inside the track preventing

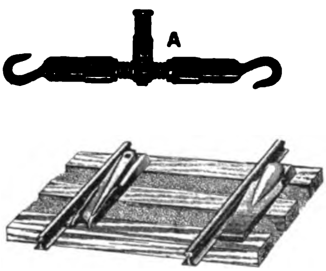

Fig. 387.—Snow Wrecking Frogs.

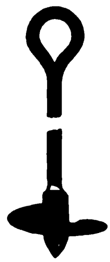

Fig. 387 B.

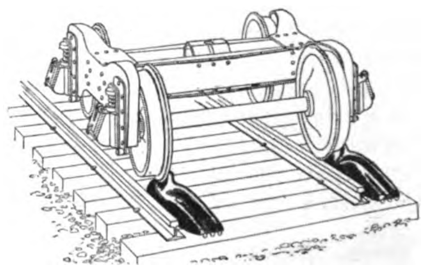

Fig. 388.—Alexander Wrecking Frog.

the truck from swinging over too far. If the derailed car is some distance from the track it is replaced by jacking one end at a time, shifting the car sidewise by swinging first one end and then the other over toward the track. In order to have the truck lift with the car it is necessary to secure it in some way to the car body. One way to do this is to chain it fast, either by taking up on the safety chains or by passing a chain over the top of the car or through the car floor. For passenger cars the practice of cutting through the car floor is, of course, objectionable. A device which obviates the use of chains is the Pearson king-bolt clamp (Fig. 381). It consists essentially of a strong bar bent double, to hold two pawls or knuckles for engaging the king-bolt under the truck bolster. As the car body is lifted the clamp holds fast to the king-bolt and the truck is lifted with the car, and, if necessary, may be swung around to its proper position on the track. Engraving *A*, over Fig. 387, shows the Pearson ratchet pulling jack, which is used where a short and powerful pull is required, as in bringing joints and connections together.

A wrecking frog is an incline of some sort for carrying a derailed wheel to the level of the top of the rail, at the same time shifting it laterally to take position on the rail. There are numerous forms of wrecking frogs, "rerailing frogs" or "car replacers," as they are variously called, and several of them are patented. About the oldest pattern, and one that is very commonly used, is illustrated as Fig. 383. It consists of a heavy bar pivoted at one end to an inverted, flanged U-strap which straddles the rail and holds the bar in position for leading the wheel onto the rail. The free end is formed into a claw for fastening to a tie. The device is used in pairs—one for each rail—and in light work gives fairly good service, but under heavy locomotives or heavily loaded cars the incline bar will bend and fail to do its work satisfactorily. Among the best known wrecking frogs or replacers are the Alexander, the Snow and the Tilden. The Alexander replacer (Fig. 388) is made of pressed steel ½ in. thick. The weight per pair is 140 to 150 lbs., the latter corresponding to rails higher than 5⅛ ins. The higher replacer of the pair is placed on the outside of the rail, and as the wheel that is derailed inside the track is lifted to top of rail the outside replacer lifts the flange of its wheel over the rail. The Snow replacers (Fig. 387) consist of a pair of inclines of dissimilar design. The inside replacer has a switch tongue which enables it to be used either right or left. At the top end of the incline on the outside replacer there is an elongated cone which crowds the wheel far enough laterally to carry its flange over the rail. On both these replacers the wheels bear on the treads, thus obviating any danger of breaking the flanges. The replacers may be laid at an angle with the rails, and when the wheels are off the ties, leads of rails can be used to carry the wheels to the replacers. As the maximum hight of the replacers is at the end, the incline is gradual, so that a locomotive can pull herself up without assistance. These replacers are made in varying weights, of cast steel for steam roads and of mallea-

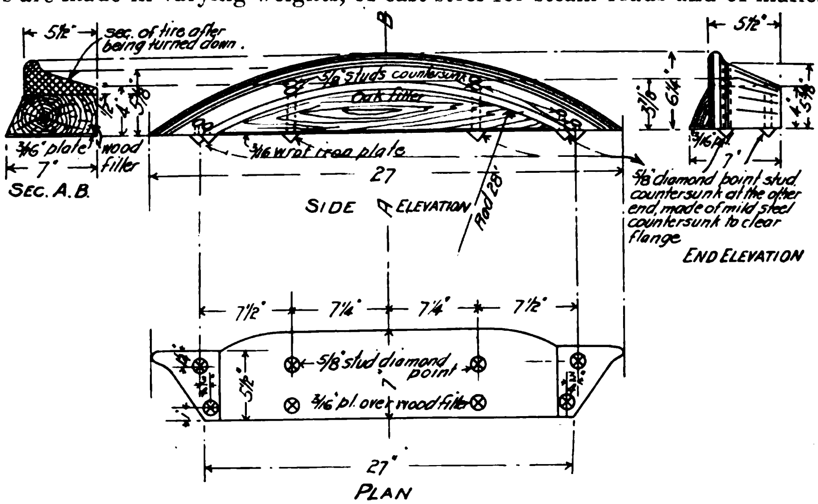

Fig. 389.—The Burlington Replacer.

ble iron for logging and electric roads. The Tilden replacer (Fig. 382) consists of a pair of segmental castings with the tops inclining transversely, so that when the wheels are lifted up they slide onto the rails. To hold the frog to its place there is a clamp fitting to the base of the rail. The Johnson wrecking frog (Engraving *A*, over Fig. 382) consists of an incline casting which straddles the rail, with ribs at the edges to guide the wheel toward the rail. In rerailing wheels a pair of frogs is used, as shown in the illustration. An obvious advantage with this frog is that it cannot slip out from under the wheel when the load comes on. The standard rerailing device of the Chicago, Burlington & Quincy Ry. is made from a segment of an old locomotive driving wheel tire, in its natural shape, with the tread beveled and the flange somewhat turned down, as shown in Fig. 389. This piece of tire is filled on the concave side with oak wood protected on the bottom by a piece of scrap tank iron, fastened with ⅝-in. steel rivets with countersunk heads and diamond points projecting ¾ in. as spurs to prevent slipping on the ties. It is made in two sizes, the smaller being 27 ins. and the larger 32 ins. in length. It was designed by Mr.

Henry Miller, while asst. superintendent of the St. Louis, Keokuk & Northwestern R. R. Heavy oak wedges about 3 to 4 ft. in length, faced with iron plates, commonly known as "wrecking inclines," are useful in lifting derailed wheels to the top of the rail, and should be included in the wrecking outfit. The bottom plate has spurs to prevent sliding on the ties.

All these tools should be stamped "Tool Car" and have besides some distinguishing mark easily seen. It is usual to paint part of the tool or its handle green or red. A skid is a useful thing to have for unloading heavy tools from the car, and it also comes handy in handling freight. The heaviest tools should be placed near the floor of the car, so as to avoid making it top-heavy. Hydraulic jacks should be kept standing upright. Such an outfit constitutes quite a little shop on wheels, but all these tools can be made use of, and besides the tool car is often needed at work other than wrecks. There are other tools which might be needed in case of a washout or bridge wreck, but most roads having numerous bridges have pile drivers and special cars fitted out with tools and appliances for bridge work.

It is money well invested to equip the traffic trains with a few wrecking appliances, as then in many cases of derailment they can help themselves and thus avoid the delay of waiting for a wreck train. Each engine should carry a pair of rerailing frogs and a pair of heavy screw jacks. Each freight caboose should carry a pair of rerailing frogs, a pair of journal jacks, a pair of 20-in. screw jacks, a pair of Pearson jacks, with king-bolt clamp; a ratchet track jack, a 3-in. switch rope 30-ft. long, with hook and link and snatch block; two $\frac{7}{8}$-in. wrecking chains, each 16 ft. long, with ring and hook; a 16-lb. sledge hammer, a machinist's hand hammer, two heavy cold chisels, a hand punch, an 18-in. monkey wrench, hand saw, pinch bar, claw bar, ax, spike hammer, two track chisels with handles, track wrench, two pairs of splices, some track spikes and bolts, some wire spikes and nails, a track shovel; a few pieces of 4x12-in. and 4x6-in. blocking, 30 ins. long, and a few pieces 2x8 ins. x18 ins. long. The heavy and bulky tools may be carried in a cellar suspended underneath the caboose.

One of the most important items of a wrecking outfit is the blocking. It may sometimes happen that but little blocking is needed at a wreck, but when it is needed in quantity it will usually be hard to find if it is not included in the regular list of wrecking appliances. Some blocking is always needed for jack footings, while on rough ground it is needed for cribbing and in soft places it comes handy for corduroying or for packing between ties. The best blocking for general purposes is sound white pine, since it is strong and light to handle, but old car and bridge timbers answer the purpose very well, and are extensively used. It is a wise provision to carry plenty of it; say 40 pieces 6x8 ins. x8 ft., 40 pieces 6x8 ins. x4 ft., 40 pieces 4x6 ins. x3 ft., 40 pieces 4x12x30 ins., 24 pieces 3x12 ins. x2 ft., 24 pieces 2x6 ins. x 2 ft., 24 pieces 1x6 ins. x2 ft., 20 oak wedges, 1x6x12 ins., and twenty 2x12x18 ins.; 1 bundle of shingles. The 6x8-in. pieces may be sawed track ties, of any light wood. There ought also to be two pieces of pine, 8x14 ins. x 15 ft., to be used as bolsters in jacking up car bodies; and 6 pieces of 7x16 ins. x3 ft. pine, or 6x14 ins. x3 ft., oak, to be used as rests for the heavy jacks. This blocking is most conveniently accessible if carried on a flat car provided with suspended side planks for steps, and with 2x2-in. strips spiked or bolted at the outside edge of the floor for grab-pieces. The blocking may be stacked up at one end, between side boards. On this car it is also well to carry six 30-ft. rails; 2 pieces of rail 12 ft. long and 4 pieces 16 to 20 ft. long, for skids;

a standard rigid frog, a set of switch points, and a ground-lever switch stand. For various purposes there might also be carried on this car several pieces each of 2x12 ins. x24 ft., 1x12 ins. x16 ft., 1x6 ins. x16 ft., 2x4 ins. x16 ft., rough lumber. On this car or on top of the tool car there should be carried a strong ladder, 30 ft long, and four short ladders which can be joined together with it. On bridge repair cars and painters' cars a long box is sometimes arranged on the roof for carrying the ladders. It is also a good plan to carry a gang plank and a runway, for transferring freight.

The wrecking outfit of the Northern Pacific Ry., at Tacoma, Wash., includes a double-deck car, designed by Mr. H. H. Warner, superintendent of shops, for carrying equipment which cannot conveniently be stored in an enclosed car, such as car trucks, rails, timbers, blocking, etc. As shown in Fig. 389 A, there is a flat car, with side stakes 8 or 9 ft. long well braced longitudinally. These stakes support the upper deck, which is about 62 ins. clear of the car floor. Of this space 40 ins. is set apart for car trucks and wheels, and 22 ins. immediately under the upper deck is used for storing long bridge timbers, etc., on rods through the stakes. Except for the stakes, the sides of the lower deck are open, but the upper deck is sided up. The lower deck is designed to carry three pairs of trucks and a pair of mounted

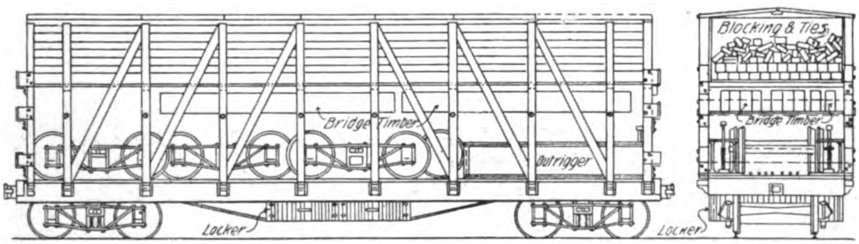

Fig. 389A—Wrecking Supply Car, Northern Pacific Ry.

wheels, on one end of the car, with the derrick car outrigging, rails, wheel skids, track levers, etc., in the center of the floor and at the sides of the trucks. The upper deck carries ties, assorted blocking, etc. Under the car there is a locker for storing small supplies, such as spikes, splice bars, track bolts, track and other tools. The respect in which the car is particularly convenient is that the appliances are arranged where they can be readily removed without having to handle over other material.

Tool Cars.—In order that wrecking tools may be readily accessible when they are wanted it is necessary to have systematically arranged tool cars. Many of the large railway systems go to considerable expense in fitting up tool cars, providing for the purpose cars mounted on passenger trucks, on the style of a baggage car and about the same size. An ordinary arrangement is to have two covered tool cars in the wrecking train, one of which is divided into two compartments—one being used for tools and the other, provided with seats and perhaps berths and kitchen accommodations also, for the regular wrecking crew. As an example of a wrecking train and equipment of the better class, reference may be made to some of the details of the outfit of the Chicago Terminal division of the Pennsylvania Lines West, omitting mention of many kinds of tools and appliances to be found in any up-to-date collection of the kind. The wrecking train consists of five cars as follows: one steam derrick car, one truck car, one "maintenance-of-way car," one block and tool car and one commissary and tool car. The truck car is an ordinary flat car carrying four heavy trucks, and an assortment of center plates, side bearings, Janney knuckles for couplers, etc., in the "possum belly" underneath the car. The maintenance-of-way car is an ordinary flat car carrying a quantity of rails, ties, spikes and other fastenings, split switches and frogs, with a full set of track tools in the "possum belly."

The block and tool car resembles a baggage car in exterior appearance, and carries a large quantity of blocking, together with a portion of the tools, including the ropes. The latter equipment includes 3-in. manila rope in lengths of 30, 300 and 600 ft., two pieces of 5-in. rope 35 ft. long, and two pieces of 2½-in. rope 300 ft. long (for block and tackle), all except the last two pieces having hooks and links spliced into the ends. For the 3-in. rope there are three large snatch blocks which are used in the place of tackle blocks, being considered more expeditious when it comes to arranging tackle. There are eight 10-ton Barrett lever jacks, a 20-ft. piece of chain made of 1-in. links, two sets of Tilden rerailing frogs, two tarpaulins 30 ft. square, a large canvas apron for transferring grain from cars, with eyelets for attaching to the sides of the door; two Wells lights, 30 hand torches, 6 Cox torches, each arranged to set upon a staff; 12 bushel baskets, 12 coke forks and 20 scoop shovels. The oils are stowed away in a separate closet. Figure 390 shows interior views taken from both ends of this car. The various pieces of hose used with a fire pump on the derrick car are disposed overhead. At one end of the car the racks extend half way to the roof, and on top of the same space is provided for a few bunks.

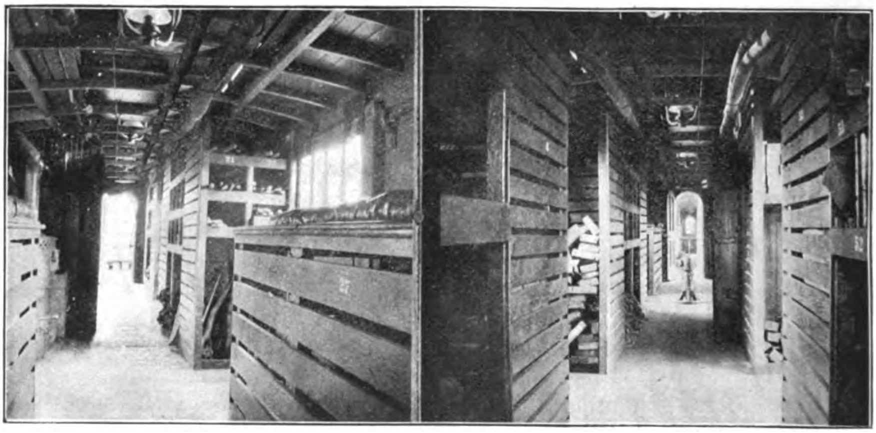

Fig. 390.—Interior Views of Blocking and Tool Car, Penna. Lines West.

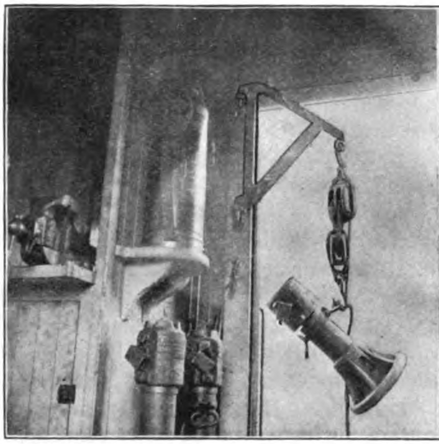
The combined commissary and tool car is of coach construction and is partitioned off into a kitchen at one end and a dining room and sleeping apartment at the other. In the kitchen there is a range, with pantry, ice box, dishes, cooking utensils, and the usual assortment of canned goods and other common provisions are carried in stock. In the sleeping room there are lower and upper single berths, with other berths located in various parts of the car, provision being made, altogether, for 16 men to sleep in the car. The upper berths have hair mattresses. Extra bedding is also carried for 16 men, consisting of a double woolen blanket, two sheets, a comforter and one pillow for each man. In the sleeping end of the car there is an office desk, and a dining table 5x6 ft. in size, as shown in Fig. 392. The tools and other appliances carried in this car include, among other wrecking appliances, a box of carpenter's tools, one hundred 2-bushel sacks, fusees, aprons and bibs for handling meat in case of wreck to a refrigerator car, white, red and blue lanterns, 12 axes, extra telegraph wire, a fence wire stretcher, two Babcock fire extinguishers and four 30-ton and two 20-ton hydraulic jacks. There is an ingenious device for passing the jacks to and from the car, consisting of a small crane attached to the door post and arranged to swing out of the car, as shown in Fig. 391. The jacks are hoisted or lowered by means of a small set of block and tackle. The arrangement is found to be very convenient and a means of saving time. One of the fire extinguishers and a vise appear also in the view, which is somewhat distorted, owing to the unfavorable position of the camera in cramped quarters. The train is provided with air brakes and air signals throughout. The wrecking crew consists of a wreckmaster, an assistant wreckmaster and an engineer for the steam derrick, assisted by a gang of nine men, who work in the shops and reside near by. These men are within call at all hours. During working hours in the shops the call for a wreck is three short blasts of the shop



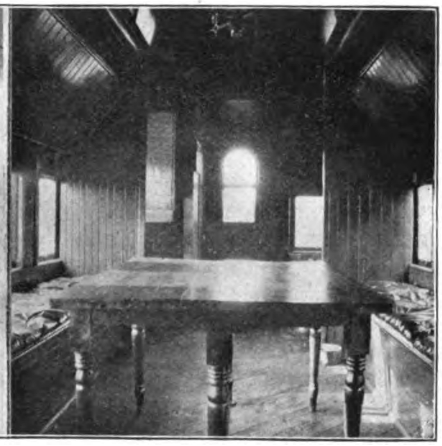


Fig. 391.—Crane for Handling Jacks. Fig. 392.—Dining and Sleeping Room. Commissary and Tool Car, Pennsylvania Lines West.

whistle. At night the men are called by an electric alarm system running around to the different homes. Ordinarily this crew handles all the work at wrecking, including slight repairs to the track. When the track is considerably damaged section men are picked up by the train en route to the wreck. In the commissary car there is carried a telegraph outfit neatly packed in a box, with wire and all facilities for setting it up at any point along the line. When running to a bad wreck the telegraph operator is taken from the nearest station and a telegraph office is set up at the wreck.

On small roads the tool car equipment is not usually as elaborate as the foregoing, and it is not necessary, for box cars can be fitted up quite as conveniently for the tools, and the work-train caboose can be used to carry the men. As a general thing the most extensive equipments are to be found with the larger roads, but the variety needed by the small road will be quite as large, if it should not contain so many pieces of each kind or so varied an assortment of each kind. The actual requirements of different roads may call for a different assortment of tools, in some respects, to suit special conditions, but in the main the list is about the same for all, so far as regards the most important tools or those most commonly used. In fitting out a box car for a tool car a large, new car, 34 ft. long inside, or longer, if possible, should be selected. The interior should have good light, which may be supplied by placing two windows in each side of the car, one on either side of the door, and a door in each end of the car with a window in the upper panel. There should be a cellar under the car, to hold rerailing frogs, chains, draw-heads, etc.; and a plank should be hung at each side of the car, under the door, to serve as a step, and convenient grab-irons should be provided for getting into and out of the car. Inside the car there should be hooks at the side, on which to string out the ropes; pegs for shovels, racks for bars, boxes and lockers for small and valuable tools, etc. There should be a flat-top heating stove well secured to the floor, some fuel, and a 6-gal. coffee pot; several packages of ground coffee, and a dozen tin cups for passing around hot coffee. There should also be a box properly lined for storing ice temporarily, which might be placed as a compartment of the cellar, underneath. There should be a small, heavy work bench with a 6-in, machinist's vise, and a good assortment of flat, quarter round, half round, and three-cornered files.

In one corner of the car there should be a closet or medicine chest under special lock and key. This closet should be supplied with a stock of medicines, instruments, bandages, stretchers, etc., such as any railroad surgeon can direct. It is desirable, however, to have an emergency chest containing such simple appliances as are usually administered in the way of "first aid to the injured," or when immediate professional assistance cannot be procured. The wrecking cars of the Cincinnati, New Orleans & Texas Pacific Ry. have ambulance chests fully equipped with muslin bandages, cotton (absorbent and carbonated), adhesive plaster, sponges, vaseline, tourniquet, scissors, and all the other necessaries for a complete emergency outfit, so that they can be readily available in case of need. With each chest are the following printed instructions for the information of the employees: "Arrest bleeding from wounds by pressure with a sponge moistened with cold or very hot water; if the loss of blood is considerable, apply the tourniquet. The pad of the latter must be applied to the inner side of the arm below the shoulder, in injuries of the arm; and to the front surface of the thigh, below the groin, in those of the leg. . . . . . . In small, clean-cut wounds, bring the edges together with strips of adhesive plaster; in wounds more than an inch in length, unite the edges with stitches. . . . . If the wound is ragged and torn, clean it as thoroughly as possible; then cover it with vaseline and a thick layer of cotton. Fix this dressing by applying a bandage as evenly as possible, and with moderate firmness. . . . . When a limb is evidently broken, place it in as natural a position as possible, until the local surgeon of the company can see the patient."

To carry the wrecking tools and appliances heretofore listed as essential to a complete outfit, at least two covered cars are necessary. Usually one car is needed for the ropes, jacks and chains. The most convenient place to carry track shovels, bars and spike hammers is in two large, strongly built and tightly covered boxes on a flat car. When box cars are used for tool cars the roofs of the same may be provided with flat racks for carrying the wire cables. The cables may be rolled up in large coils, and when carried aloft they should be securely tied in place. To keep them from rusting rapidly when thus exposed they may be painted.

The tool cars, with their contents, should be placed in charge of one man, who should have a list of everything in them, be accountable for everything leaving them, and, as far as possible, be expected to get everything back. He should live within easy reach of the car, and arrangements should be made to call him, either by day or by night, by an electric bell operated from the dispatcher's office. He should accompany the wrecking train on all occasions, and be provided with a cot or bunk so that he can stay with it; and provision should be made for some one to take his place in case of sickness. An ingenious blacksmith is the best man for such a position, because he can usually be given steady work about the company's headquarters, and time spent with the car can be considered part of his duties; and also because a blacksmith is always a handy man to have around any place where promiscuous work is going on. He should, after every occasion on which the tools are used, be allowed time to put the cars in order; repairing broken or bent tools; making requisition for those broken beyond repair, or for tools lost; washing dirty rope and splicing broken ones; cleaning and oiling tools, etc. The large blocks should be carefully examined after doing heavy service, taking them apart occasionally to inspect for bent pins, chipped sheaves or cracked strops. He should closely inspect the wrecking cars, including the derrick car, and see that the axle boxes are kept well oiled, so that they may stand a long, fast run without heating; in short he should have the cars, in every detail, always ready to go at a moment's notice.

The proper care of the large ropes requires considerable attention. They should be kept clean, and it is worth a good deal of pains to keep them free from oil, which greatly weakens rope. In order to have tackle overhaul freely the extra turns should be taken out of the new rope when it is uncoiled, and it should be rove with the lay. In using triple or quadruple blocks with tackle that is not liable to be pulled "block and block," the rope should be rove through the outside sheaves first and the middle or intermediate sheaves last. This arrangement crosses the ropes on one side of the tackle, but the hauling part of the tackle pulls directly on the center of the block and keeps it in line; whereas if passed through a side sheave it will cant the block with the first strain, and the ropes will not render freely. As it is sometimes necessary to lug tackle a considerable distance to a wreck, the best plan is perhaps to unreeve it each time it is put in the tool car and keep the blocks and rope separate. It is easier to carry in this shape, and, taking one time with another, more quickly rigged, than when carried around already rove. The ropes are also easier to clean, they will dry quicker after being wet, and the blocks are more accessible to inspection, if the tackle is unrove each time it is taken in from a wreck. Two good articles on the design of blocks and the rigging of tackle for wrecking purposes, by Mr. P. W. Hynes, of the Burlington, Cedar Rapids & Northern Ry., were published in the Railroad Gazette of Dec. 5 and 19, 1890.

Derrick Cars.—A wrecking outfit is never complete without a derrick car. Although its use is not always indispensable, scarcely no road can afford to be without one, because it can be used to much advantage in handling heavy objects generally. The lifting mechanism of a wrecking car is sometimes a derrick and sometimes a crane, but in common practice the distinction is overlooked and a car equipped with either machine is called a "derrick car." (The essential difference between a derrick and a crane is that the former is rigged with tackle for raising or lowering the boom, while in the latter the inclination of the boom, while lifting, is fixed.) The best derrick cars are made principally of steel. The frame of the car body is of steel I-beams or channels and the mast of the derrick (if a hand machine) is heavy riveted plate. As a means of increasing its stability the car is equipped with adjustable grappling hooks or tongs for fastening to the rail, and with car jacks for supporting the car under the side sills. The mast of a hand derrick car should be hollow and so arranged that a rope may be passed down through it, over pulleys, to be pulled by the locomotive, when convenient and desirable to do so. Steam derrick cars having a lifting capacity as high as 40 tons are extensively used, and are often made to lift a loaded box car bodily and swing it onto a flat car; and frequently a light locomotive is lifted bodily. Hand derricks are serviceable, but are slower of movement in lifting than steam derricks and are not made of nearly so large capacity, 15 tons being about the maximum.

The convenience of a derrick car depends a good deal upon the location of the derrick on the car. A derrick on one end of the car can reach farther over another car when loading than where the derrick is in the middle of a short car; but when it happens to come the wrong end to the work, it (the car) must first be turned around, thus frequently causing troublesome delay. Another advantage with the short car mounting a derrick in the middle is that pieces of the wreck, like a truck, for instance, may be lifted from the ground in front of the car and swung around and loaded upon a flat car in the rear; or in placing good trucks under wrecked car bodies, they may be taken from a flat car in rear of the derrick and swung around to the front. In either case the derrick has free action in front. The best form of hand machine is a car with a derrick on each end. It has the advantage of always having a derrick on the right end of the car, the lifting capacity of the two derricks can be united, and frequently both derricks can be used at the same time independently of each other. Hand derricks

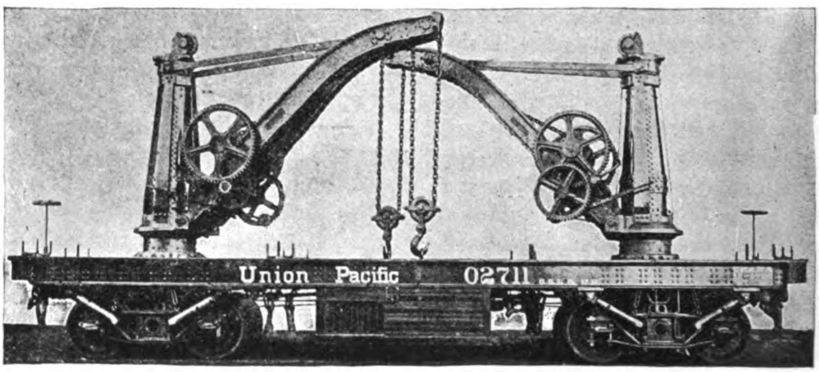

Fig. 393.—Hand Wrecking Car, Union Pacific R. R.

should have two speeds for lifting. The boom should be curved, so as to allow of more freedom of movement in turning objects lifted high, such as box cars, and its reach or radius should be at least 16 ft., and the lift at least 12 ft. above the rail. The lower block of the derrick should be heavy, so as to assist in overhauling the tackle, and at the same time short, so as to permit a maximum hoist for the hight of the boom. It should have a heavy swiveling hook. The stability of the car becomes less as the derrick works at a greater angle from the direction of the track. A beam or outrigger running out opposite the derrick mast and supported at its end by a jack or upon blocking, affords one means of increasing the stability of the car under a heavy side lift. The top of the mast should be provided with attachments for guy ropes, so that it may be stayed to surrounding objects when an extra heavy load is to be lifted.

Figure 393 is a view of a double-masted hand power wrecking car used on the Oregon Short Line branch of the Union Pacific R. R. (The standard wrecking cars of the main line are each equipped with a steam power derrick.) The car is 33 ft. long, 8½ ft. wide and weighs 69,235 lbs. The car frame is composed of four 12-in. I-beams and the masts of the cranes are constructed of rolled steel plates riveted together. The jibs are built up of steel channels and plates. The hoisting mechanism consists of spur gearing, arranged for two speeds in hoisting, and provided with an automatic brake which holds the load in any position and prevents the winch handles from flying back. The loads may be lowered by reversing the handles or releasing the brake. The capacity of each crane is 15 tons. When lifting on single gear the crank makes six revolutions to one of the drum and when on double gear, 11 revolutions to one revolution of the drum. The weight of the crane and machinery is carried by a series of steel balls upon the top of the crane post, and roller bearings are also provided at the base of the mast. Each crane is provided with a locomotive pulling attachment, for handling heavy loads rapidly, the rope passing over a sheave at the end of the jib, thence down through the mast and out under the car to the drawhead of the locomotive. There are four car jacks and four sets of rail tongs at each end of the car, and the car is air-braked. Under the middle of the car there is a cellar for carrying snatch blocks, ropes and chains.

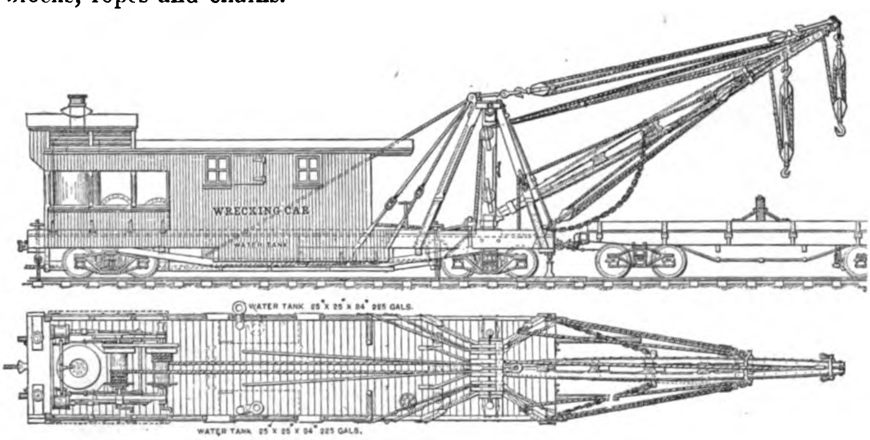

Fig 394.—Wrecking Car with Wooden Derrick.

Taking up steam wrecking cars in the order in which they were evolved, the first to receive attention are cars with wooden derricks, and such are still extensively in service and capable of doing heavy work. On general lines the car shown in Fig. 394 is typical of this style of construction, although certain details of the design are objectionable. The power consists of a double-cylinder engine with two drums, one of which works the tackle for raising and lowering the boom and the other the main lifting tackle suspended from the end of the boom. The tackle suspended at the shorter radius is worked by a locomotive line passed under the car deck at the foot of the mast and out under the rear of the car, as shown. Such is not generally used on a steam derrick car, but is drawn in the figure to show the arrangement for emergency and for derricks not operated by steam The car shown has a trussed boom, but a 12x12-in. stick of timber is frequently used for this purpose. For setting bridge material out ahead, a boom as long as 40 ft. is sometimes used, and on some roads as many as three booms of different lengths are carried with the car for various kinds of work. The boom is swung laterally by means of hand tackle anchored at the front corners of the car. The stability of the car in heavy side lifting is assisted by grappling tongs and body jacks, as shown. The front stiff-legs which brace the top of the mast, when arranged as shown, do not permit enough lateral swing for the boom, and in this respect the design is improper. These stiff-legs should brace the mast transversely with respect to the car, so as to permit the boom to swing to a right angle with the car. The sills of these cars are frequently built of steel I-beams or channels.

Figure 395 is a view showing one of the early types of steam wrecking car designed and built by the Industrial Works, of Bay City, Mich. It is in use on the Chicago & Western Indiana R. R., Great Northern Ry., Chicago & Eastern Illinois R. R. and other roads. The jib is a box girder constructed of plates and angles, and straddles a mast built as a Phoenix column. The forward end of the car is supported upon two locomotive trucks, the I-beams appearing just above the car floor, on either side of the mast, serving as equalizers. The jib radius for lifting is 24 ft. and the jib is supported cantilever fashion by two struts and two tension bars attached to a collar revolving about the mast. The inclination of the jib for lifting is fixed, but while in transit the jib is lowered to a horizontal position by slipping the pin holding it to the two tension bars. It is lowered or raised to or from the horizontal position by tackle operated by steam power. When in position for service the jib bears against the mast by a saddle about 4 ft. above

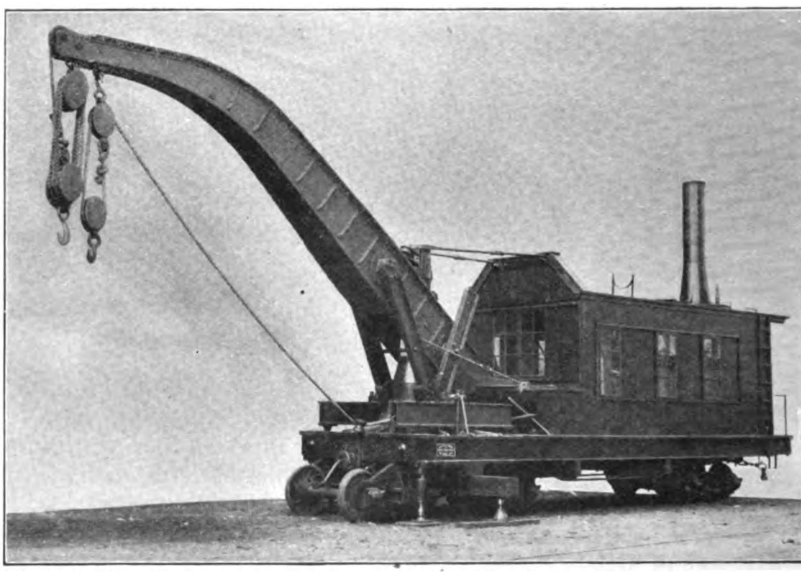

Fig. 395.—Steam Wrecking Car, Great Northern Ry.

the deck of the car. The lifting capacity of the crane is rated at 35 tons at a 24-ft. radius, but loads of 40 tons have been lifted by it repeatedly. The crane is turned by a pinion engaging with a segment gear at the lower end of the jib. The car is self propelling. The car body is of steel I-beam construction, and the total weight of car and machinery is 64 tons. Figure 396 shows an earlier form of this car, with the jib lowered into the horizontal position. With the exception of the jib, which is of tubular construction, of flanged and riveted steel boiler plate, the two cars are very similar. The plates of the jib are riveted to a heavy casting encircling the mast. The thickness of the plates varies from 5/8 in. at the casting to 3/8 in. at the end. Cars with this form of crane are in use on the Denver & Rio Grande, the Atchison, Topeka & Santa Fe, the Chicago & Northwestern, the Michigan Central, the Grand Trunk and other roads. The weight of the car (D. & R. G. R. R.) is 128,900 lbs.

An early design of steam wrecking car made by the Bucyrus Co., South

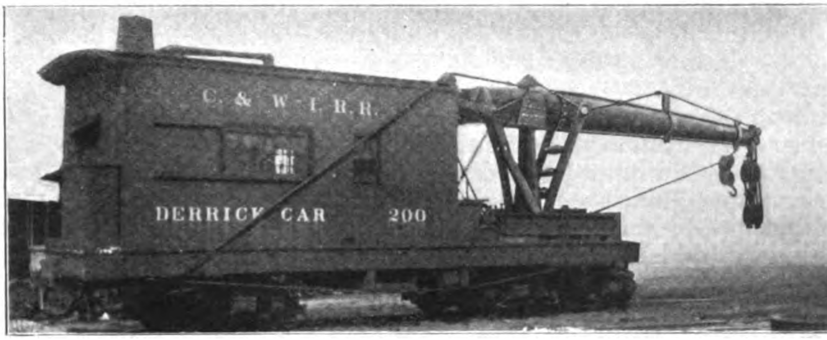

Fig. 396.—Steam Wrecking Car, Chicago & Western Indiana R. R.

Milwaukee, Wis., is shown in Fig. 397 in actual service. It is known as the "converted steam-shovel" type. It is carried on three heavy 4-wheel trucks, one at the rear and two at the front end, where the load is distributed from a center bearing on an equalizing frame between the car sills. The crane consists of a structural steel A-frame, pin connected, and a 33-ft. jib made of two 15-in. steel channels with cover plates, forming a solid box girder. The back guys and jib guys are solid steel eye bars, the latter (two) having a rear extension to provide for a pin connection with the A-frame when the jib is lowered to prepare for transit. The auxiliary equipment includes two removable winch heads, commonly called "nigger heads," for direct pulling independently of the main hoist, or for hauling the car along the track by warping. The jack arms, which are pin connected to the bottom member of the transverse A-frame and form a continuation of it, take the extra weight of loads lifted, and when not in service are folded up against the A-frame.

A more recent design of Bucyrus wrecker is the powerful machine illustrated in Fig. 397A. The lifting capacity is 100 tons on the 6-part hoist, 35 tons on the 2-part hoist at a radius of 30 ft., and 14 tons on the single-part hoist, same radius. The three hoists are ready for use at all times, and the single hook may be used simultaneously with either of the others. Loads may be lifted either by the hoists or by winding up on the boom. The end jack arms are pivoted at the upper corner of the car body and are balanced to swing out like a pendulum and remain in extended posi-

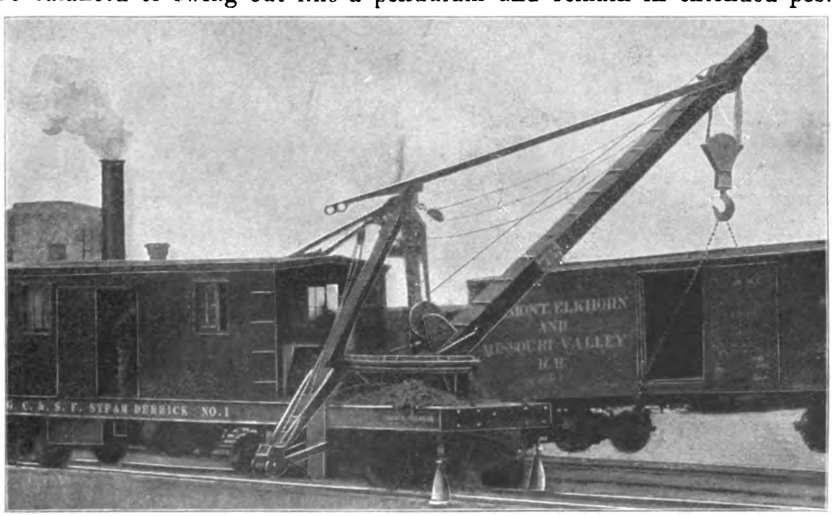

Fig. 397.—Steam Wrecking Car, Gulf, Colorado & Santa Fe Ry.

tion without being held. A bolt secures each arm in folded position during transit. The center jack arm is not used for loads under 60 tons at 16 ft. radius or 29 tons at 25 ft. radius. All the jack arms stand high and make room for substantial cribbing without digging. The car is 21 ft. long, permitting a load 8 ft. wide, at 16 ft. radius, to swing past the corner. The total weight of the car and machine is 87½ tons.

Figure 398 illustrates a type of modern derrick car, this design, on general lines, being standard with many of the large railway systems. The body of the car shown is of steel construction throughout, with longitudinal and transverse sills composed of 20-in. I-beams securely connected by plates and angles. The car is 24 ft. 1½ ins. long, 9½ ft. wide and runs upon trucks of especially heavy design with steel-tired wheels. Both air and hand brakes are provided. The engines are double, with cylinders 9x12 ins., fitted with link reversing motion. The hoisting is done with steel wire rope, but chain may be used for this purpose if desired. The raising or lowering of the boom, the hoisting, and the swinging of the derrick, are all accomplished by engine power. The radius of the boom ranges from 16 to 25 ft., and the extreme hight of lift (from the hook of the hoisting tackle to the rail) is 23 ft. On one end of the axle of the drum, outside its side bearings, there is a "nigger head" for hauling on loads direct. This car has three sets of outriggers, as follows: At each end of the car there are two telescopic steel I-beams 15 ins. deep, mounted on rollers carried by the plate brackets. These outriggers may be pulled 4 ft. beyond the side of the car, on either side, where they are supported on jacks with broad bases or upon blocking, as shown in the figure. In lifting loads up to 25 tons the end outriggers only are used, but for heavier loads there is a central outrigger of box section, formed of two 24-in. I-beams with cover plates, which extends to a distance of 10 ft from the center of the car. There are two of these, one for each side of the car, and being too long to be carried in position under

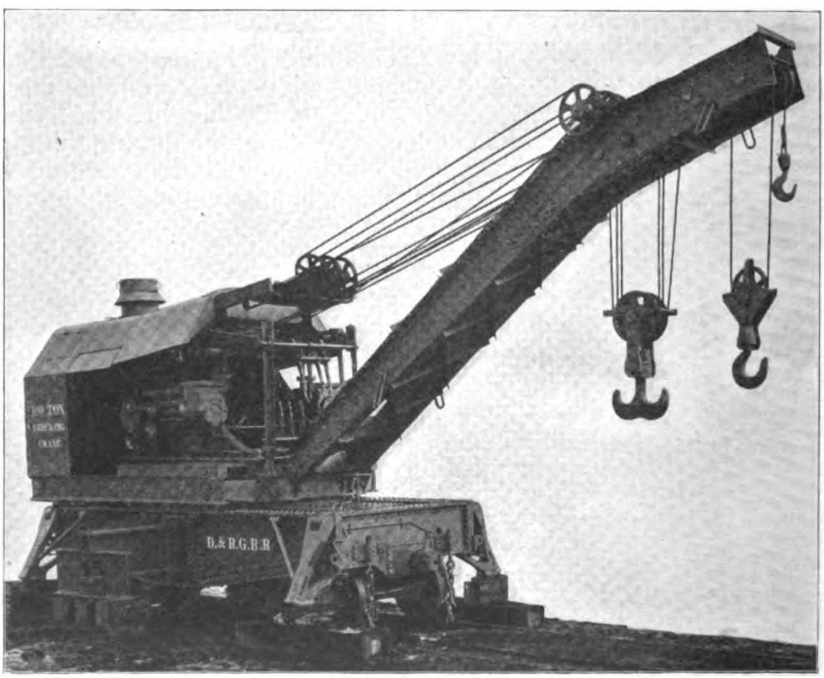

Fig. 397A—Steam Derrick Car of 100 Tons' Lifting Capacity, D. & R. G. R. R.

the middle of the car during transit, they are placed either upon the deck of the derrick car or upon the tool car, being easily swung to position by the derrick. The guide for these center outriggers is arranged in the form of a box with a removable cover plate at each end, so that it may be used as a tool box when the outriggers are not in place. The lifting capacity of the derrick, at a radius of 20 ft., with the outriggers in use, is 40 tons; at a radius of 25 ft., with the outriggers in use, 30 tons; at a radius of 16 ft., independent of the outriggers, 15 tons; at a radius of 20 ft., independent of the outriggers, 10 tons. In actual service these derrick cars frequently pick up one end of a 60-ton locomotive or lift a loaded box car or light locomotive bodily. The largest machines of this type are built upon heavier cars and have a lifting capacity of 100 tons. The engine is mounted in a heavy frame on a turntable with a circular rack, the boiler and water tank at the rear serving as a counterbalance for the boom. The turntable is at the middle of the car and the derrick can be swung through an entire circle with the load lifted. At each corner of the car there is a pair of heavy rail clamps.

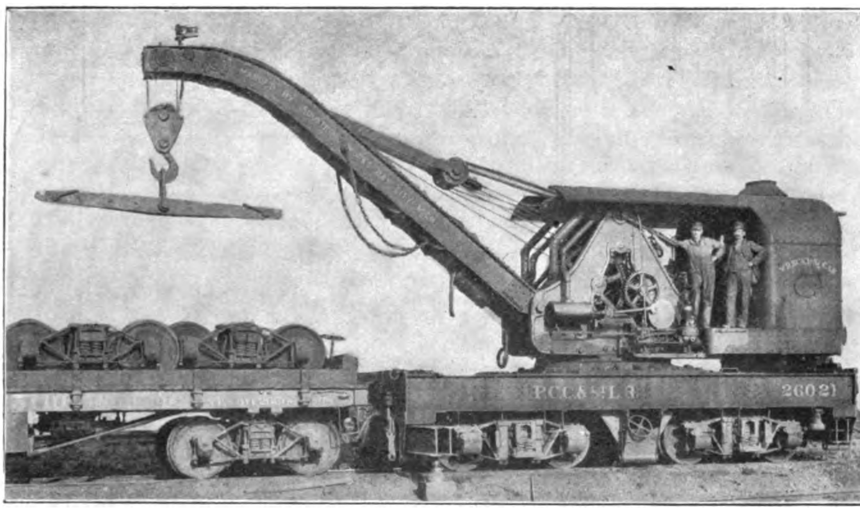

Fig. 398.—Steam Derrick Car, P., C., C. & St. L. Ry.

The particular derrick car shown in Fig. 398 was built by the Industrial Works for the Pittsburg, Cincinnati, Chicago & St. Louis Ry., and is in service on the Chicago Terminal division of the Pennsylvania Lines West. One of the interesting features in the equipment of this car is the provision for lighting when working at night, consisting of a Buckeye torch of 2500 candle power fixed at the end of the boom, and fed by a reservoir at the foot of the boom, as shown in the illustration. The pressure for the reservoir is pumped by machinery on the car. This arrangement fulfills a convenience which is much appreciated, as the light is always present in the direction in which the boom is working, it is out of the way, and is located so high that few if any things can intervene between it and the work to cut off the light. Another very useful auxiliary to the derrick car is a fire pump, arranged, as shown, just underneath the main hoisting engine of the derrick. This pump is provided with 125 ft. of 2½-in. wire-wrapped suction hose and 300 ft. of 1½-in. discharge hose. A novel feature of this part of the equipment is that the pump is detachable, and may be set up for duty temporarily at a distance of 125 ft. from the car, wire-wrapped steam hose of that length being provided to make the connection. As the pump can force a stream 90 ft. from the end of the hose, the radius of effective duty is more than 500 ft. The heavy horizontal bar hanging from the hoisting pulley of the derrick is known as the "singletree," and is used as a spreader when lifting a box car or locomotive, being placed over the top of the car or engine cab to prevent the chain from crushing in the sides. For lifting box cars two wire cables with L-hooks at the ends are attached to each end of the singletree and made fast under the side sills of the car. When the front end of a locomotive is lifted, cables are suspended from the singletree and fastened to the ends of the pilot beam; when a locomotive is lifted bodily the singletree stands parallel with the boiler. A particular advantage in the use of this device is that it divides the weight equally among the cables and hooks used in lifting the car or locomotive. All movements of the derrick when at work are controlled by bell signals given by a cord in the hands of the wrecking foreman.

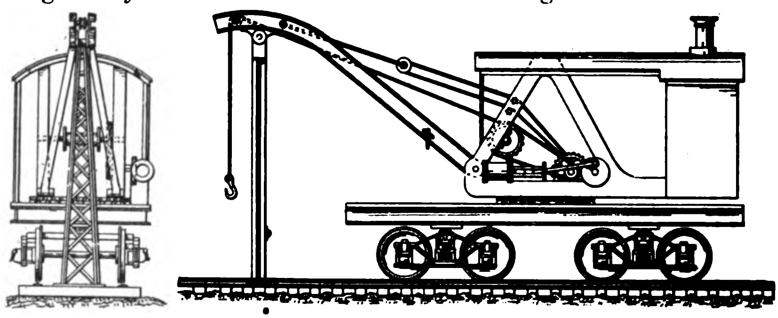

Fig. 399.—Stability Strut for Derrick Car, Norfolk & Western R. R.

On some roads a steam shovel is used for the wrecking car, the only change necessary to convert such a machine into a derrick car being the dropping or removal of the dipper, which, with some machines, can be quickly done. The hoisting capacity of some steam shovels is sufficient, of course, for ordinary wrecking purposes. The principal objection to the plan of depending upon a steam shovel for a wrecking car is the liability of delay. If the steam shovel is in service at the time it is needed at a wreck, the chances are that it will be found on an isolated piece of track or possibly at the far side of some gravel pit securely blocked in by 50 to 100 ballast cars put away for the night. Bridge erection derrick cars are very frequently called into service at wrecks.

To increase the stability of wrecking cars for very heavy lifting, especially for sidewise positions of the derrick, Mr. J. E. Graham, for some years wreckmaster of the Norfolk & Western R. R., designed and has used a bracing strut hinged to the boom of the derrick near the end, as illustrated in Fig. 399. The strut consists of two channel pieces diverging downwardly to a broad base plate which rests upon the track or blocking. These channels are cross braced, and when not in service the strut is folded up against the under side of the boom. When lifting is to be done that is beyond the capacity of the car with the ordinary stability supports, the strut is swung out and blocked up for the support of the boom. The strut is serviceable either for heavy straight pulling with the main hoisting tackle or for a heavy side lift. In either instance force may be applied to the full capacity of the hoisting engine and tackle without straining the derrick or car. Although the device cannot render assistance in cases where loads have to be lifted and swung, nevertheless there are many situations in which it should be useful; as, for instance, for quickly raising a locomotive into a more favorable position for blocking, or for rolling over a locomotive which has fallen upon its side, or for pulling on a locomotive straight away, with the main hoist.

Running to Wrecks.—The wreck train proper consists of a locomotive work-train caboose, tool cars and derrick car, and all should be air braked. These cars should stand on a side-track near the shops and where egress to main track cannot be blocked by other cars. Steam derrick cars are usually kept with a banked fire in the boiler, so that steam can be raised quickly. It is well to always have a car loaded with spare freight trucks, and another with about 20 rails and 200 ties, to take along, unless it is known before starting that such material will not be needed. On some roads the truck car is provided with a light hand crane for lifting the trucks to and from the car. This outfit consists of an ordinary flat car with the crane set in the middle of the car, the bottom of the mast being supported beneath the car floor, so that the car decking acts as a stay instead of guy ropes or rods. A locomotive truck is sometimes habitually carried on the truck car. The work-train kitchen and bunk cars and a cook should be taken along or sent out at first opportunity, because men called suddenly to go to a wreck do not always have time to get a good supply of lunch, and through excitement and hurry no attempt is usually made to provide anything to eat until the men are nearly famished; and then, owing perhaps to the remoteness of the locality or to misunderstanding, somewhere, it is sometimes not possible to get anything to eat for several hours longer. Many old trackmen know how it feels to work hard at a wreck for 12 hours or longer without anything to eat. When men get real hungry there is then something besides the company's interests which will engage their attention. Perhaps the safest way, under any circumstances, is to keep on hand in the tool car at all times a barrel of soda crackers or hardtack and a case of canned meat. As it sometimes takes several days to pick up a bad wreck, it is well to have the bunk car at the nearest side-track and to let the men have sleep, if needed, as soon as the track is cleared and put in running order. More profitable work can be done in this way than by working men completely out before giving them time to rest. The wrecking train can then remain at the wreck until everything is done, and waste no time running to and fro, if the distance to headquarters be considerable. Where it is seen that a long job is at hand the best method to pursue is to divide the men into day and night shifts, at the first.

When taking the first report of a wreck the train dispatcher should endeavor to get all the necessary information from the man giving the report; otherwise only a meager idea may be had of what is on hand. The matter of first importance is, of course, to ascertain whether any one has been killed, or injured seriously, and to what extent, so that medical assistance may be sent. At a bad passenger wreck it is best to send a surgeon whether injuries are reported or not, because a railroad company is often sued for injuries which are not made known on the spot. And it is best to send a company surgeon, because he understands the importance to the company of making thorough examination of the injuries at the first. The exact location of the wreck, the cause and time it happened; the length of track torn up or blocked; the condition of the locomotive, if wrecked, and its position and location with respect to the track; the number of cars off the track, in what condition, and with what loaded; the number of cars each side the derailed or wrecked ones; whether the derrick car is needed, and from which end it can work to best advantage; and what track material is needed, if any, are information that is indispensable to the train dispatcher. In case of double track the report should state particularly whether both tracks are blocked, and, if so, which one can be cleared first; or whether one track is clear, and which; and in any case whether there is a side-track through which trains may be got around the wreck. What trains, if any, are being held by the obstruction; what working forces have gathered at the wreck; what must be done to get the track clear; how many empty cars, and what kinds, are needed to hold the freight to be transferred, and such other information as circumstances may dictate should be ascertained and made known to the man in charge of the wreck train before he starts.

Some railways have a list of numbered questions covering all the information usually desired, arranged in the form of a blank report, and a supply of these blanks is kept on hand at all telegraph stations. In transmitting a report the operator then gives only the numbers of the questions and their answers. Some railway officials prefer that the first information of the wreck shall be a primary telegraphic report, stating briefly "what happened, where it happened, when it happened and what is needed." This enables the dispatcher to order out the wrecking train in the shortest time possible, and in the meanwhile the conductor of the wrecked train can think out a more complete report, which would likely be forwarded before the wrecking outfit would be ready to start and would probably cover more desired information than would be the case if he attempted to tell the whole story when first arriving.

The work train or wrecking crew, if at their homes, are usually called out by many long blasts of the locomotive whistle (thus arousing the whole neighborhood) or by messengers sent from house to house. In some cases where the organization of the crew has been carefully planned, the homes of the crew are connected with the dispatcher's office by electric bell or by telephone. If there is no crew organized, and the work train proceeds to the wreck during working hours, one may be made up by picking up the section men along the road, while on the way; or if after working hours, all available men at headquarters should be pressed in, and section men who can be reached by wire should be notified to get ready and flag the train when it comes, so that there shall be no needless stopping in anticipation of getting section men who fail to show up. Then if a sufficient force is not had by the time the wreck is reached, recruits should be brought on the first train following. If the work train is out on the road when the wreck occurs it is not usually advisable to have it first run a long distance back for the tool and derrick cars, but to send it (the work train) immediately to the scene of action and send the wrecking cars with a heavy engine to take the place of the other in case it be too light for the work, or to assist it. If a locomotive in the wreck is badly off the track both engines will be needed. It will frequently happen that in this way the work train, with the switch rope and the few other appliances which it always carries, will be able to have the track cleared before the wrecking outfit arrives. In this connection, also, the locomotive of the wrecked train, if able, should be set to work as soon as possible to clear main track; and section foremen should have the understanding that whenever they hear of a serious wreck within 10 miles they should go to it as soon as possible with hand car, men, and tools, without waiting for special orders.

Where the headquarters are at one end of the division this arrangement of wrecking with the work-train crew is no doubt as expeditious as any, because the train in daytime will always, if working, be in the direction of the wreck, and sometimes near by, so that by a little extra effort in some way, word can usually be got to it without much delay. At night the work-train crew, if at headquarters, can, of course, be called out as soon as any other crew, and in the same manner. If the work train was lying out on the road at night it could get off more quickly, for the crew would be with the train. For this reason the work train should lie over, with steam up, at a station where there is a night operator; or at any rate an operator should be sent to the station to remain during the night, if a night operator is not usually stationed there. Where, however, the headquarters are at some intermediate point of the division, a wrecking crew taken from the shops would probably be able to get to a wreck with less delay in most cases during daytime, and certainly so in any case where a work-train crew is not steadily employed. The wreck train should carry a telegraph operator, who is a lineman, who should tap the wires as soon as he arrives at the scene of the trouble, put himself in communication with the dispatcher, and keep him informed of the progress of the work, so that trains may be moved as soon as the track is clear. The best arrangement is to have this man employ his time with the crew, whether a telegraph office is needed at the wreck or not. In many instances this plan proves more satisfactory than that of taking an operator from a near-by station or even that of taking one along from headquarters when it is thought he might be needed. In any case the crew must necessarily include a lineman, or a man who is able to use pole climbers, as very few telegraph operators are likely to be found equal to such a task. The lineman of the wrecking force should make the necessary splices and put the line in its original condition after the wreck has been cleared up, thus saving the expense of sending a line repairer.

The use of the telephone on railroads affords a convenient and ready means of communication with division headquarters in time of wrecks. Some railway systems have telephone wires on the right of way along the main-line divisions and the more important branch lines. Where such a circuit is at hand the wrecking outfit should include a compact telephone set, which may be attached to a telegraph pole at the scene of the wreck, establishing direct means of communication with the dispatcher, the superintendent or with the signal towers at the ends of the block, as soon as connection is made with the circuit. On the New York, New Haven & Hartford R. R. use has been made of portable telephone instruments on such occasions.

At the last switch passed on the way to the wreck the locomotive should be shifted and the train approach the wreck made up in the following order: derrick car, truck car, blocking car, locomotive, tool cars. If the truck car has a crane of its own, or if the derrick of the wrecking car does not swing through a complete circle, the blocking car should then be coupled in next the derrick car. A flagman should be left at this switch and the track should be kept clear that far back. Empty cars taken along to be loaded with transferred freight should usually be left in a near-by side-track until they are needed. While switching, the men should get out such tools as will surely be needed—ropes, jacks, etc.—and place them on the derrick car. If the men work lively they can do this without holding the train much, if any. But such preparation might be made before, while running, in case the derrick car happens to be coupled next the tool cars. In the other direction from the wreck a flagman should be put out, and the locomotive of the first train arriving should be brought up to help clear the wreck from that side. Where oil tank cars have been wrecked and oil is lying around on the ground there is danger in running a locomotive or steam derrick car into the vicinity, and unless a good deal of caution is exercised there is liability of setting the whole wreck on fire. One way to do the work and still keep the locomotive away is to push the derrick car up to the wreck at the end of a string of cars. Oil lying exposed may be covered with dirt, and if work is to be done at night lanterns or closed lights should be substituted for hand torches. Although it is to be assumed that ordinary men would be cautious about handling lights in the presence of highly inflammable or explosive materials exposed in a wreck, it might be best in some cases of the kind to suspend night work altogether, especially if there is a clear track around the wreck. In all cases when beginning work at a wreck the wreckmaster should ascertain the character of all freight involved in the wreck, so that precautions may be taken in case there is danger of conflagration or explosion. Where oil cars are on fire or in danger of taking fire and cannot be got out of the way, the wrecking crew should endeavor to get everything movable out of reach as soon as possible, so as to prevent the fire from spreading.

Clearing and Picking Up Wrecks and Aid to the Injured.—The first duties of a train crew in time of a wreck are to see that signals are placed to protect other trains, to look after the injured, if there are any, and to protect the wreck from fire. Railway surgeons recommend that when a person is bleeding freely the limb or bleeding part should be elevated and the edges of the wound should be drawn together. A closely folded clean handkerchief may be applied to the wound and tied snugly, but some judgment must be exercised as to the time, or the bandage may be kept on too long. Cloths wrung out of hot water and applied to the bleeding part are a good means for stopping bleeding. When a person is suffering from shock the head should be kept low, on a level with the body, so that blood will flow easily to the brain. To keep the blood in circulation warmth should be applied to the body, and the hands and feet should be rubbed. A crushed or fractured limb should always be supported, and a temporary splint may be applied to prevent the broken bones from doing additional injury to the flesh. For transporting persons who are seriously injured, common passenger coaches are better than Pullman cars. The winding entrances of the latter are inconvenient for the passage of stretchers, making it necessary to handle the bodies by other means. The seats of ordinary day coaches are also easier to arrange for the reception of persons on stretchers, and they permit the injured to lie in better position for surgical aid.

Many railways have established schools or meetings wherein train and other employees are instructed in what is commonly known as "First Aid to the Injured," and in the use of emergency appliances for injured persons. On the Pittsburg & Lake Erie R. R., for example, the emergency box contains bandages, assorted sizes; sublimated gauze, rubber tourniquet, cotton, safety pins, etc.—enough to care for two or three injured persons. The folding stretcher contains two blankets and one rubber blanket, and four splints, assorted. Each caboose and each baggage car has a set of these supplies, and each station and telegraph office is similarly supplied. A small handbook has been issued to the men, and a circular has been placed in the hands of the men, entitled "Aid to Memory," an abstract of which is as follows:

First Aid Package.—For small wounds on any part of the body.

Gauze.—For large wounds.

Cotton.—To cover over on top of the gauze.

Rubber Band (Tourniquet).—To fasten around a limb or around the head to stop hemorrhage, particularly in case of crushed limb.

Adhesive Plaster.—To hold dressings, but never to be applied to an open wound.

Cotton Bandages.—To be used over first dressings where there is much bleeding.

Gauze Bandages.—To fasten splints in place and to support light dressings where there is no hemorrhage.

Safety Pins.—To fasten bandages, etc.

First—Don't give a drink of whisky.

Second—Don't pour ice or very cold water on wounds.

Third—The patient should be placed on his back, with head low, and this position should be continued in transporting.

Fourth—If the person is suffering from "shock," that is, pale with pinched expression of face, drooping eyelids and cold surface of body, with feeble pulse, give spoonfuls of hot tea or coffee; if this cannot be had, teaspoonful of whisky or some other alcoholic stimulant, in a tablespoonful of hot water every ten minutes until five or six doses have been taken. Wrap in a warm blanket and put hot water bottles or heated bricks about the body.

Fifth—Remove the clothing from the wounded part by cutting it away. Do not attempt to tear or draw clothing off, as this may further injure the wounded part. Always see the wound and know by your eye just what the nature of it is.

Sixth—If a limb is crushed or torn, apply over the wound a thick pad gauze, then a large covering or pad of cotton, fastened with several turns of the bandages, handkerchief or an elastic suspender.

Seventh—Hemorrhage. This follows shock and is very rarely severe unless reaction takes place. Too much stimulation increases hemorrhage, and for this reason it is best to give only a little stimulant, well warmed, and repeat the dose if reaction is delayed. Bleeding is of two kinds: First, arterial, when the blood comes out bright and red in spurts; second, venous, when the blood is dark and flows in an even stream. Avoid trying to stop bleeding by twisting cords or handkerchiefs around limbs with sticks. When the wound is large and blood comes out in spurts, apply the rubber band tightly just above the wound, previously raising the wounded member or part, especially if it be a limb. Be careful to put the band on uninjured flesh (if the limb be crushed) and about 3 ins. above the crushed tissues, else it will slip down and increase the hemorrhage. Be careful to see that the band be firmly hooked and fixed before leaving it. Small wounds, even though the hemorrhage be arterial, require only a firm compress of the sublimated gauze, placed immediately over the wound and bandage tightly in place with one of the muslin bandages. It is best after this to bandage firmly from the extremity of the hand or foot upward to beyond the wound with muslin bandages. Venous bleeding, which occurs when the wound is shallow (does not go deeper than the skin), as a rule, requires firm pressure over the wound, and especially below it. If the wound be quite small, put a pad of styptic cotton into it and over it and bandage tightly in place and then apply a bandage from below upward. If only the scalp is involved, it may also be controlled by drawing a rubber band around the head, encircling it just above the eyebrows. This is very painful, however, and unless the bleeding is severe, it may be controlled by bringing the wounded or torn surface together and applying along the wound a thick layer of styptic cotton, and over this another layer of absorbent cotton and a tight muslin bandage. It is well to pass the bandage under the chin if the wound be on top of the head, as this holds it firmer and tighter.

Eighth—After hemorrhage has been controlled apply gauze next to the open wound, always, and never let an open wound remain uncovered longer than is absolutely necessary to control the hemorrhage; but remember, a soiled or dirty covering is worse than none at all.

Ninth—If a leg or arm is broken, straighten it gently and lay on a pillow, then tie the pillow up with several strips of muslin, bandage or splints found in the stretcher. Laths or barrel staves, padded with some soft material, may be used for this purpose. This should be done before the injured person is moved any distance.

Tenth—Compound fractures are fractures accompanied by a wound of the soft tissues at the point of fracture, so that the bone is exposed to the air. In these cases treat hemorrhage and the wound according to the foregoing rules and then apply splints. If the bones project beyond the skin, remember to bring them back into place by pulling the extremity in the direction of the displacement until the ends of the fragments are quite free from over-riding. Remember to always cover these wounds with the sublimate gauze and bandage.

Eleventh—Burns. Carefully remove the clothing by cutting it off, if the part be clothed, and apply immediately three or four thicknesses of the sublimate gauze (dry or wet, in warm water in which one tablespoonful of the bicarbonate of soda to the quart has been dissolved). As a rule never attempt to clean burns immediately after they occur. Cover the wounded part immediately, as directed above, and leave the cleansing to the surgeon afterward. Extensive burns are attended with great shock, as a rule, and require free

stimulation. As the burns are rarely followed by hemorrhage, stimulants may be, and should be, given in considerable quantities.

Twelfth—Prostration from Excessive Heat.—In these cases (not sunstroke) the face is pale, lips colorless or blue, breathing slow, pulse slow and very weak. Place the patient on his back, with his head level with his body and loosen clothing. Apply heat to the surface of the body and extremities. Bathe the face with warm water into which a little whisky or alcohol has been poured, and if he can swallow, give the patient an ounce of whisky in as much water. When prostration is caused by drinking too much ice water when overheated, the face is red or even purple, breathing heavy and irregular, pulse irregular. Loosen clothing, place on back, with head slightly elevated. Give hot drinks, apply heat to the spine and the extremities.

Thirteenth—Position in Which a Person Should be Placed After Injury.—Injuries to the head require that the head be raised higher than the level of the body. In all cases, if practicable, lay the patient on his back, with the limbs stretched out in their natural positions; loosen the collar and waist bands, and unless the head be injured, remember to have the head on the same level as the body; do not bolster it up with anything.

Fourteenth—To Place a Person on a Stretcher to Carry Him.—Three persons are necessary to do this; two to act as bearers of the stretcher and one to attend to the injured part. Place the stretcher at the head of the patient, on a line with the body, the foot of the stretcher being nearest the patient's head. One bearer kneels on each side of the patient and joins hands underneath his hips and shoulders with the bearer on the opposite side. The third man attends to the wounded limb or looks after any bandages or splints that may have been applied. The bearers then rise to their feet, raising their patient in a horizontal position, and by a series of side steps bring the patient over the stretcher. He is then lowered gently on it and made as comfortable as possible. One bearer starts off with his left foot and the other with his right; should they keep step, the stretcher would roll badly.

When a freight train is wrecked the wrecking crew should include a check clerk from the freight department, or one who is familiar with methods of accounting for freight transferred. This man should carefully examine damaged goods, keep a record of damaged or destroyed freight, and obtain on the spot all other information which might be necessary for the uses of the claim agent. In too many instances such accounting falls to the wrecking foreman, who should be relieved of all duties minor to that of clearing the track and picking up the wrecked property in the most expeditious and economical manner. Where different kinds of freight are mixed up, or where only one empty car can be run into position for loading at a time, it is sometimes necessary to load the freight indiscriminately and move it to some convenient point for assortment.

The first work to perform on a wreck, if too much will not be sacrificed, is to clear the track of obstruction and put it in condition to let the traffic trains pass slowly. In some cases of very bad wrecks the quickest way of opening the road to traffic has been to lay temporarily a piece of track around the obstruction; but it can usually be done most quickly by placing on the track such cars as are in the way and easily got on; or by pushing aside those which are badly disabled; or by dragging them out, if there is not room to push them aside, as would be the case at a wreck in a through cut. Some cars may be so badly damaged as to be not worth saving. No care need therefore be given to the handling of such cars, and as a usual thing the quickest way of getting them out of the way is to cut them up. The initials and numbers of all cars destroyed should, of course, be reported. Where there is double track, one track, if clear, may temporarily be used by trains going in both directions, and then the work of picking up the wreck on the other track may be immediately begun without first clearing away. But if both or all tracks are blocked one of them must be opened up, and this should be the one requiring the least amount of work. The wrecking outfit of the New York division of the New York, New Haven &

Hartford R. R. includes a portable emergency crossover, devised by Mr. F. R. Coates, while roadmaster there, which is used in running trains around a wreck or other obstruction in case one of the tracks is clear. The device consists of frogs laid on blocking, to cross over and above the track rails, and raised switch points which are laid down on top of the track rails, thus lifting the wheels above the ordinary track rails. Under ordinary conditions it can be laid and made ready for the passage of a locomotive in from 15 to 25 minutes. It is also used for setting steam shovels, pile drivers and camp cars off the main line and in replacing derailed locomotives and cars. The Southern Pacific Co. has standard plans for laying temporary tracks around wrecks, washouts and other obstructions of like consequence. At each end the run-by turns out from main line by either a 10 or 15-deg. curve, reversing at the end of a 50-ft. tangent to bring the track parallel with main line. Figure 400 shows a diagram of the arrangement and tables of ordinates for staking out the curves.

If fastenings run short when laying track at wrecks, there are ways of "borrowing." Spikes may be obtained quickly by pulling every other one from the gage sides of the rails on tangent, and half the bolts may be taken from any of the joint splices. Where bolts have been sheared from one side of the track by a derailed car, as sometimes happens for long distances, half the bolts may be taken from the other side to secure the splice bars on the damaged side. Part of the spikes may also be taken temporarily from the gage side of a rail to replace broken spikes on the other side of the track or on the other side of the same rail.

Cars not badly off the track should be pulled on with the replacing frogs and hauled out of the way. In running wheels over blocking placed lengthwise, the flanges will cut into the wood and the tendency is to follow the grain. Cross-grained pieces are therefore not good for such service. A truck which has become skewed to the track may be swung straight by pulling on one corner of it with a switch rope. If the car is loaded, first take the weight from the truck by jacking, and block between the ties to keep the wheels from sinking in. A car body may be put to one side, out of the way, by lifting one end with the derrick and swinging it out, and by hauling the other end around on a skid with switch rope and snatch blocks so placed that the rope will pull away from the track. If no derrick is on hand the heavy switch ropes or the tackle may be used in this manner to drag cars out of the way. A car body may be rolled over by first unloading the freight and then catching hold under the sill and lifting with the derrick. On a high fill or steep bank cars put down the bank should be put aside endwise, so that they will not start rolling. A car body off its trucks may be dragged out by placing it straight with the track, lifting its front end with the derrick, placing a tie under it crosswise, and skidding it along on the rails, oiling the rails if the load is heavy. After hauling it some distance, ditch it by rolling over, if it be much damaged; or swing one end over at a time, hauling the hind end around with the switch rope attached to the hind corner toward the ditch and lifting the front end over with the derrick. It is almost always necessary to remove the freight from cars which are badly off the track. A car off its trucks and crosswise the track can be swung straight with the track by attaching a switch rope to one end and hauling it around on skids. It may happen that while the locomotive is hauling at the wreck a part of the force may accomplish a good deal on some other part of the wreck hauling on tackle by hand. The men are strung out along the rope and pull by the word. In a very heavy pull the 1-in. rope tackle may be used as the hauling part on the larger tackle.

An easy way to get freight up a steep bank is to pile or lash a lot of it on a car door and then haul it up on skids, with tackle, by hand, or with the derrick or locomotive. Heavy boxes, castings, machinery, barrels of oil, etc., can usually be handled with the derrick. It is well to have two barrel slings for handling barrels or hogsheads by the chime, such as are used on board ships for that purpose. It consists of a piece of rope or chain with chime hooks at the ends and a ring at the center. If the freight cannot be transferred directly to cars and locked it is well to place a watchman over such of it as can be carried away, for there is usually an eager crowd standing ready to help themselves to the "spoil." When meat refrigerator cars are wrecked and broken open they should be boarded up as soon as possible, so as to keep the outside air from the meat. It may sometimes occur that extra refrigerator cars, newly iced, can be provided to hold meat transferred from wrecked cars, but if cars other than refrigerators must be used they should be swept out and well scrubbed. The floor should then be covered with a layer of clean ice in large cakes closely placed. If the meat cannot be hung up it may be supported on clean planks laid on the ice.

If trees or other stable objects cannot be found near enough to attach pulleys or guy lines, "dead men" or other anchorage must be put in. The planting of a dead man consists in digging a trench crosswise the direction of the pulling, and burying a log, piece of lumber or rail, or a tie, to which is attached a guy rope. The guy is led to the surface through another trench dug at right angles to the first one, at its middle, at a downward slant, so that the stress will pull the log against the bank of undisturbed earth instead of straight up. By looping the guy about the log and bringing both ends to the surface it may be got out, when through with, by pulling on one end with the locomotive. Or if it be desired to save the piece of timber or rail it may be got out quickly without digging by pulling straight up with the switch rope over a samson post. A wire rope sling about 16 ft. long is the best attachment that can be used. The ground should be looked over carefully and, if possible, each dead man should be placed where it can serve as a stay for pulling from several different directions. Idle section men or other men not used to wrecking can be doing this work while the engine is pulling at the wreck. There is a device, known as the Stombaugh guy anchor (Fig. 387B), which may be used in lieu of dead men. It consists of a helix 12 ins. in diam. cast around a heavy wrought iron bar of square cross section. The bar is 6 ft. long and the upper end terminates in a welded eye 3 ins. in diam. By means of a lever placed through the eye the anchor may be bored into the ground in a few minutes, and it can be removed with equal facility. As the ground is not greatly disturbed, the anchor will withstand a tremendous pull.

In picking up a wreck the old trucks and car bodies should be used, as far as possible, in hauling the wreckage to the shops. A car body may be put on trucks by the derrick car in the following way: Skid or roll the body onto, and straight with, the track, first getting a truck beyond it. Raise the end with the derrick and support the body just beyond the middle, so that the end next the derrick will slightly overbalance. A strong timber horse is sometimes provided for such support, but a handy one may be quickly arranged by supporting a piece of rail 14 or 16 ft. long upon a pile of blocking at either side of the track, or a car truck, with some blocking on top, will answer the same purpose. After the support is in place under the car let the derrick end of the body down. This will throw up the other end so that the truck may be run underneath it. Then raise the end again with the derrick, run a truck under that end, take out the rail or horse and let the end down upon the truck. It is well to see that the journal bearings are in place before letting the body down on to the trucks. A passenger coach is too long and too heavy to be handled in this way, and must usually be raised by the slower process of jacking. Place a jack under or near each corner and keep the car cribbed up as it is raised. A freight car body may be loaded upon a flat car by balancing it across a horse or other support and running the flat car as far under the body as possible. Then lift the other end and run the body on the rest of the way on dollies or rollers while the end is held up by the derrick. Whenever the air brake apparatus would be injured in handling a car it should first be removed and placed inside the car. Car bodies broken in two and disabled trucks are loaded upon flat cars. All pieces of iron should be picked up and thrown upon the cars. All traces of the wreck should be removed—either by loading upon cars, giving away or burning.

Considerable care must be exercised in handling passenger coaches that are but slightly damaged. As the tops of these cars are of light construction they cannot be hauled on as with the tops of box cars. When such a car is on its side it may be rolled by passing several ropes or slings through the ventilator openings in the roof, looping them around blocks padded with grain sacks and placed crosswise the openings, and bringing all these ropes to a common center, so that all bear as nearly as possible an equal stress. Where passenger coaches have rolled or run down a bank they can generally be got back easiest by laying a piece of track to them at an incline, diagonally down the bank, and hauling them up with switch ropes or tackle. A foundation for the track may be had by digging into the bank on one side and laying timbers or rails upon cribs of ties or blocking, to support the other side, or by cribbing under both sides. If the material cannot be obtained in any other way, it may be had by taking up some near-by side-track. This track may be hastily built, spacing the ties at wide intervals, and it may be connected to the main track at the top by cutting and throwing the main track over to it. The derrick car, if needed at the bottom, may be let down this incline. When a locomotive is to be hauled up a bank in this way a more substantial foundation for the track is required, and it might be necessary to cut a bed out of the bank the full width of the track. Where cars have run away from the track, on the level, they may be easiest got back by cutting the track and throwing it over to them between train times, or by building a piece of temporary track, to which the main track may be thrown to connect. The cars should be ready to haul onto the track as soon as it is thrown over. A car down the bank or to one side, resting on its sills, may be hauled to the track by swinging first one end and then the other, with the derrick. If the bank is steep the advantage gained at each hitch should be held by a rope anchored to the track rail.

A locomotive off the rails but not off the ties may be put on by using the replacing frogs or wedges and hauling straight ahead. It will frequently save time, however, to lay pieces of rail in front of the wheels and throw the track rails over to connect with them. In pulling locomotives or cars around very sharp curves on temporary tracks it is well to oil the rails. If one side of a locomotive is off the ties, sunk into the mud or ballast, and the machine badly tilted, or if it is tipped completely over on its side, not much can usually be done with the jacks. The locomotive may be righted by passing a chain around the dome and hauling on it with tackle attached to a dead man or other object off at the side. A collar or strap is sometimes made to go around the dome of a locomotive as a means of attachment in turning it over. In rolling over a locomotive a leverage may be had by lashing a heavy stick of timber to the side and pulling on the end of it. If the timber can be placed under the locomotive, the bottom end would be chained to the frame and blocking would be arranged for a bearing against the dome; otherwise, the timber lever would be applied to the top-side, with the foot bearing on the frame or against a driving wheel, and lifting by means of a chain around the dome. A start may be had by jacking against this timber for a ways, or by pulling over a guyed samson post, or by hitching the tackle to the top of a strong telegraph pole securely held with guy ropes. In righting a locomotive where one side is on the ties, lift the machine a few inches at a time and follow it up with blocking. If the locomotive is upright but sunk deeply into the earth, jack it up and run ties and rails under it before attempting to haul it away. Where an engine has gone down over a high bank or through a bridge, a powerful tackle must be arranged, and two or more locomotives will be required to haul it back. If it is overturned it must first be righted and put in line with a piece of track laid to it down an incline. If the incline is steep it is well to pull on it with double sets of tackle secured to several dead men or trees; otherwise it may be hauled by attaching to it directly with steel cables. It

Fig. 400.

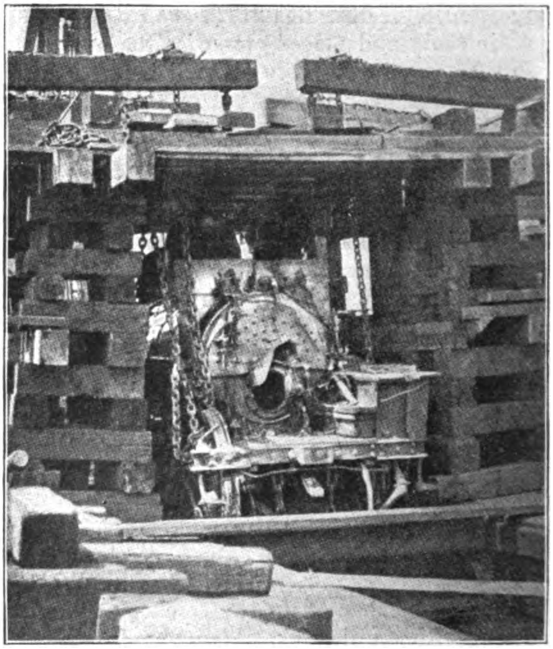

Fig. 401.—Rear View of Locomotive.

is usually best to first dismantle a locomotive, especially if it is to be much handled. The shafts, connecting rods, headlight and many other parts which might be damaged should be taken off; and the locomotive can also be pulled somewhat easier, especially if some portion of the driving parts are bent. Wherever close movement is required and heavy pulling is to be done there should be as few cars as possible attached to the locomotive that is doing the pulling, and in such cases the tool car, derrick car, etc., may be run back out of the way.

Cars which have fallen through a bridge into deep water are sometimes lifted out by a dredging machine and placed upon barges. For work of this kind the dipper and dipper handle of the dredge are removed and heavy block and tackle is hung from the boom. Locomotives may be lifted out of deep water by hoisting between two scows. Figure 402 is a view showing the manner of lifting a 44-ton locomotive of the Chicago, Milwaukee &

St. Paul Ry. out of 18 ft. of water in the Chicago river, the locomotive and passenger train having run into an open drawbridge. By the aid of a diver a line was passed under the boiler, just back of the cylinders, and this line was used to haul under a heavy chain. Another chain was made fast to a toggle placed inside the firebox door. Two scows, each measuring 85x22x6 ft. and capable of carrying 250 tons, were then run over the locomotive and partly filled with water so as to settle considerably. The chains were

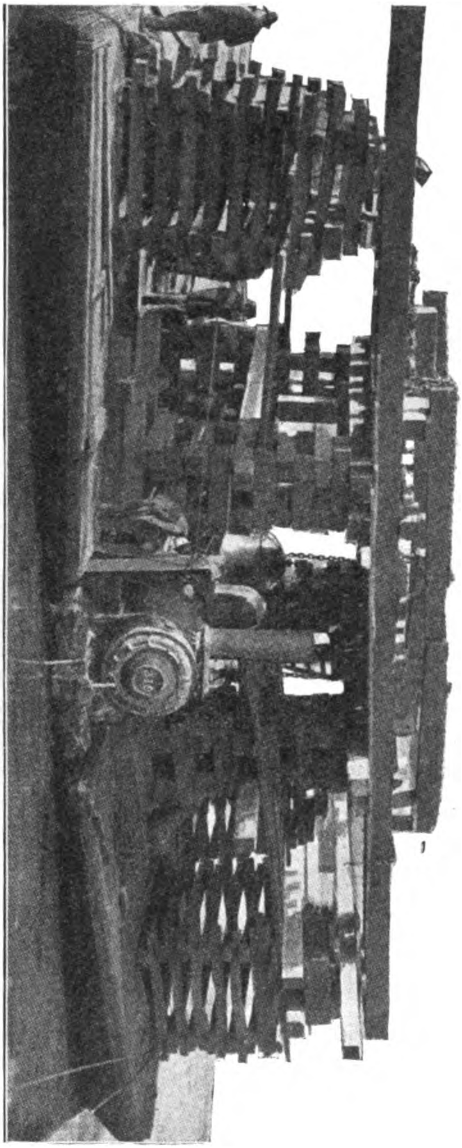

Fig. 402.—Raising a Sunken Locomotive, C., M. & St. P. Ry.

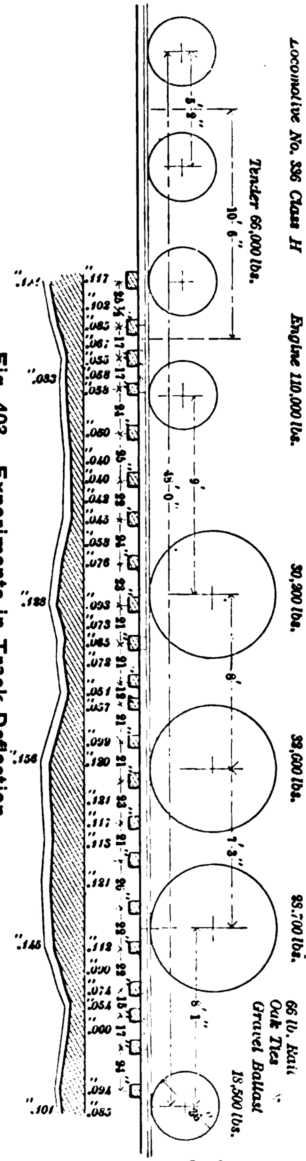

Fig. 403.—Experiments in Track Deflection.

then made fast to the scows, when the water was pumped out and the locomotive lifted off the bottom and carried farther from shore, in order to obtain more room. The locomotive was then dropped and the scows placed alongside—that is, one on each side of it—9 ft. apart and securely braced so as not to separate. In order to facilitate placing the locomotive on a track after being lifted, it was raised as near as possible to one end of the scows. Four 16x16-in. spruce beams, each 56 ft. long, were then placed crosswise the scows and supported on blocking 14 ft. high. Chains were then made fast to each of the four drivers, in addition to the chain looped under the head end of the boiler, previously noted, and passed to 12x12-in. oak levers supported on the spruce timbers, as shown in the figure. These levers were six in number, arranged in three pairs, and operated by screw jacks. The chains were held to the levers by toggles, and to hold the chains while dropping the levers, in order to take up on the chains, toggles were arranged on the beams underneath the levers. A rear view of the locomotive, in which these levers appear more clearly, is shown in Fig. 401. After the locomotive was righted and raised to a sufficient hight the scows were swung "end on" to a piece of track laid down the bank and supported at the end upon two piles driven into the bed of the river. The work was accomplished in 7 days with a crew of 14 men, considerable delay being occasioned by the limited room for handling the scows and the necessity for dropping the locomotive and raising it a second time.

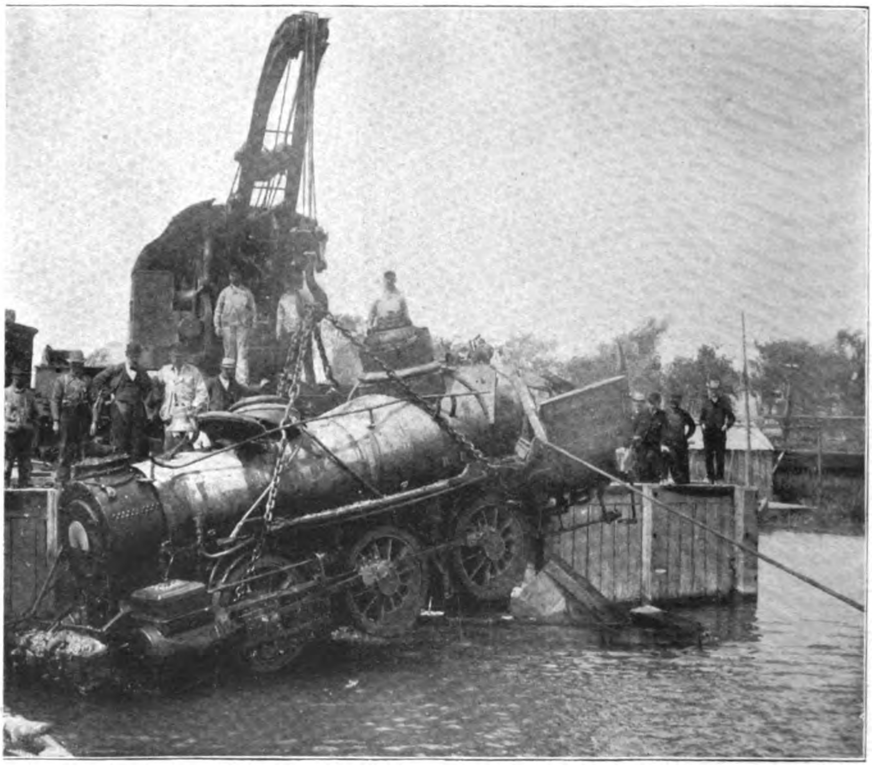

Fig. 404.—Recovering a Sunken Locomotive, Niagara Junction Ry.

In some cases locomotives have been fished up by running chains under them and fastening to water-logged scows. At low tide the scows would be pumped out, lifting the wreck, and at high tide they would be towed into low water. When the tide fell again the water logging and pumping operations would be repeated, and the locomotive carried shoreward until finally it would stand dry, with the tide out, when a piece of track would be laid to the site and the locomotive hauled away. At Terre Haute, Ind., a locomotive of the Cleveland, Cincinnati, Chicago & St. Louis Ry., at one time, was raised out of water by means of sets of heavy block and wire rope tackle fastened to a bridge. The tackle was pulled by a locomotive on the track over the bridge, and to prevent side strain on the bridge trusses the tackle was suspended from special wooden chords laid upon the bridge and secured against lateral movement or pressure by guy lines run to the shore. The wrecked engine was lifted 10 or 12 ft. above the water and let down upon a scow, and finally hauled away on a temporary track built to the scow landing. As heretofore stated, locomotives of light weight are frequently lifted bodily by steam wrecking derricks. An instance of such recovery is illustrated in Fig. 404. A locomotive and six freight cars of the Niagara Junction Ry. ran off the end of a dock into the Niagara river and sank in about 15 ft. of water. The picture shows a "Bay City" derrick car (like the one in Fig. 398) in the act of lifting the locomotive out, at a radius of 18 ft. The chains were fastened by a diver, and after the locomotive was lifted high enough to clear the dock it was swung around and placed upon the track. The weight of this locomotive was 42½ tons.

In the absence of the roadmaster, if he be wreckmaster, the foreman of the work train, or the highest assistant in authority under the wreckmaster who is present, should take charge until the wreckmaster arrives. The wreckmaster should keep his head cool and avoid hasty speech. Some men appear to think that a wreck gives them good excuse for cursing or abusing their subordinates upon the slightest mistake or irregularity; and some men in authority show more ingenuity in finding fault than in handling a wreck. On the other hand, there is no better opportunity for an official or foreman to gain the good will of his men than by keeping patient and civil while they are engaged at hard and hurrying work. He should give the signals to the engineer when ready to pull at the wreck and see that men stand clear where they will not be liable to injury by the breaking of ropes or chains. At night he should carry a lantern with a colored globe, so that he may be readily found when sought. He should be able to rig block and tackle to best advantage, and should acquaint himself with a few ways of making hitches and tying knots in large ropes. A knowledge of how to tie knots comes handy when ropes break.

Knots and Hitches.—Figures 405 and 406 show a number of the most common knots and hitches, the former illustration being reproduced by permission of the C. W. Hunt Company, West New Brighton, N. Y., from a plate published in a pamphlet entitled "Manila Rope." This publication also contains instructions for splicing ropes. In order to show clearly the position of the parts the engravings in Fig. 405 were made open, or to represent the rope before being drawn taut.

The principle of a knot is that no two parts which would move in the same direction if the rope were to slip should lie alongside of and touching each other. Sketch *C*, Fig. 405, shows the wrong way to attempt to tie a figure-8 knot, as it makes an overhand knot identical with *B*, except that one is right hand and the other left hand. Sketch *OO*, Fig. 406, shows the correct way to tie a figure-8 knot, the right-hand end going first under, and then over, the loop instead of over and then under, as in Fig. 405.

One of the most serviceable knots is the bowline, used in fastening a rope to a tree or post. It will not slip, and after being strained is easily untied. The three steps in tying the knot are shown as engravings *F, G* and *H*. in Fig. 405. The square or reef knot (*I*) is used in joining the ends of two ropes and is difficult to untie. If the short ends be wound together in the reverse way the result is a "granny knot," which will slip under strain. The weaver's knot (*J*) may be used to join the ends of two ropes or to fasten the end of a rope to a bight in another rope. The stevedore knot (*M*) is useful where a rope passes through an eye and is held by the knot, as it will not slip and is easily untied after being strained.

The Blackwall hitch is used for attaching the end of a rope or a sling to the hook of a block. When the rope spreads away to its load—that is, when both ends are attached to the load, as when using a sling—the hitch is made as in Sketch *W*, Fig. 405. This hitch causes the rope to jam when

the strain comes on and prevents the sling from slipping through the hook and tilting the load in case the latter meets with some obstruction while being hoisted. The rope is easily detached when the strain is relieved. If the end of the rope is to be used it should be passed twice around the hook, as in Sketch *GG*, Fig. 406. With only one turn, as in Sketch *W*, the rope is liable to slip when subjected to heavy pull, especially if it is wet. When the rope is too long for convenient manipulation of the end it may be secured to the hook by a cat's-paw hitch, Sketch *HH*, Fig. 406. This hitch is made by taking hold of the rope with both hands at points about 2 ft. apart and twisting it two or three times either way, when the ends of the loops thus made are applied to the hook. The twisting prevents the rope from becoming jammed and the hitch is easily loosened.

A wall knot, or wale knot (*AA, BB, CC,* Fig. 405) is a knot made at the end of a rope by interlacing the strands, and is used to keep the end from drawing through an eye or hole. It is made by proceeding as follows: Form a bight with strand 1 and pass strand 2 around the end of it, and strand 3 round the end of 2, and then through the bight of 1, as shown in the engraving *Z*. Haul the ends taut, when the appearance will be as shown in the engraving *AA*. The end of strand 1 is now laid over the center of the knot, strand 2 laid over 1 and 3 over 2, when the end of 3 is passed through the bight of 1, as shown in the engraving *BB*. Haul all the strands taut as shown in the engraving *CC*. By going a step farther than what is done in Sketch *Y* and making another half hitch, and then drawing taut, the end of the rope will hold without wrapping, and it then becomes a good hitch to make around a tree.

Sketch *DD*, Fig. 406, shows a method of shortening a rope which is too long for some temporary purpose. It consists of a half hitch at each end of one or more bights laid up to shorten the rope to the required length. If several bights are laid up the standing part is passed through the ends of all and pulled tight. The illustrations *EE* and *FF* show hitches for securing a small rope to one of larger diameter. In the swab hitch (*EE*) the end of the smaller rope is sometimes passed twice around the bight of the larger, instead of only once, as shown. Sketch *FF* will be recognized as the clove hitch, identical with Sketch *T*, Fig. 405. The hitch *JJ* is used on barrels and similarly-shaped things when it is desired to hoist the vessel in a vertical position. The illustrations *KK* (open hand knot), *LL* (Englishman's tie), and *MM* (ordinary tie) show various knots for tying the ends of two ropes together or for uniting the two pieces of a rope at a break. When the knot *KK* is tied in the bight of a single piece of rope it is known as a loop knot. Sketch *NN* shows the parbuckle hitch, for rolling a barrel or similar load up an incline with a single length of rope.

For heavy pulling with manila or hemp ropes the spliced eye (*TT*, Fig. 406) is the most efficient method of attachment, as it will stand a pull sufficient to break the rope in the straight part. Next in efficiency come the timber hitch, the slip knot and the double half hitch, in about the order named. Numerous tests made at the engineering laboratory of the Massachusetts Institute of Technology give the relative average efficiencies of various hitches as follows: Spliced eye, 100 per cent; timber hitch, 74 per cent; double half hitch, 69 per cent; slip knot, 73 per cent; bowline, 58 per cent; Flemish loop, 50 per cent. These figures apply to manila and Russian hemp rope. With American hemp rope the efficiencies proved to be higher in every case, being 84 per cent for the timber hitch, 90 per cent for the double half hitch, 92 per cent for the slip knot; 80 per cent for the bowline and 76 per cent for the Flemish loop. With cotton rope the eye splice was not found as efficient as the timber hitch.

None of the knots will withstand a pull as great as the strength of a straight rope. The Englishman's tie (*LL*, Fig. 406) is the strongest. The relative average efficiencies of knots, as determined by tests at the Massachusetts Institute of Technology, were reported as follows: Englishman's tie, 61 per cent; ordinary tie (*MM*, Fig. 406), 57 per cent; square knot (Sketch *I*, Fig. 405), 52 per cent; open hand knot (*KK*, Fig. 406), 46 per cent.

150. Fighting Snow.—The task of clearing the track of snow falls to the track department. In certain portions of the country, particularly in the Northwest or upper Mississippi valley states, the handling of snow is a work of much importance; indeed the regularity of the traffic in winter time depends much upon the alertness, the industry and, quite frequently, upon the ingenuity, of the man or men in charge of it. Of snow plows and other appliances in use for removing snow there are many kinds, but, generally considered, they may be divided into five types, namely: push plows, pilot plows, machine plows, wing plows and flangers. On eastern roads, or roads east of Chicago, the most common type of plow in general use is some form of push plow; between Chicago and the Rocky mountains the type of plow in most general use is the pilot plow; while on the Rocky mountain roads one finds the machine plow in common use.

Push Plows.—A push snow plow has fixed parts, runs upon its own wheels, and in operation is pushed ahead of one or more locomotives. The plow proper is usually constructed at the end of a flat car or box car, and it usually takes one of two shapes, namely, V-shaped or square-nosed. A plow shaped like a locomotive pilot would be one example of a V-shaped plow. Its tendency is to crowd the snow out or throw it aside without lifting it much. A V-shaped plow having its faces vertical, or perpendicular to the track, crowds the snow aside without lifting it any, and it becomes a difficult matter to hold such a plow down in compact snow. There is then the further objection that snow handled in this manner will fall back under the wheels after the plow passes. A square-nosed plow is one the front and lower edge of which extends squarely across the track the full width of the plow. Its action is first to lift the snow, as dirt is lifted in a scraper, and then to throw it aside, without crowding. The upper part of the plow is V-shaped. The face of the plow is in principle a rectangular inclined plane surface having a V-shaped plow of the same width set upon it some distance back from the front edge. For use in snow of moderate depth a plow at the end of a flat car is frequently employed. One such in the service of the Michigan Central R. R. consists of a wooden plow with vertical faces (V-shaped), suspended from the overhanging end of a 12x14-in. beam running longitudinally over the car and hinged to the frame of the car at the rear end. At the front end of the car there are two vertical brake cylinders, one at either side of the beam, for lifting the plow at crossings and switches. These cylinders are supplied with air piped from the cab of the locomotive and are under the control of the engineer, who raises and lowers the plow as necessity requires. It is therefore not necessary to the operation of the plow that an attendant should remain on the car. The car is weighted down and is pushed ahead of the locomotive. The Pennsylvania R. R. has a plow of somewhat similar construction, the front and rear ends of the car being loaded with old car wheels. At the front end of the car there is a plow, and just back of the front truck there is a flanger. This flanger is attached to the ends of two struts hinged in front of the rear truck of the car and raised either by an air cylinder or by a long lever, which is used when air pressure is not available. The Boston & Albany R. R. also uses a snow plow rigged at the front end of a flat car. The plow device is 6½ ft. high and there is a small house or cab on the car for the pilot.

One of the best known push plows is the Russell design, first put to service in 1885 on the Intercolonial Ry., in Canada, and now used on a large number of roads. This plow is of the square-nosed type and is very solidly built. The incline or face of the plow is formed upon a 12x12-in. white oak timber known as the "backbone," and the plow is pushed at the front end by a 12x12-in. oak timber called the "power bar," which lies between the two center sills of the car frame, extending the entire length of the car to the "backbone," to which it is hinged by heavy straps. The rear end of the timber is left free to move laterally a distance of 4 ins. each way from the center, so that it readily adjusts itself to curves. The nose of the plow or cutting edge is 10 ft. wide and reaches within a few inches of the rail. The rear portion of the car is 6 ins. narrower than the width at the incline, so as to relieve the car of the friction of snow against its sides. The share or center cutter of the plow starts some distance back from the cutting edge and both it and the portions of the incline subjected to heaviest wear are faced with steel plates. The surfaces which come into contact with the snow at the rear of the face are long, sweeping curves. The front end of a square-nosed plow is subjected to heavy downward pressure from the snow and hence a very strong forward truck is required. One difficulty with such trucks has been the heating of the journals, due to the excessive load. To overcome this trouble the forward truck of the Russell plow is made especially heavy and of special design Each axle is provided with four journals—that is, a journal each side of each wheel—thus giving the necessary strength and ample bearing surface. The face of the plow and the exterior of the car are covered with matched yellow pine, planed smooth and shellacked. so that it presents a smooth surface. The front of the plow is provided with a draw-bar, attached to straps anchored in the framing of the plow, so as to enable the car to be coupled up in a train, when necessary. The top of the car is fitted with a raised portion for the lookout, who communicates with the engineer by means of a bell cord and directs the movements of the car.

This plow is made in three styles: a single-track plow, with a symmetrical front, throwing to both sides; a double-track plow, with unsymmetrical front, throwing to one side only; and a "wing-elevator" plow, for either double or single track. Each of these styles is made in three sizes. Figure 407 is a view of the single-track plow, intermediate size, as made for the New York Central & Hudson River R. R. This plow is 34 ft. long, 11 ft. high at the front and weighs 46,000 lbs. without ballast. The rear buffer is mounted on the end of the "power bar" and is shown in the rear view. To facilitate coupling with locomotive draw-bars of varying hights it has four pockets. The Russell plow for double track is constructed on the same general principles as the single-track plow, the only essential difference being in the location of the share or cutter, which, of course, is placed at one side of the incline instead of at the center, so as to throw all the snow to one side. The plow is

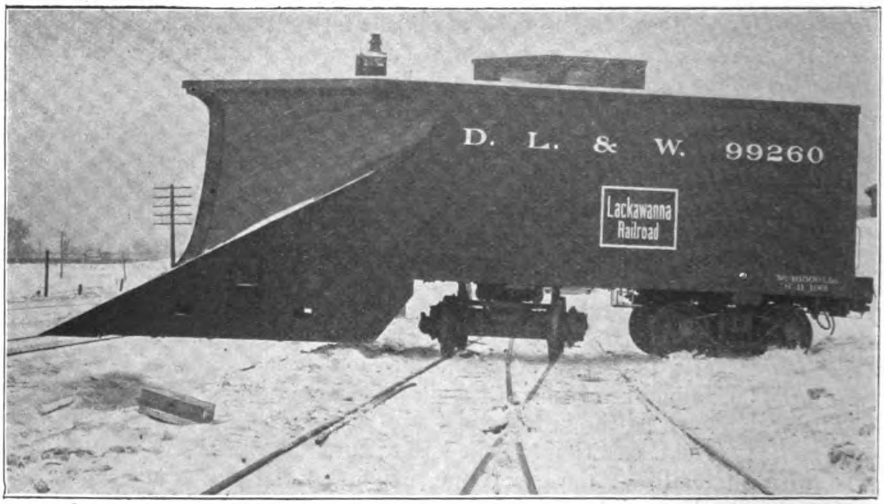

Fig. 408.—Self-Turning Snow Plow, Delaware, Lackawanna & Western R. R.

made for either right-hand or left-hand running. The usual method of clearing a double-track road is to run the plow over one of the tracks, turn the plow and return by the other track. As some double-track roads (including the Lake Shore & Michigan Southern and the Chicago & Northwestern) run left-handed—that is, the right-hand, or engineer's, side of the engine coming between the tracks instead of on the outside—the snow plows for such roads, in order to run in the customary direction of the train movements, must necessarily throw to the left. These double-track plows, if they happen to be turned the right way, are well adapted to side-hill plowing. The cutting edge of the share is 5 ft. back of the front of the incline, so that the incline is securely held down by the weight of snow in advance of the point where the side pressure on the plow begins, and there is no danger of the plow being thrown off the track by side pressure. It may also be stated that in side-hill plowing with a single-track plow, the bank side of the plow will fill up and all of the snow will be thrown to the other side, or away from the bank. One way to clear both tracks of a double-track road, and the midway at the same time, is to run a single-track plow over the track on the windward side, with the wings open, and follow behind with a side plow on the other track, opening out the wing on the lee side. In order to do this it is of course necessary to have both tracks clear of traffic.

In fighting snow the demand often arises for some arrangement whereby a snow plow may at any time be made quickly ready for use in either direction. It is sometimes the case that snow at one end of a division is deeper or more troublesome, from drifting or because of other conditions, than at

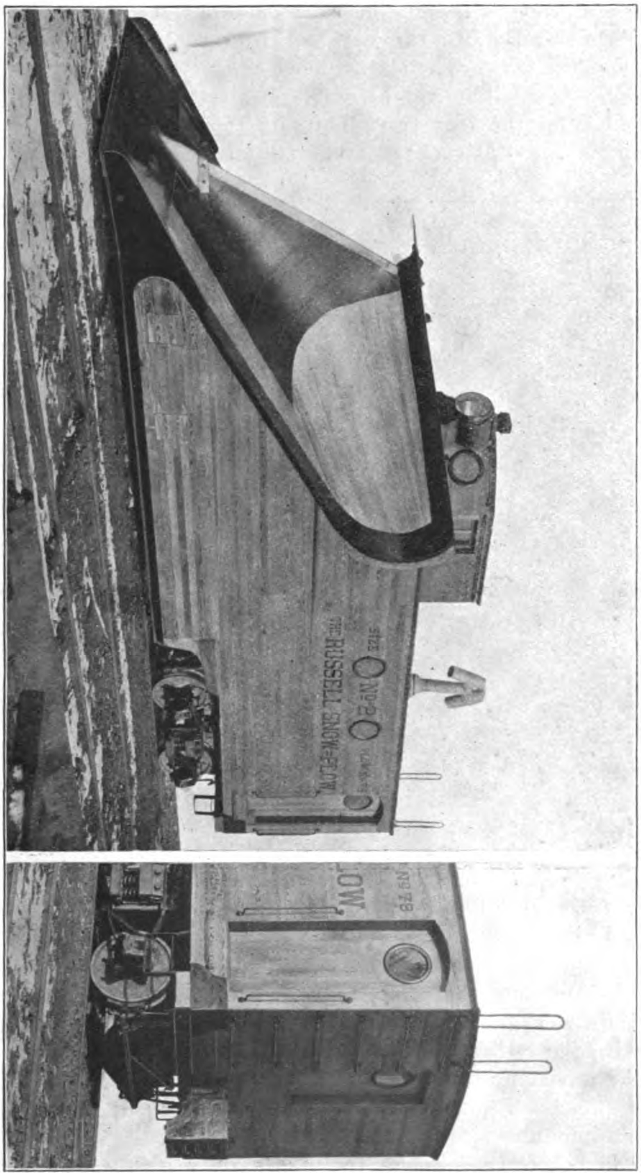

Fig. 407.—Russell Single-Track Standard Snow Plow, N. Y. C. & H. R. R. R.

the other, and in cases of this kind it frequently happens that it is desirable to stop at some intermediate point on the division and return. Such might be the case on double track, where, after having covered the district over which the snow is most troublesome, it is desired to take a crossover and plow back over the other track; or, indeed, in event the snow is rapidly drifting, it might be desirable to start the plow back over the same track, as on a single-track road, thus saving time which would otherwise be wasted in running to the nearest turntable, which would usually be at the end of the division. To meet the requirements of such a situation the Delaware, Lackawanna & Western R. R. has a push plow with a turntable arrangement self contained with the car, for turning the plow end for end at any point on main track. There is a turntable track 4½ ft. in diameter attached to the front truck of the car, and near the center of the car, which is 37 ft. long, there is a bolster with a center bearing to fit the truck, and six 8½-in. wheels arranged in a circle to bear upon the turntable track. In order to turn the plow the front end of the car is raised, by means of compressed air cylinders, to clear the forward truck, which is then rolled back under the center bolster or bearing. The weight of the car is then supported by the truck under the center, the rear truck hanging to the car body. The turntable device being located at such a point that the car body is balanced over the

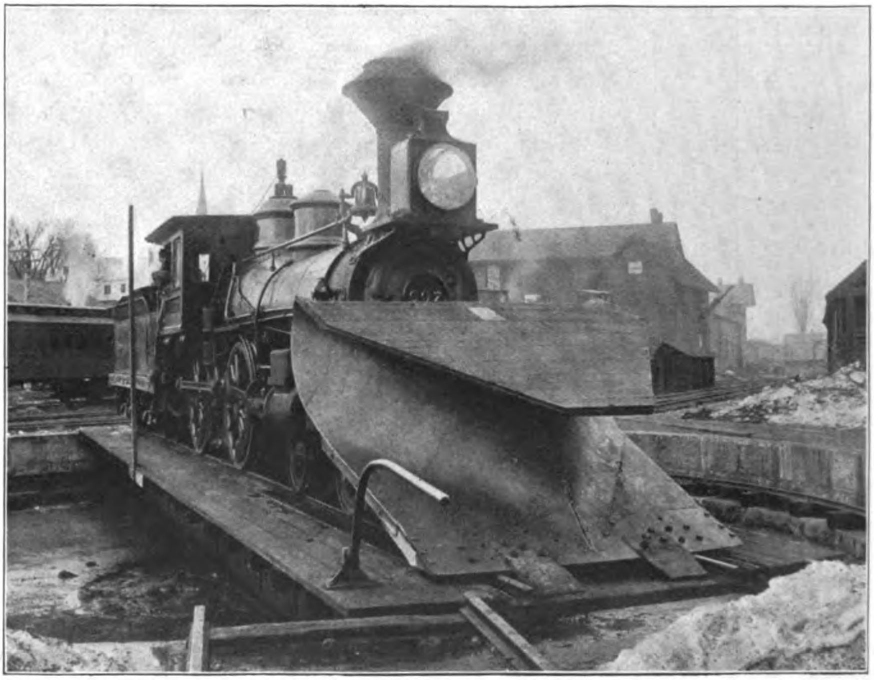

Fig. 409.—Pilot Snow Plow and Flanger, Vermont Valley R. R.

center truck, the plow is turned by pushing it around with a gang of men, three men being a sufficient force. Figure 408 is an illustration of this plow in process of turning. The arrangement for hoisting the front of the plow clear of the truck at that end is a 12-in. air cylinder on each side of the car, opposite the center of the truck. It has a downwardly acting piston which takes a bearing on blocking placed on the ends of the ties.

Pilot Plows.—Pilot snow plows, sometimes called Congdon plows, are of various kinds and sizes, ranging from moldboards of boiler plate 2 or 3 ft. high attached to the pilot of the engine, to a plow extending as high as the top of the boiler. In the latter case the steel plate face or moldboards of the plow are usually backed by a wooden frame attached to the pilot and braced against the engine frame, or in some cases the pilot is removed to give place to this frame. One fault with many pilot plows is that when the engine runs backward the moldboards will pull snow into the track, and in hard snow the moldboards are sometimes broken off in this way.

One way to overcome this difficulty is to place guard plates at the sides of the plow, in rear of the moldboards. Pilot plows are usually intended for service in snow of moderate depth, say not to exceed 4 ft., the intention being to equip all or part of the trains with such plows and keep the road clear by the frequent passing of the trains. In cases, however, such plows are made to do heavy work, the locomotive equipped with the plow being assisted by one or more locomotives as pushers. On a number of roads plows as high as the pilot are permanently attached to locomotives for the winter season, remaining on the locomotives while making their regular trips. Thus, on the Wisconsin Central Ry., all the passenger engines and about 25 per cent of the freight engines are equipped with pilot plows reaching to the top of the bumper beam, while one engine for each division has a pilot plow 8½ ft. high, or extending to the top of the smoke box, for heavier duty in emergency.

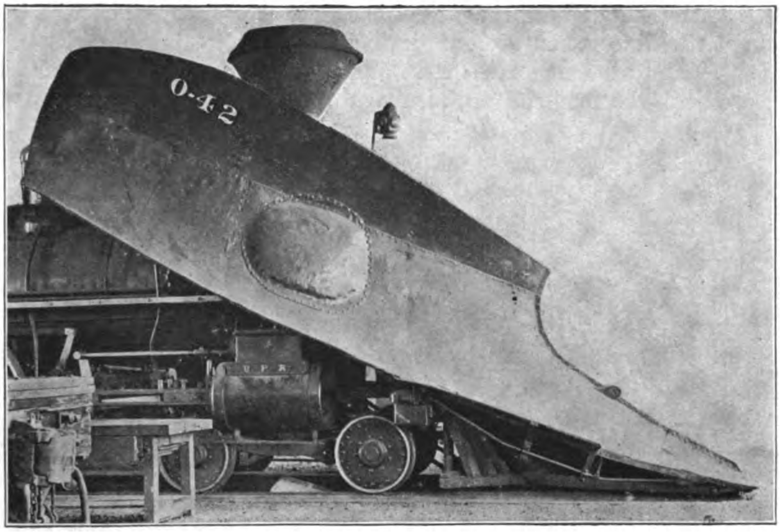

Fig. 410.—Pilot Snow Plow, Union Pacific R. R.

Figure 409 shows a pilot plow used on the Vermont Valley branch of the Boston & Maine R. R., for all except the deep snows. The plow is built of heavy framed timbers, sheathed with hard pine and faced with ⅛-in. iron plate. The plow is 4 ft. high, above the rail, at the front end and 6 ft. high at the rear end. The plow is attached to the locomotive by means of a hinge at the bottom. The hinge rod or pin extends the entire width of the plow, running through the hinge castings on either side. The abutment for the plow, on the locomotive, is arranged similarly to the old-fashioned "broom guards." The top of the plow is connected by rod and crank to an air cylinder which stands in a vertical position directly over the front axle of the engine truck. When in service the nose of the plow rests upon cast iron shoes which slide upon the rails. When not in service it is lifted from the working position by means of the air cylinder and held clear of the rails. The "cutters" or flangers consist of heavy steel plates bolted to the nose of the plow, as seen in the picture, which shows the plow in the working position. This arrangement provides for quickly replacing the flangers should they become torn loose by an obstruction. They are adjustable by means of the bolts, and when the plow is used at night they are taken off. To provide for service in the case of sudden calls the pilot of the engine is removed in the fall, and this engine is then used for switching purposes, so that it is in readiness at any time. The plow can be attached to the engine or detached from it in five minutes. The crew for operation consists of the engineer, fireman and a conductor, the engineer handling the plow. Figure 410 shows a plow attached to the pilot of a light engine of the Union Pacific R. R., which is kept in the roundhouse at Rawlins, Wyo., for service in snow of 3 ft. depth and less. For heavy work, in hard snow, two engines are used to push the plow, and in snow of the depth stated the plow is said to do efficient work.

Machine Plows.—The machine snow plow might be described as a modified type of old-fashioned fanning mill, of monster size, on wheels, with the hopper turned up squarely to the front. The pressure of the machine forward crowds the snow into the hopper and the swiftly revolving fan throws it violently through an opening high into the air and to one side, in a stream as large as a flour barrel. By adjusting the opening or exit passage the stream may be thrown to either side, as desired. The wheel in one style of machine is a propeller, similar in action to the propeller of a steamboat, and in other machines it is simply an immense screw or auger, which bores out the material crowded against it, throwing it out of the

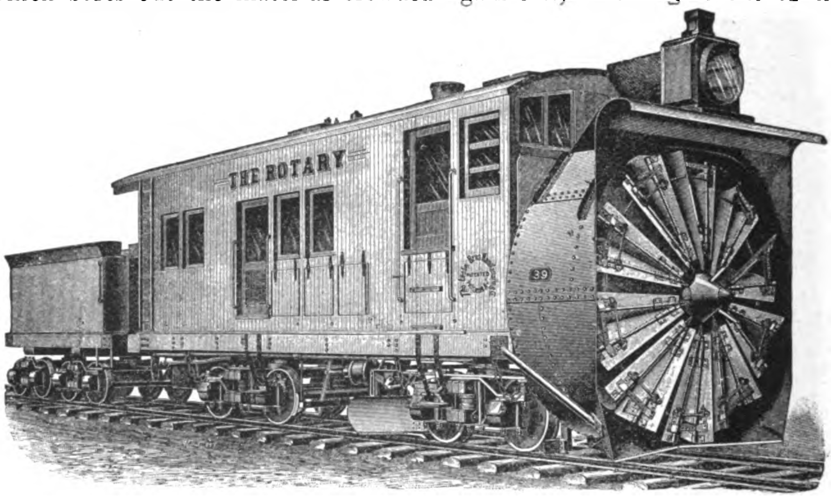

Fig. 411.—The "Rotary" Snow Plow.

chute directly or into a fan wheel. It is turned by power furnished on the machine itself, the rotary or plow portion being but the head end of a long car. The first machine snow plow to see real service was designed by Mr. Orange Jull, and was tried for the first time on April 1, 1884, in the yards of the Canadian Pacific Ry., at Montreal. This plow had a rotating wheel with cutting blades and was the prototype of the modern "Rotary." The first machine snow plow used in the United States was an improved form of this plow, and saw service in the winter of 1886-87 on the Union Pacific R. R.; but up to the year 1888 this was the only machine plow to be put to work. During the years 1888 to 1890, inclusive, machine plows were vastly improved upon and came into use quite extensively, particularly on the Rocky mountain roads. The three types which then came into use were the "Rotary," the "Centrifugal" or Jull plow, and the "Cyclone." On general principles the construction and operation of all three machines are the same, except in the form of the excavating device. They all take the form of a box car with a rotating device or excavator enclosed within a hood at the front of the car.

The "Rotary" snow plow (Leslie machine) is shown in Fig. 411. At the front of the car there is a hood formed of steel plates, with cutting edges at the sides and bottom. The width of the hood is 10 ft. and the bottom cutting edge is carried only 3 or 4 ins. above the rail. This hood tapers into a circular drum, within which the rotator revolves at about 200 revolutions per minute upon a longitudinal shaft turned by two vertical engines combining 800 horse power. At the rear of the car there is a locomotive tender to supply fuel and water. In the old form of Rotary plow (Fig. 412) the excavator consists of a knife wheel with flat cutting blades, with a fan wheel in the rear, both being attached to the same shaft and turning together. In the improved machines, however, the fan wheel is dispensed with and a new form of wheel is provided. This wheel is composed of ten hollow funnel-shaped scoops, arranged radially on the wheel. The scoops widen or flare from center to circumference of the wheel, and each scoop is open its entire length on the front side, through which the snow is taken in. On each side of the opening on the front side of the scoops there is hinged a knife or cutting blade, the knives of each two adjacent scoops being linked together, as shown, so as to automatically adjust

Fig. 412.—Rotary Snow Plow (Old Design).

themselves into cutting position whichever way the wheel is turned. The center of the wheel projects ahead of the hood, while at the circumference of the wheel the hood projects 3 ins. in advance of the cutting edges of the knives. At the top side of the drum within which the wheel revolves there is an opening with an adjustable cover, arranged so as to throw the snow to either side, as desired. The action of the wheel is to cut the snow into the scoops, from which it is thrown at high velocity, by centrifugal force. As the snow is revolved at high speed within the scoops it leaves the wheel at a tangent as it meets the opening. In order to change the direction in which the snow is thrown, as sometimes becomes necessary, in order to throw to the down-hill side or to avoid throwing the snow against the wind, the wheel must be revolved in the opposite direction. The chute through which the snow leaves the drum is just in rear of the headlight, and the cap or adjustable cover of the chute is so arranged that it can be reversed from the pilot house when the wheel is turned to throw the snow to the opposite side of the track. The pilot house is in the forward end of the cab, being partitioned off in front of the front end of the boiler. A curved deflector plate or apron is placed across the top of the hood to prevent snow from flying and obstructing the view of the pilot. In front of each forward wheel of the car there is an ice cutter, secured to the lower end of an arm of a wrought iron frame, by two bolts. This ice cutter is composed of two parts, known as the wing and the cutter. The wing projects over the rail and the cutter drops down inside the rail. Should the cutter strike a guard or crossing rail it will shear the lower bolt holding the arm to the frame, and the cutter will be deflected backward without further injury. To repair the damage it is necessary to replace only the broken or sheared bolt. It is said that this ice-cutting device works efficiently, and prevents the derailment of the car when working through drifts of snow frozen at the bottom. At the rear of the front truck the car is provided with a flanger, hung on the rear end of the frame of the truck and drawn by wrought iron arms which are journaled on the rear axle of the truck. The flanger is raised or lowered by an air cylinder operated by the pilot or lookout stationed in the pilot house. The flanger points are four in number and are the only parts which extend below the top of the rail. These parts are bolted to the bottom of each wing of the flanger with ½-in. bolts with countersunk heads, so as to be readily torn loose in case the flanger meets with an unyielding obstruction. The ice cutter and flanger are both connected by means of iron rods to cranks on a balance shaft mounted on the truck frame about midway, thus permitting both to be raised and lowered simultaneously by the air cylinder. In the operation of the plow the pilot or lookout operates the air brakes on the entire snow-plow train with an engineer's valve, in the pilot house. He also operates the flanger and ice cutter. In case the air pump on the rotary becomes disabled while the plow is in service, the flanger and ice cutter are operated by steam instead of air. The ordinary weight of the plow is 70 tons, and the length without the tender 36 ft. A later design of this machine, built for the Colorado Midland Ry., has a hood 12 ft. wide, built of ⅜-in. steel plate, and a 12-tube rotator 11½ ft. in diameter. The hood cuts a passage wide enough to permit long Pullman cars to pass around 16-deg. curves without rubbing the inside bank. The car is strongly built on 12-in. I-beam sills, and the total weight is 85 tons.

The "Centrifugal" or Jull machine snow plow consists of a heavy iron car with a hood in front, like the "Rotary." This plow was designed by Mr. Orange Jull, the designer also of the original rotary pattern, as stated. It was brought out during 1889 and was first put to service on the Union Pacific R. R. between Granger, Wyo., and Huntington, Ore., in the winter of 1889-90. The working portion of this plow consists of a cone of 7½ ft. diameter at the large end, with four spiral-shaped, curved blades of ½-in. steel, making about ¾ of a turn in the length of the cone. At the base of the cone these blades are 2 ft. wide, tapering to the apex of the cone. The cone is set diagonally across the hood, pointing to the right-hand rail—that is, the small end or apex of the cone is journaled at the lower right-hand side of the hood (looking forward) and the rear portion or large end of the cone is journaled in the diagonally opposite corner of the hood, or rear left-hand side. The cone is run at from 250 to 300 revolutions per minute by a powerful engine and the snow is discharged through the chute in the top of the hood by centrifugal force when leaving the cone, without the use of an auxiliary fan. The chute or outlet for the snow at the top is 5½x2 ft., and the opening is adjustable, so that the snow may be thrown to either side of the track. The weight of the machine is 65 tons.

The "Cyclone" snow plow was brought out during the year 1889 and did its first service on the Central (now Southern) Pacific Ry. also during the winter of 1889-90. The working portion of this plow consists of a large auger revolving within the hood upon a longitudinal shaft turned by a vertical engine of 600 horse power. This auger is $10\frac{1}{2}$ ft. in diameter at the rear portion and tapers down to a conical head at the extreme point. The auger is formed by three spiral-shaped blades of steel, $\frac{3}{8}$ to $\frac{1}{2}$ in. thick, the blades being conical in outline. Attached to the edge of each blade there is a $3\frac{1}{2}$-in. steel angle, beveled on the cutting edge. At the rear of the auger there is a fan wheel 10 ft. 4 ins. in diameter, composed of 12 blades of $^5/_{16}$-in. steel plate, turned by two engines of 600 horse power each. The hood is made of $\frac{1}{2}$-in. steel plates and is provided at the top with two openings with a swinging door between, to serve as the chute for discharging the snow. Of these three kinds of machine snow plow the Rotary or Leslie machine is the most extensively used. The manufacture of the Cyclone plow was discontinued long ago, and as late as 1904 only a comparatively few Jull plows were in service.

The ability of machine plows to handle snow of any depth ordinarily met with on railways is well established. Such plows will bore their way through a bank of snow as high as the top of the hood with all ease, and if the snow bank is much higher than the hood it is only necessary to tumble the snow down in front of the plow in order to have it thrown clear of the track. In snow exceeding 8 ft. in depth or wherever snow becomes hard packed or frozen, they are particularly in demand. For mountain districts, where snow falls very deep, and also for heavy drifts in cuts, it is the most effective type of plow. Its progress is much slower than the push plow doing ordinary open work, but nothing short of a solid mass of ice can stall it. It also throws the snow well clear of the track, whereas the push plow can not always fling the snow out of deep cuts. No road which has difficulty in keeping the track clear with push plows should be without one. In side drifts that are hard packed or mixed with sand or dirt, where it might be dangerous to use a push plow without first shoveling down the high side, the machine plow can be operated without difficulty and without leveling up the drift. These plows will throw the snow in a solid stream of about 4 ft. diameter, from 50 to 150 ft. from the track, the plow traveling at a speed which will perhaps not exceed 6 miles per hour in heavy snow and 12 or 15 miles per hour in light snow. The records of the Fremont, Elkhorn & Missouri Valley R. R. (Chicago & Northwestern Ry. system), where as many as six rotary machines have been in service at one time, show that the machine has gone through 400 ft. of snow 8 to 12 ft. deep in 2 minutes, 1830 ft. of snow $6\frac{1}{2}$ ft. deep in $3\frac{1}{2}$ minutes, 1200 ft. of snow 7 ft. deep in $5\frac{1}{2}$ minutes, etc. In heavily compacted or frozen snow of good depth the speed is one mile per hour or less.

The enormous power of the machines may be judged from the fact that in January, 1890, the "Centrifugal" plow, working between Glens Ferry and Huntington, Ore., ran afoul of a steer on the track, cutting the animal in two and throwing it out with the snow without the least impediment to the machinery. During the same winter the Denver daily papers reported a similar occurrence with a "Rotary" plow on the Colorado Midland Ry. As the story goes, a herd of cattle had taken refuge in a cut and frozen to death and eventually were buried under 15 ft. of snow. It is said that the Rotary "went right through the cut, shedding beefsteaks all over the country." These plows can work their way through heavily filled cuts where it would be impossible to lift the snow with any form of push plow, not to speak of throwing the snow out of the cut. On the switchback of the Great Northern Ry., in the Cascade mountains, before the construction of the Cascade tunnel, rotary snow plows were required almost continuously during winter time to keep the track clear. In order to avoid having to turn the plow when changing from one spur of the switchback to the other, it was arranged to have two rotaries in the same train headed in opposite directions, with two consolidation locomotives coupled between. In this manner the rotaries came alternately into service as the train moved from one leg of the switchback to the other. On the New York Central & Hudson River R. R. the rotary plow is used to widen cuts cleared by the push plow. After the push plow has been run through the cut the men throw the side banks of snow down upon the track and the rotary is then run along to clear out the cut again.

Wing Snow Plows.—A wing plow is one having extensions or wings at the sides for widening a cut previously plowed out. A very common arrangement is to attach wings to the sides of a box car or some special

Fig. 413.—Wing Snow Plow and Flanger, Vermont Valley R. R.

car and couple it on at the rear end of a train. On the Minneapolis, St. Paul & Sault Ste. Marie and the Duluth, South Shore & Atlantic roads a rotary plow is first used to clear the cut, after which a wing plow is run through the cut pulling down the snow from the bank on either side and depositing it in the track behind the car. A second trip of the rotary clears out the cut again. This wing plow is formed by constructing a heavy framework on a flat car, to which is attached, on either side a wing, opening to the front. These wings shear the snow 8 ft. from the center of the track. The purpose of widening cuts through snow is to make room for snow thrown out by flangers and to facilitate plowing out later accumulations of freshly fallen or drifted snow. The use of a wing plow in deep snow may thus enable pilot plows to take care of light snowfalls or drifting snow from that time on. Where a cut through deep snow is not widened out beyond the ordinary clearance lines refuge niches should be cut in the walls of the snow at intervals to protect workmen from passing trains.

The most approved arrangement is to combine the wings with a push plow. A good example of this kind of construction is a car built by the Vermont Valley R. R., shown in Fig. 413. The plow is 7 ft. 8 ins wide on the cutting edge and 8 ft. 2 ins. wide above the cutting edge, which is made adjustable, for flanging purposes. The car is 32 ft. long and the outside width of the car body is 7 ft., being narrower than the width of the plow, to afford recesses for the wings. The extreme hight of the car is 13 ft. 8 ins. and the hight of the plow is 10½ ft. above top of rail. The framework, especially at the forward end, is strongly built and the car is mounted upon locomotive trucks. The plow is heavily ballasted, the space under the flooring, between the sills, in the vicinity of the trucks, being filled in solid with pieces of old rail. The weight of the car is 54,000 lbs. The plow is built strong enough to stand up under work requiring three locomotives for the pushing force, if necessary. The plow is faced with hard pine, which is covered with galvanized sheet iron. Extending over the face of the plow there is a guard to prevent snow from flying against the lookout

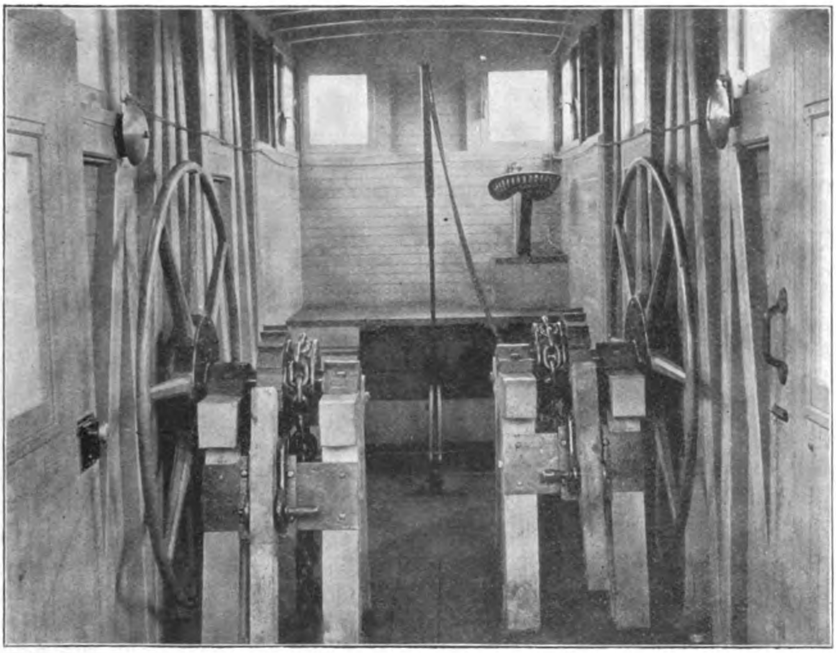

Fig. 414.—Interior of Vermont Valley Wing Snow Plow.

windows. On this guard there is placed a locomotive headlight and a locomotive bell. The wings are huge doors hung at the sides of the car and operated from within. They are constructed of two thicknesses of heavy plank bolted together, and a strip 3 ft. high from the bottom edge is faced with ¼-in. steel plate. When the wings are extended their full width they have a sweep of 17 ft. To secure firm anchorage for the hinges of the wings the sides of the car are reinforced with plank. The mechanism for operating the wings and the nose of the plow is shown in the interior view, Fig. 414. The large wheel at each side of the car operates a sprocket wheel and chain, the latter running over pulleys in a manner to pull on the end of the arm or strut which throws out the wing on the same side of the car. One end of the chain is attached to the wing direct and the other end to the end of the arm, thus affording a means for moving the wing either outward or inward. To hold the wings up to their work there is a large cast iron ratchet on the shaft of the sprocket wheel, which is engaged by a $2\frac{1}{2}$x3-in, red oak dog, which will split and save the mechanism from breakage in case the wing should meet with a solid obstruction. When the pressure against the wing is very hard it is released by striking the dog with a hammer. In case the dog becomes split it is reversed on its supporting pin and this expedient may be resorted to until all four corners become split off. The seat for the lookout or pilot appears in the right-hand corner. In front of the seat there is a conductor's valve, for operating the air brakes, with which the car is equipped, for use in emergency, and a cord runs to the locomotive bell in front. There is also a cord running to an alarm bell in the locomotive cab. The signals for operating the wings are delivered by bells, one bell for each wing. These bells have different tones, to avoid mistakes when it is desired to operate only one of the wings. The long lever in the center of the car adjusts the movable nose or cutting edge. The lifting mechanism consists of roller-ended struts operated by the lever. The movable point or nose is a heavy cast

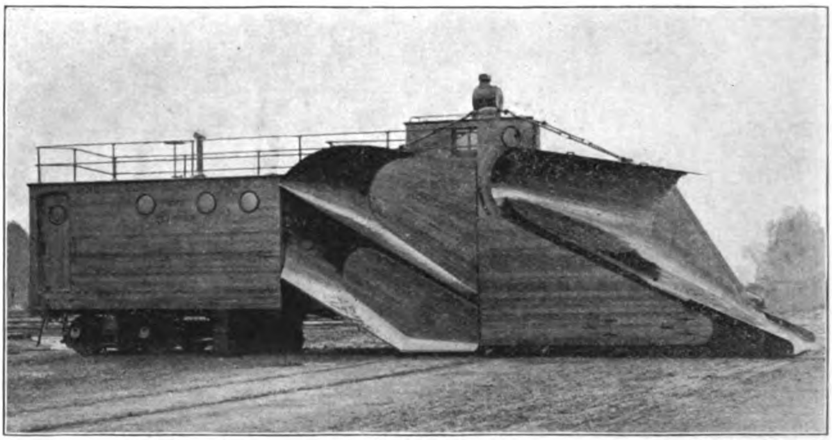

Fig. 415.—Russell Wing-Elevator Snow Plow, C. & W. M. Ry.

iron plate. For flanging out the space between the rails there is a 1-in. steel plate bolted to the nose casting (Fig. 413), and the side cutters consist of $\frac{5}{8}$-in. steel plates bolted in the same manner. To facilitate adjustment the bolt holes of these cutter plates are slotted. The cutter or flanging plate between the rails reaches 3 ins. below top of rail and the outside plates reach as low as top of rail. When the nose is dropped for flanging it bears upon shoes which slide upon the rails. The plow is usually operated by the roadmaster with the assistance of four men. When operating on double track it is usual on the first trip out to run the car at high speed, with both wings wide open, throwing the snow on the inside clear across the other track. On the return trip the plow is run slowly, with only the right-hand or outer wing open. The plow has given satisfactory service in snow 8 ft. deep and in bucking hard packed snow in cuts.

The Russell "wing-elevator" snow plows are heavily built and extensively used. Figure 415 shows a plow of this type, with a flanger, built for the Chicago & West Michigan branch of the Pere Marquette R. R. The largest plows of this design are 44 ft. long, 13 ft. 10 ins. high, 10 ft. 1 in. wide at the front and 16 ft. 4 ins. in outline width with both wings open. The plow is carried upon two 4-wheel trucks, the front truck being of special design, with eight journals—one each side of each wheel. The weight is 35 tons. The wing feature of the plow consists of a heavy framework constructed of double courses of oak plank and hinged to a post at either side of the car. The outer face of each wing is formed into two concave portions or chutes, called "elevators," slanting upward at an angle of 30 degrees with the horizontal, so that when the wing is swung into working position the snow is carried outward and upward. This wing is hinged at its front end and the rear end is stayed by a truss rod running over the top of the post, as shown. When the wings are not in use they hang within recesses at the sides of the car. They are operated by a man in the car with hand-wheels and bevel gear, at the command of the lookout, who has a gong and code of signals. The wing can be forced out and held at any point within the limit of its movement, and the wing on one side of the car can be operated independently of that on the other side. The action of the wings is to cut under the snow and lift it, throwing it 30 to 60 ft. away, according to speed of the train, instead of crowding the snow to one side, which would be difficult if the snow was packed hard. The car is also fitted with a flanger, which is located just forward of the rear truck, and is described further along.

Snow Flangers.—A flanger is a device for holding blades in position to throw snow out of the track as the contrivance is trailed along. The blade scrapes the top of the rail or very near the top, and is notched down so as to scoop out 2 or 3 ins. below top of rail inside the track. On roads where the nuts of the track bolts are placed on the gage side of the rails the flanger blades must be notched with offsets to clear them. These blades may be placed on the pilot of an engine or be trailed behind a caboose. It is more usual, however, to rig them under a flat or box car. The blade is run slantwise to the rail, with the inner end ahead, and must be raised when approaching switches, guard rails, cattle guards, wooden insulation splices and road crossings—generally at a signal by whistle from the engineer. The apparatus for raising it may consist of a system of levers, block and tackle, windlass, or a pneumatic cylinder and piston, the supply of air being taken from the train pipe through extra auxiliary reservoirs and check valves, so as not to set the brakes. Another way in which flangers have been operated is to cut out the air brake cylinder under the tender and other cars in the train, thus rendering the brakes inoperative for the time being, so as to permit the flanger to be worked by the engineer, from the engine cab. The flanger usually consists of two parts —moldboard and knives. The knives are usually attached to the moldboard in such a manner as to be easily torn loose when meeting with an unyielding obstruction. In rear of the flanger there should be a wire broom to clear the rail of snow dug up by the flanger. The principal advantage in flanging is to make room for the wheels to crowd out accumulations of freshly fallen or drifted snow. When wheels cut their way through snow a rut is formed along each rail, and eventually the snow at the sides of these ruts becomes hard packed, and sometimes frozen into ice. When snow drifts these ruts become quickly filled, and since, owing to the conditions, the wheels cannot readily throw the snow out or crowd it aside, a good deal of it must go under them, making traction difficult and increasing the train resistance.

One of the best known snow flangers is the Priest device, designed by Mr. A. F. Priest, master mechanic of the Duluth, Missabe & Northern Ry. The cutting blades and deflecting plates are attached to a cross bar supported upon the front boxes of the engine truck by extending the outside equalizing bars. It thus works but a few inches in front of the forward wheel, or just in rear of the pilot, in which position the depth of cutting is not affected by the teetering motion of the engine on rough track, and the blades cannot move across the rails on curves. The flanger is operated by an 8-in. air cylinder placed under the running board and connecting by means of a reach rod, and is controlled by a special three-way cock in the cab, within reach of the engineer, who can instantly raise the blades or knives to clear crossing plank, guard rails, frogs etc. The backward thrust of the knives is received against the forward truck boxes. The cutting knives are $^5/_{16}$-in. steel blades and each knife is held to its wing support by a pin and bolt. In case the knife becomes broken or bent it may be disengaged by the removal of only one bolt. The knife is held 1 in. above the rail and $1\frac{1}{2}$ ins. clear of each side of the rail head; so that it will not remove torpedoes placed for danger signals. It makes a cut 12 ins. wide by 2 ins. deep inside the rail and 12 ins. wide by $\frac{1}{2}$-in. deep outside the rail. A safety latch is provided for holding the cutting knives in their raised position without continued use of the air. The Temple flanger is fitted to locomotive cowcatchers. The Russell flanger, already referred to, is shown as Fig. 416. The lower edge or knives of the flanger are separable from the moldboards and are easily replaced in case of breakage at guard rails or crossings. The knives drop $2\frac{1}{2}$ ins. below top of rail and are operated either by compressed air cylinders or hand levers inside the car. The flangers shown in Figs. 409, 411 and 413 are described in connection with the plows with which they are combined.

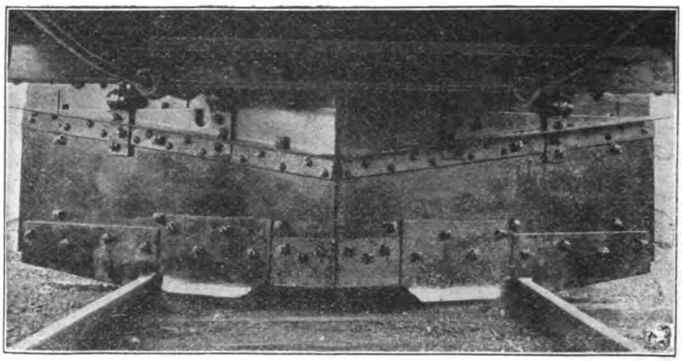

Fig. 416.—Russell Snow Flanger.

The Union Pacific and Oregon Short Line roads have a number of four-wheel flanger cars of short length, one of which is shown in Fig. 417. The car is 11 ft. long and is loaded down with old car wheels and other scrap iron to a weight of 30,000 lbs. The flanging devices consist of a set of knives and a moldboard of boiler plate on each side, the latter to lift the snow and throw it out of the way. The flanger knives consist of a steel plate 10 ins. wide by $1\frac{1}{2}$ ins. thick, each side of each rail, attached to a rock shaft made from an old car axle, which is supported crosswise the track upon braced hangers strongly stayed to the back end of the under side of the car framing. Safety chains suspended from the car prevent the knives from being dropped too low. These knives can be raised and lowered either by hand, with the lever attachment shown, or by air from the train pipe controlled by the engineer through the brake valve in the cab. In operation the flanger car is hauled behind a locomotive, and to indicate to the engineer whether or not the flanger is working, there is a target on a staff in connection with the shaft which carries the flanger knives. Another contrivance sometimes used for flanging track on this road is a

Rodger ballast spreader car (Fig. 43) with the ballast plow removed and a snow flanger substituted in its place. In winter, while there is no other use for the spreader car, the flanging knives remain attached to the car, ready for service. The Chicago & Northwestern Ry. uses a type of flanger designed for double track, to throw all the snow to one side. The flanging arrangement is on the moldboard style, something similar to the one shown in Fig. 417, and there are three of them disposed in tandem, diagonally across the track, under a box car. There is a flanger on each rail and one between these two to scoop out the middle of the track, the flanger on the right-hand rail being in the advance (for left-hand running), with the middle flanger just to the rear and to one side of it, while the flanger on the left side is just in rear and to one side of the middle flanger, which scoops out the track 1 in. below top of rail. Each of the outside flangers is notched at the rail and bears upon the rail by a sliding shoe. The flangers are attached to rock shafts operated from the car above. On each side of the car there is a projecting box with a window in the front side to serve as a lookout.

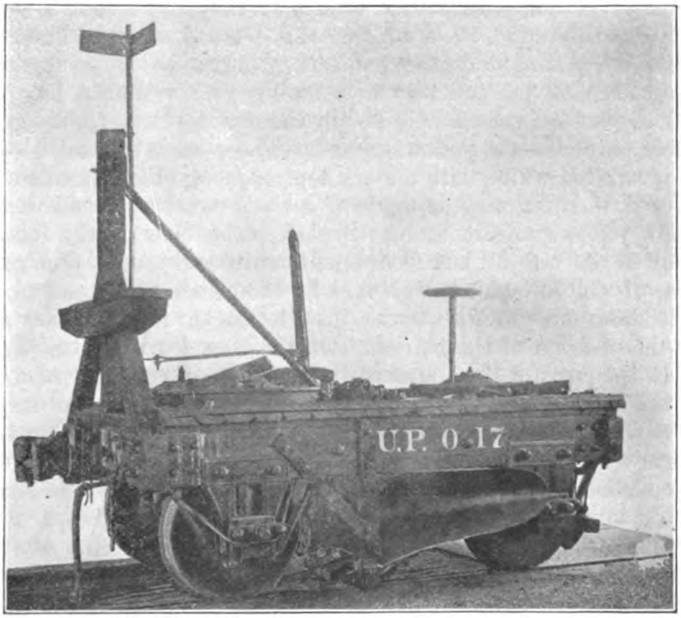

Fig. 417.—Snow Flanger Car, Union Pacific R. R.

For handling snow and ice in the Adirondack mountains the New York Central & Hudson River R. R. has a specially designed strongly-built car of the freight caboose style, with the lookout centrally located on top, as in Fig. 408. Under the car there are two pilot-shaped plows arranged for service in either direction. Each of these plows consists of vertically adjustable plates backed by heavy cast iron knees or brackets rigidly suspended from the car sills. The flanging plates are notched to plow out deeper than top of rail on the inside of the track, and they are lowered and raised by a 10-in. air cylinder, pressure being supplied by the air brake system through storage reservoirs on the car. At the sides of the car, on the flanks of the flangers, there are narrow wings hinged at an incline, to remove snow to the desired clearance for any kind of equipment. These wings are operated by an air cylinder lying horizontally on the car floor.

The operation of the flangers and side wings is controlled by air valves in the pilot house. The detail drawings are shown in the Railway and Engineering Review of March 15, 1902.

Each year before snow falls the section foremen should see that snow plow markers are set in advance of any obstruction which will interfere with the operation of the flangers. On some roads there is a fixed date on or before which all the markers are required to be up. Markers are usually placed on the engineer's side, except on some double-track roads, where it is occasionally the practice to place them across the other track. As no snow is thrown toward that side a clear view is always obtained, except when passing a train on the other track, so that, after all, the practice has its objections.

A common form of snow marker is one or two pieces of fence board 18 to 24 ins. long nailed to a post set some standard distance from the track, like 6 ft., and 30 to 50 ft. in advance of the obstruction. It is common practice also to nail a marker board about 3 ft. long well up on the first telegraph pole in advance of the obstruction. In the largest practice it is not considered necessary to paint snow markers, and they are removed in the spring and saved for future use; otherwise they are liable to be stoned by the boys and knocked off or broken up. On a few roads, however, particularly in New England, the markers are got up in good shape and painted, and remain permanently in place the year around. The Vermont Valley R. R. uses a 24x8-in. board with the corners cut off, having a 7-in. black circle painted on a yellow ground. The post is square in cross section and is painted white, with a black top. Among other conspicuous signs that are used, mention may be made of a black panel with two white bull's eyes, and a yellow panel with black spots. The New York, New Haven & Hartford R. R. uses a black board with white stars, on a post consisting of a piece of old rail painted black. If the panel gets knocked off, the black post shows up prominently against the background of snow and still indicates the position of the marker. On the New York Central & Hudson River R. R. the post for the standard snow plow marker is 2x4 ins., pine, 12 ft. long, set 4 ft. in the ground, 7 ft. from the rail. Up to 4 ft. above ground the post is painted black, and above that, white. The sign is a ¾-in. board 8 ins. wide and 2½ ft. long, painted black with a white margin. The board is nailed to the post at one end, so as to stand out at one side of the post, at the top of the same, and it points diagonally upward and away from the track at an angle of 45 deg. with the post. The ends of the board are cut off vertical.

The exact limits from the rail and below top of rail within which any object would constitute an obstruction to the flangers, should be made known to the section foremen; and any obstruction that is not necessary to a sufficient purpose should be removed. Badly rail cut ties which project high enough to be struck by the flanger blades should be adzed down. Some roadmasters keep on file a list of all obstructions to the flanger, and this list is revised from time to time as changes are made in the track, the section foremen reporting such changes at the time they are made. The list is always carried on the flanger car and consulted when running after dark. When the headlight does not give entire satisfaction this list is found to be a great convenience. It is also necessary to watch for and remove obstructions which might interfere with the operation of snow plows. At grade highway crossings the material for some little distance outside the rails and between the rails should be leveled down to the top of the rail; on the inside of curves it should be made somewhat lower, owing to the elevation. Where side-tracks turn out from the inside of curves the lead rail from the switch and the rail at the heel of the frog should run low enough to clear the nose of the plow as far as it extends laterally. In anticipation of the use of a wing plow all unnecessary obstructions should be kept cleared away from the track the required width, and a plow should be run over the road in the fall, with the wings open, so as to see that everything of the kind is clear before winter sets in, and to take note of bridges and other structures or obstructions which the plow will not pass with the wings open.

Snow Plow Work.—Outside of mountain regions, or wherever the snow fall is normal, and where drifting into cuts is not bad, snow is most quickly removed by a push plow, or "wedge" plow, as it is sometimes called. The pushing force required will, of course, depend upon the depth of the snow and its compactness. It is usual, however, to start the plow out with two locomotives to do the pushing, with a third locomotive following in the rear, commonly called the "drag-out," to assist in extricating the plow and pushers in case they get stuck in a cut. Some companies forbid the use of more than two locomotives with a push plow, on the theory that in case of derailment of the plow at high speed the great momentum of a number of locomotives is liable to cause a dangerous wreck. On the other hand, some companies favor the use of three or four and sometimes five locomotives, the idea being that with this number it is not necessary to run at high speed in order to push through a cut or heavy bank of snow, since the large capacity for traction will enable the plow to do its work at a moderate pace, thereby reducing to a minimum the ill effects of derailment, should one occur.

While a bad snow storm is in progress it is best not to start out the heavy freight trains, or at any rate the trains that are sent should be of short length. It is better to have trains in the yards than to have them stalled out on the road. In districts where the snowfall throughout the winter is frequent, it is a good plan to sheath the pilots of the locomotives to within two or three inches of the rail. Such provision will enable the regular trains to make their own way through 2 or 3 ft. of snow, and in this way the road can, in many instances, be kept open without a special plow. At any rate when snow is falling fast it may accumulate as deep as 2 ft. soon after the plow has passed, so that pilot plows are to be recommended in any event where snow is particularly troublesome. On the Chicago, Burlington & Quincy Ry. strips of wood are nailed in between the bars or slats of the pilots, so as to form a solid face or surface. It is not always best to hold the plow back waiting for the storm to stop, lest it may get the start of things. As soon as the depth of the snow begins to look threatening or as soon as it begins to drift, the plow should not wait any longer. Some roads make it the practice to run the plow continually during snow storms, after the snow once becomes deep enough to plow off. In starting out, the heaviest, best steaming freight locomotive should be taken. It should be coupled to the plow short, leaving little or no slack. Rather than use a bar coupling a switch engine should be taken or else the pilot may be removed from one of the road engines. The same precaution applies to additional engines which may be sent along as helpers. It is well to carry a piece of steam hose for heating water in the tender tank, so that snow may be melted as a water supply if need be. Water should be taken at every tank passed whether needed at the time or not. A car-load of coal should be carried next the tender of the "drag-out," the work-train boarding car and caboose, and the work-train crew, supplied with scoop shovels and some sharp picks. No flanger car need be run until after the track is once cleared. It is best, however, to run the wing plow early, while the snow is soft, and herein lies the advantage in having the wings combined with the push plow; otherwise it may be hauled by the "drag-out." In snow of moderate depth the wings of a push plow may be opened out part way or perhaps to full extent on the first trip over the road, but in deep snow it may not be practicable to open them out fully until making the second trip: this is a question of motive power. At the most there need be but four cars besides the locomotives and push plow. All section foremen should be under instructions to keep watch of snow accumulations in time of storms and report early by wire to the roadmaster the condition of things along their sections, as far as they can ascertain. If, then, before starting, it is known that the snow along any part of the division is exceedingly deep, or that cuts are badly drifted; or if the wires are down, so that information cannot be had, the third locomotive or "drag-out," already referred to, should by all means follow, hauling the train and hands, the first two handling simply the plow. It is best to have these two engines coupled together, whether both are needed constantly or not, especially after dark or while snow is falling thick. Cars should never be placed between two engines which are pushing a snow plow. If all the engines are used in making a run at a bad cut it is well to cut the train loose and hold it back until the cut is cleared, so that there will be no possibility of the whole train getting stuck in the cut.

In plowing snow where the track is not raised much above the surrounding level the train should be run at considerable speed, so as to throw the snow a good distance and scatter it. In such places it is undesirable to pile the snow up at the side of the track, as if the snow drifts it will settle on the track as high as the side heaps. The plow will not usually find difficulty except at cuts. Here, if the snow be deep, the engine or engines and the plow back up and take a run at it, striking at good speed; hence the term "bucking" the cut. If they fail to go through, the plow, and usually one or all the engines, will be stuck fast and unable to get either way until shoveled out by the crew. Before striking the cut the man in charge must make sure that no one is working in it. No men should ever work in a cut filled with snow unless there is a watchman posted on top to warn them of approaching trains; but the whistle should nevertheless be sounded before entering the cut. If, upon approaching a drifted cut, the appearance of things is not entirely satisfactory, it is usually best to stop and look the cut over. If the snow at the mouth of the cut is shallow and compact or frozen it should be shoveled away until a depth of 3 ft. is had, on the leaving as well as the entering end of the cut. If the wall of snow at the entrance is hard, it should be undercut. The hardest snow is usually found at the ends of the cut. Diagonal drifts across the mouth of the cut, especially if the snow is mixed with sand or dirt, are the most dangerous, and before striking such a drift its face should be squared up. Ice in the cut may be discovered by probing through the snow with a bar or by sinking test pits.

If the plow cannot be got through a cut after repeated attempts, or if the bottom is frozen into ice, such that the plow will leave the rail, resort is sometimes had to hauling out the snow in blocks, with locomotive and switch rope. The snow is cut into blocks about 10 ft. square, by shoveling around in trenches. The switch rope is attached to the block by running it around near the bottom, placing short pieces of board at the corners to keep the rope from cutting in too deeply. Another way of getting through a hard cut has been already described; that is, by shoveling out sections of the snow at intervals. Such preparation is frequently completed by the section men in advance of the arrival of the train. If the cut is deep the snow must be handled over several times, perhaps, before it can be got out of the cut. The usual method is to arrange the men on benches, or ledges cut in the snow, each shoveler passing the snow on to the next shoveler above, and so on—a slow and laborious process.

Engineers who push snow plows should be men of good judgment, willing, able to handle their engines to advantage, and not in the least timid. Only judgment gained from experience can teach men what would be a reckless speed under any given circumstances. A speed too slow will frequently be the cause of getting stuck. It is work always attended with more or less danger, but it must be done with decision and firmness, else poor success. The roadmaster or man in charge must needs be the responsible party, and he should therefore not shrink from taking his post where the danger is. He should not accuse an engineer of timidity when he is afraid to ride with that engineer in the cab. In handling push plows the flying snow usually obscures the vision of the engineer, so that, in the movement of the train, he must be guided by signals from the pilot on the plow. Such signals are usually given by bell and cord. It has sometimes been the practice to use the locomotive whistle as a means of signaling the engineer, the pilot on the plow having a line running to the whistle for that purpose. Whenever such a system is used it should be the understanding that the engineer must do no whistling at all, for if he should the pilot would have no way to signal him while he is blowing. The plow should be equipped with a conductor's valve, for applying the brakes on short notice, and also with a locomotive bell to warn people to get off the track.

A difficulty often experienced is the inability to see ahead from the plow, on account of the blinding effect of snow thrown up by the plow, or by snow sticking fast to the lookout windows. It is usually an advantage in this respect to look ahead from the windward side, and alcohol may be wiped over the glass to prevent snow from sticking. Use is also made of portable bay windows, to some extent. Of these there are two different styles, namely V-shaped and box-shaped, and they are pushed out of a hole in the side door, or in the side of the car. Another scheme that has been put into practice on several roads is to extend a long box-like peep tube forward from the lookout window at each side of the front end of the plow car. These tubes are about 12 ins. square in cross section, are made of boards, and extend ahead of the plow or far enough to be ahead of the snow thrown up by the plow.

After the train with the plow has got over the road it should start back with the flanger, if the storm is over by that time. It is, of course, an advantage to have a flanger on the plow, as then both plowing and flanging may be done simultaneously and a clear rail may be made for the engine pushing the plow. Where the plow is not so equipped it is frequently the practice to couple a flanger car on behind the engine or engines that are pushing the plow. It is a good plan in any case to do the flanging early, while the snow is soft. If a thaw comes and the snow next the rail suddenly freezes into ice, it cannot be flanged with the machine, but must be dug out with pick and shovel. The stretches of track missed in lifting the flanger at the marker boards are cleaned out by the section men. On the way back it is well to run through all side tracks with the plow, so as to save section men the work of cleaning them out. Necessary repairs to snow plows should be made before they are put away for the summer, else the matter may be forgotten and left until snow begins falling again. Snow is usually most troublesome to roads not prepared for it, as is instanced every few years by blockades in the East when snow falls to a depth of 4 or 5 ft.

CHAPTER XI.

MISCELLANEOUS.

151. Fence.—In nearly all the states railroad companies are required by law to fence in their tracks. As applying to unimproved or unenclosed lands, the law in some cases is modified or made inapplicable where the need of a fence is not shown. Thus, the obligation of the company is sometimes determined by the railroad commissioners of the state; or in other instances, and in well settled districts, often, the owner of land adjoining the company's right of way must first enclose his land with fence on all boundaries except that of the right of way, before the need of a fence along the right of way is supposed to exist. In their specifications or terms the fence laws of the different states are almost as varying as the number of states, except in the one particular—that the whole expense of building and maintaining right-of-way fences must be borne by the railroad companies. Failure to comply with the law usually places the company liable to heavy fines, which in cases are made accumulative; or for the market value of stock killed, or double the market value; or for the single or double appraised amount of injury to stock done by trains; or for injury received from an illegal fence; or for crops destroyed by stock gaining ingress over the company's right of way; and in other instances failure to provide fence makes the company liable for the actual cost of the fence when built by the adjoining landowner, or for a certain price per rod of fence so built, with usurious rates of interest until paid.

In most of the states the maintaining of a legal fence and cattle guards in good condition releases the railroad company from payment for damage to animals getting on the track through the owner's negligence. The laws of some states also provide that where abutting landowners are under contract with the railroad company to keep up the fences, the latter cannot then be held liable for killing or injuring animals which get on the track or right of way, except where such killing or injury is willfully done. In view of such enactments it behooves the railroad company, when building fence, to conform to what constitutes in the state a legal fence, whether such be compulsory or otherwise. It is important to have it everywhere the full legal hight, for the slightest variation from this requirement might have great weight with a jury. Although there is no fence which can be constructed at a reasonable cost that will hold certain unruly animals, yet if the law does permit a choice or any improvement on the legal fence it will generally pay the company to build only the best—making it as nearly "bull-proof" and "hog-tight" as a reasonable expenditure will permit. Exemption from payment for animals killed or injured should not beget with the railroad company an indifference as to whether or not animals shall be kept from trespassing the right of way. An animal struck while lying in the track, or by a slow-moving train, has often thrown the locomotive from the track and damaged the railroad company more than the cost of right-of-way fence for half a division.

A fence 4½ ft. high comes nearest to the legal fence in the majority of cases. One or more of such kinds as board, wire, part board and part wire, worm fence, and some others, are allowed in cases, but the wire, or part board and part wire, nearly always. Generally considered, barbed wire is the best material for a railroad fence. It is cheap, reasonably efficient and durable. It cannot be burned, or, at most, nothing but the posts can, and fire cannot travel along it as it can along board fence. It catches less drifting snow than a board fence and is less favorable to the growth of weeds. The chief objection to the use of barbed wire is the fact that it will injure stock if the animals get astride of it. If a board or rail be used for the top of the fence, however, so that the animals can see the fence in the night, there is but little danger of severe injury to stock. On this account the combination part wire and part board fence is well liked, and sometimes two top boards or a top board and cap are used. For a top rail a 2x4-in. scantling, mortised into the posts, is commonly used, but split rails are more durable. Split chestnut rails mortised into the posts are used a good deal in the East, and they last a long time. The top board or rail is also useful in another way, in that it serves as a brace to keep the posts properly spaced.

Touching now a point just merely mentioned above, it is not always desirable that right-of-way fence should hold drifting snow; as for instance, on level ground, where there is no liability that the track will be drifted, a board fence might cause the formation of snow banks which would extend to the track; while with track in a cut, where drifts are liable to form, the board fence, if at the proper distance, may be made to answer for a snow fence as well as a line fence. The same applies to stone fence, which is used in some parts of the country where stone is plentiful and convenient to the location. The proper hight for a stone wall fence is about 4½ ft. It will not rot or burn down, and when it is well built but very little work is required to keep it in repair. It is also an absolute stop to small animals.

Fence Posts.—Posts for fence should be of durable wood, like white or red cedar or chestnut, and the bark should be removed. When the bark is left on it hastens decay of the post, and in dry weather it increases the liability of catching fire. Locust is very good, but generally scarce, and white oak is quite durable. The life of a fence is in its posts. The bottom or buried portion of the post can be preserved either by charring the outside or dipping it in hot coal tar, and a small heap of stones placed around the post will have a tendency to keep back the weeds and afford it some protection against fire. On some roads it is the practice to reverse the posts after the bottom part becomes considerably rotted in the ground. In this way the bottom can be made to last until the entire post is about gone. The liability of wooden posts to burn and the growing scarcity of timber in some quarters have led to the use of metal fence posts to a considerable extent. It is to be remarked to the credit of metal posts that they are, or ought to be, more durable than wood, they are not lifted out of the ground when overflown by the rising of streams; and grass, weeds and rubbish along the fence can be burned without injuring the posts.

The International steel fence post is tubular in form, tapering slightly from bottom to top, and is rolled from a sheet of cold metal (No. 16 gage), so that an open seam remains. The 7-ft. post is 2¼ ins. in diam. at the top, 3½ ins. in diam. at the bottom and weighs 13 lbs. The post is driven into the ground with a wooden maul, the blows being received upon a driving cap placed on the top of the post temporarily while it is being set. As the post is driven it spreads open at the bottom and thus takes a form well suited to resist being pulled up. After the post is driven the top is compressed by a pair of tongs and a permanent cap is slipped on. Holes are punched at proper intervals for the wires, which are held by long staples passing through the post. The end post is braced by a piece of gas pipe fitting against the post by a collar, or by stay wires anchored to a stone or piece of timber buried in the ground. The Kokomo steel fence post is an angle bar of V-shaped section, with a spear-shaped point reinforced by a cast block fitting into the 60-deg. angle of the steel bar. Just beneath the surface of the ground there is a 9x3-in. breast plate riveted to the post to resist the sidewise pull. The post is set by driving and the wires are fastened with staples secured in holes punched through the angle of the bar. The end and corner posts are made of 3-in. heavy angle steel and are braced by a truss formed by two $1\frac{1}{2}$x$\frac{1}{2}$-in. pieces of steel $7\frac{1}{2}$ ft. long with spools between. The bottom of the post is riveted to a cast iron anchor plate 10 ins. square and $\frac{1}{2}$ in. thick, while near the surface of the ground there are two breast plates 4 ins. wide and 20 ins. long set at right angles to each other. The total weight of the 8-ft. end or corner post is 105 lbs. The Avery post is semicircular in section, tapering from bottom to top. Near the bottom there are upwardly pointing prongs or barbs stamped out of the

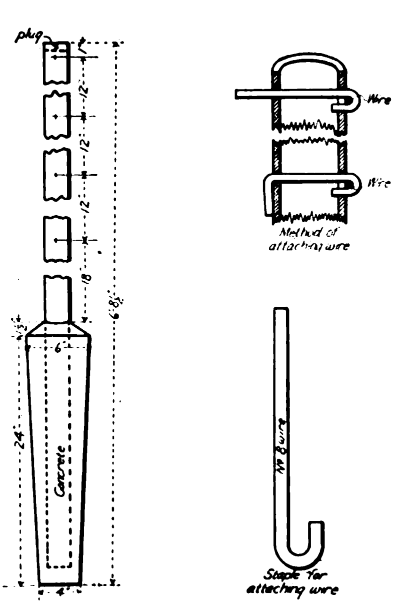

Fig. 418.—Boiler Tube Fence Post, B. & M. R. R. R.

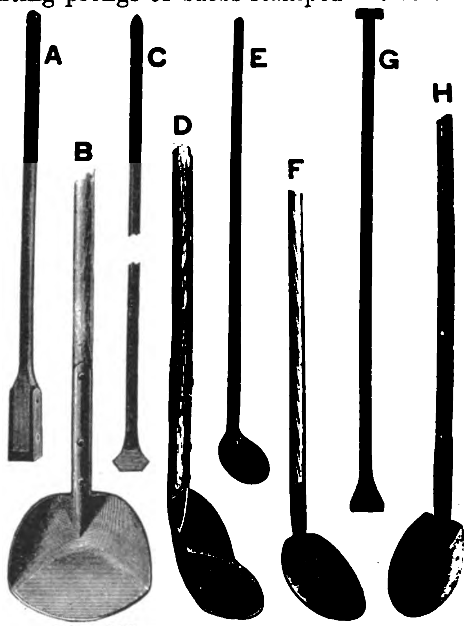

Fig. 419.—Tools for Setting Telegraph Poles and Fence Posts.

post to give it firm anchorage. The Mathews steel fence post is Y-shaped in section, with legs $1\frac{3}{4}$x$\frac{1}{4}$ in., and is securely attached to a piece of vitrified sewer pipe 6 ins. in diameter and 12 ins. long, for setting in the ground, as shown by Engraving *C*, Fig. 427. In setting the post the dirt is tamped both inside and outside the pipe, and the bottom of the pipe has a rim about $2\frac{1}{2}$ ins. wide which prevents the pipe from being pulled up. The end and corner posts are made heavier, of T-shaped sections $2\frac{1}{4}$x$2\frac{1}{4}$x$^5/_{16}$-in., attached to a piece of sewer pipe 10 ins. in diameter and 2 ft. 4 ins. long. The post is set $3\frac{1}{2}$ ft. deep and is braced by an angle bar footing against a stone in the ground.

The use of steel or iron for fence and sign posts is now generally in combination with a base of brick, terra cotta, vitrified clay or concrete moulded about the foot to give the post sufficient bearing in the ground, and protect it from corrosion. Some steel shape, like an angle, a "T," a channel or an I-beam section, or a tube is commonly used, and as for the base or butt there are many patented devices. The Climax fence post has a base of hollow vitrified and glazed fire clay, square in cross section, with ribs on the corners. In this there is a high-carbon steel angle set with cement. The "Durable" post is a combination of wood, iron and cement In the cement butt, which is 26 ins. long and 4 ins. square in cross section, are embedded two iron straps about 2½ ins. apart and projecting about 8 ins. above the top. Between these straps is bolted a painted oak post, which can be renewed without digging up the butt. The "ravine" pattern, designed to withstand the upward pull of fence wires stretched taut across a ravine or other depression, has a butt which widens out toward the bottom like a pyramid. It is to some extent the practice to mould the butts of combination concrete posts in the ground. A post hole is dug and filled with freshly mixed concrete, and into this the post is driven and the concrete permitted to set. As soon as the concrete hardens the post is firmly embedded without tamping. One scheme when setting posts in this manner is to sink a wooden stake into the concrete, and after the latter sets an iron or steel post is screwed into the stake. When the stake rots it can be pulled out and a sound one driven in its place.

The Burlington & Missouri River R. R. has made extensive use of combination fence posts by utilizing discarded boiler tubes, which are a staple scrap article with railroad companies. The post is constructed by moulding a concrete butt 25½ ins. high, 6 ins. square at the top and 4 ins. square at the bottom, around one end of a section of boiler tube 6½ ft. long. For line posts 2-in. and 2¼-in. tubes are used, and for corner posts and braces 2½-in. tubes. The corner post has a concrete base 10 ins. square and 6 ins. high, surmounted by a mass of concrete 6 ins. square and 24 ins high, the bottom part thus forming an anchor to prevent the post from being pulled out. At the foot of each brace piece there is a concrete pyramid 10 ins. square at the base and 21 ins. long, to afford bearing for the brace in the ground. The details of the line post are illustrated in Fig. 418. To protect the post from rust at the surface of the ground, the top of the concrete butt is sloped down for 1½ ins., so that dirt will wash down and keep from contact with the iron. The concrete is composed of one part cement, three parts of sand and three parts of screened crushed stone in sizes from that of a grain of corn up to a walnut. The posts are made in batteries of 48 moulds each. Before the concrete base is put on the tube is filled with mortar made of cement and sand, and then plugged at the top. This filling serves to stiffen the tube and keep it from rusting on the inside. After the post is made the iron is coated with a hot mixture of pitch and gas tar. The company has a plant at Lincoln, Neb., worked to a capacity of 150 posts per day, produced by the labor of about 4¼ men, on an average. Since 6000 to 8000 boiler tubes are scrapped each year, and as this material is of but little value as scrap iron, the posts can be produced relatively cheap. The cost varies from 16 to 19½ cents per post, as against 12½ cents for red cedar and 16 or 16½ cents for oak posts. The wires are held to the post by staples running entirely through the post and clinched on the back side. The details of the design of the post were worked out by Mr. T. E. Calvert, general superintendent. A source of extraordinary expense before these posts were used was the loss of wooden fence posts by prairie fires. It was estimated that an average of 10,000 posts were lost annually from this cause, as experience showed that more than half of the wooden fence posts along the line were destroyed by fire during the natural life of a wooden post.

Building Fence.—Wooden posts should not be set by driving, because such method necessitates sharpening the post, and a sharpened post is much more liable to be heaved up by frost than a post with a squarely-cut end at the bottom. In sharpening a post for hand driving it is necessary to hew it down to a long point, and the large amount of material cut away shortens the life of the post, as there is then less timber at the bottom of the post to resist decay. In the prairie states small pile drivers built on wheels have been used to some extent for driving fence posts. When thus driven a blunt point answers the purpose sufficiently well and is better for the fence.

A common length for fence posts is 7 ft. and the usual depth for setting the post is 2½ ft., but 3 ft. is a better depth for posts in soft ground or ground that freezes deeply in winter. Increased depth of setting, requires, of course, a longer post. The post should be at least 6 ins. in diameter at the large end and that end should be set in the ground. For either board or wire fence the posts should stand an equal hight above the general surface of the ground and they should extend but little above the top board or wire. To obtain such uniformity it may be necessary in cases to vary slightly the depth of setting. If the lengths of the posts vary—which they should not—the tops of the long posts may be sawed off, if the digging is too difficult for setting the post an extra depth, but posts considerably shorter than standard length should not be used.

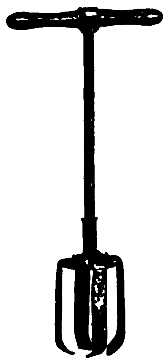

Fig. 422.

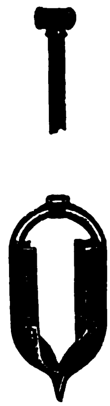

Fig. 423.

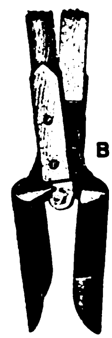

Fig. 424.

Post-Hole Augers and Diggers.

The right of way boundary is usually located by measuring out from the center of the track. On tangent such measurements need not be taken at nearer intervals than 100 or 200 ft., as the posts between can be lined by the eye, or perhaps better by stretching a chain tagged at intervals corresponding to the spacing of the posts. Along curved track the distance to the boundary should be checked at least every 50 ft. Post-hole excavators or "diggers" are much used in setting fence posts, and in mellow ground or where there are but few stones they are labor-saving devices, doing the work more rapidly than a bar and shovel or "spoon" (Engraving *E*, Fig. 419). An ordinary post-hole auger is shown as Fig. 420. Figure 424 shows the lower portion of the Eureka post-hole digger, commonly known as the "scissors" type. It consists of a pair of pointed segmental spades so jointed together that when rotated they cut a cylindrical hole, and by spreading the two handles apart they close upon the material, tongs-fashion, so that it may be lifted out of the hole. In hard ground the material must first be loosened by jabbing with a bar. Figure 421 shows the Champion digger with an iron handle. Figure 423 shows the Rapid post-hole auger and Fig. 422 the Monarch post-hole auger. The blades of the latter are radially adjustable to bore holes 7 to 9 ins. in diameter. In favorable material the blades are usually filled in four revolutions. This auger has been used in digging wells as deep as 30 ft. These excavators will take out about a gallon of dirt at each lift and they dig a hole but little larger than the post.

Three men can work together to advantage in setting posts, one man digging the holes and two men setting the posts and tamping the dirt around them. The man who digs the holes cannot keep out of the way of the post setters, and so whenever they overtake him he goes ahead and starts a new hole, while one of the post setters completes the unfinished hole and the other man carries posts over from the track. Under very favorable conditions three men have dug the holes and carried and set 180 fence posts in a day, but an ordinary record would be about 100 posts per day.

In boggy land where fence posts will not hold, and on rocky ground where post holes cannot be excavated by ordinary methods, the posts may be mortised or drift-bolted to sills of old ties or old bridge timber laid down transversely to the line of the fence. To secure the post in the upright position a brace piece may be spiked to the side of the sill and the side of the post. On rocky ground A-frames are sometimes substituted for posts, such being made by using two posts for the legs and tying them across the bottom by spiking a piece of fence board on each side.

Posts for a board fence are usually set 8 ft. apart center to center, and the boards in most common use are 1x6 ins. x 16 or 24 ft. long, of culled pine, hemlock or other cheap lumber. A fence four boards high will answer, but it is better to have five boards, especially if there are small animals, like pigs and lambs, to keep out. In a four-board fence the bottom of the first board should be about 4 ins. from the ground, then a 6-in. spacing between it and the second board, the two other boards dividing equally the remaining space. All of the boards should be nailed to the field side of the posts and be cut to meet those of another panel end to end, instead of overlapping. It strengthens the fence very much if the boards are made to break joints at the posts, but on uneven ground this plan is not practicable; otherwise, that is, if the ends of all the boards meet at the same post, a 1x6-in. batten as high as the fence should be nailed over the ends of the boards to cover the joints. It also strengthens a fence to use a cap board. This board is sometimes nailed flat on the tops of the posts, but it is considered better practice to cut the tops of the posts off to an angle of 25 to 45 deg. with the horizontal, and it is preferable to have the cap meet and cover the edge of the top side board. Each board should be nailed to each post with three 10d wire nails at the ends and with two at the middle post. A fence built of 16-ft. boards without battens will require 45 lbs. of nails per mile per one board high. There are 65 10d wire nails in a pound. A good way to arrange the work of nailing on boards is to have two men go ahead and tack them to the posts, with one man to follow after and complete the nailing.

Ordinary barbed wire, commonly known as "cattle wire," consists of two twisted strands with a two-pointed barb about every 3 ins. The weight of a single wire per mile is 330 to 380 lbs. "Hog wire" has four-pointed barbs and weighs about 400 lbs. per mile of single wire. Buckthorn barbed wire is a steel band or ribbon with ¼-in. saw-teeth barbs about 1-in. apart on the edges of the band. In order to present barbs in all directions the wire is twisted. This wire is more easily seen by stock than strand wire. Both twisted ribbon and twisted strands without barbs are used to some extent for fence wire. Barbed wires stretched over long panels are sometimes tied together by pieces of band iron at intervals of about 8 ft. between the posts, to prevent the wires from sagging or being spread apart. Staples, of the size commonly used in building wire fence, number about 70 to the pound, so that about 5 lbs. are required per wire per mile, posts 16 ft. apart.

Wire fence should be at least four wires high, or three wires with a board or stretcher at the top; but six wires alone or five wires with a top board are considered only ordinary construction; it requires six or seven wires to keep hogs, sheep and calves from crawling through. To hold such animals there should be four or five wires within 2 ft. of the ground, the lower wire not farther than 3 ins. from the ground and the next two spaced at 4 ins. In some states the law allows posts for railway wire fence to be placed as far as 30 ft. apart, if pickets are interwoven between and the wires stapled to the same, to make them act together and maintain them at an even spacing. Thirty feet, however, is too far apart. Where a board or rail is placed at the top the posts should not be farther than 12 ft. apart and the boards should extend over two panels. For an all-wire fence the posts should be not farther than 16 ft. apart, or 20 ft. where there are pickets or stays fastened to the wires between the posts. On some roads the posts are set as close as 8 ft. apart.

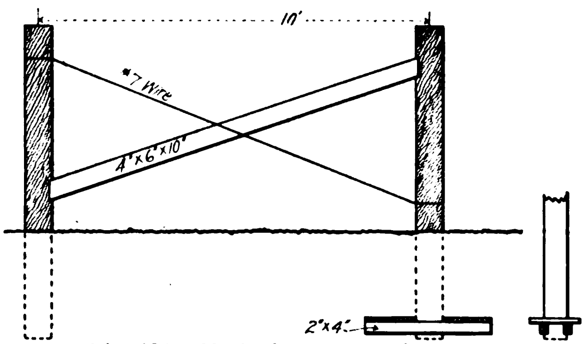

Fig. 425.—Methods of Anchoring End Posts.

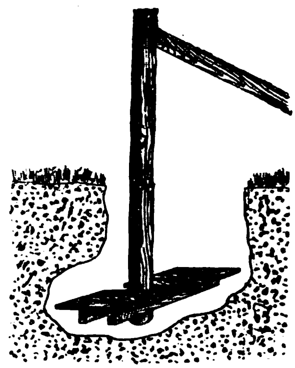

Fig. 426.

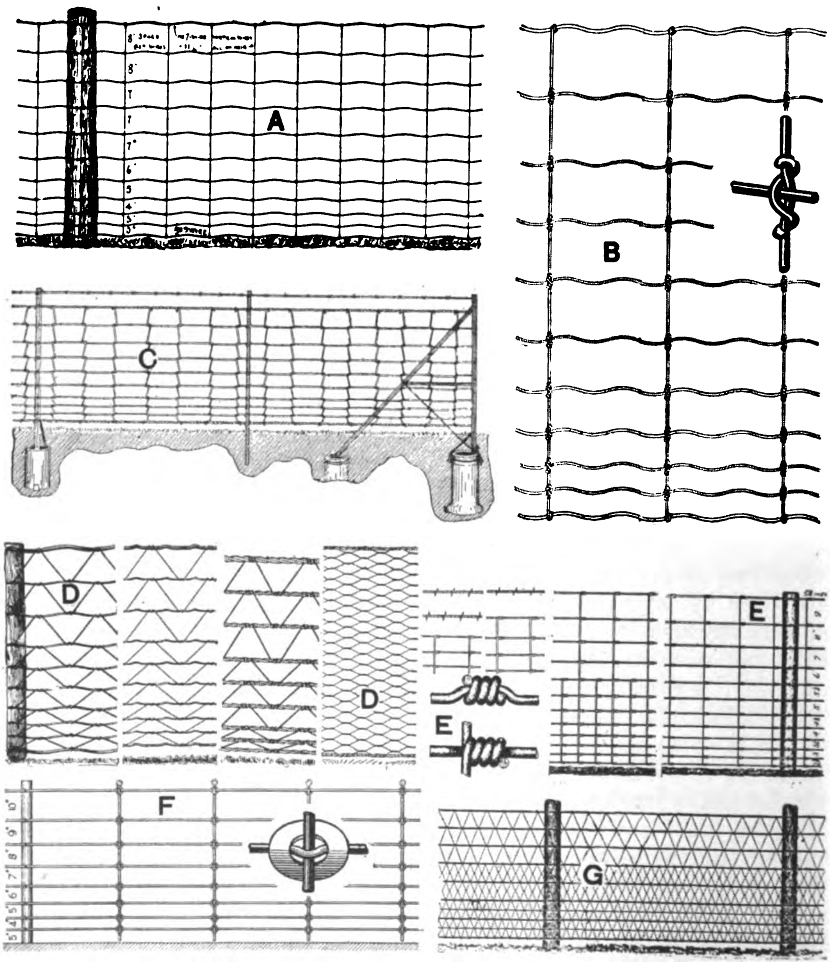
Posts at the end of a wire fence or at each side of a gate or cattle guard should be braced by a leaning post, the foot of the latter being supported against the adjoining fence post at the ground, or against a stake firmly driven; and posts at intervals of 200 ft. should be braced, either with two leaning posts or by heavy stay wires wrapped around the top of the post and anchored to adjoining posts at the ground. Figure 427A shows another method of bracing end posts. End and corner posts should be larger in diameter and longer than the intermediate ones, and should be set 4 to $4\frac{1}{2}$ ft. in the ground. Additional bracing may be given to an end post by nailing an anchor board across the post near the bottom, on the rear side, and another near the top of the hole on the front side, with reference to the direction in which the wires pull. Corner posts should be braced with leaning posts butting at the ground against other fence posts (Fig. 425) placed at half panel distance from the corner. A braced post or a post which comes in a hollow should be anchored, to resist being pulled up by the tension of the wires. One way of doing this is to bore a hole through the post near the bottom and run a bar of iron through the hole; another way is to spike a piece of board across the post near the bottom, and preferably on each side of the post. A very secure method of anchoring a post is shown in Fig. 426.

The bottom wire may be anchored between the posts by driving a stake into the ground and securing the wire to the stake with a staple, or a stone with a tie wire attached may be buried 18 ins. or 2 feet deep to serve as an anchor. The necessity for anchoring the bottom wire arises where the posts are a long distance apart or where the wire crosses a low spot in the ground.

If the fence is a combination board and wire structure the boards should be nailed to the posts before the wires are stretched. On uneven ground only one wire should be reeled out and stretched at a time. Where two or more wires are unrolled before any is stretched they get tangled. Some prefer to follow this plan in all cases, but where the ground is even over long distances it is commonly the practice to first reel out all the wires ready for stretching, the wires lying on the ground some distance apart or at different distances from the fence line, to prevent tangling. Then men are stationed 15 or 20 rods apart, and one man does the stretching with block and tackle while the others pick the wire up out of the grass and hold it off the ground until it is tight enough, when each staples it to the post where he is standing. This procedure is repeated with each wire until they are all up and stapled to enough posts to prevent appreciable sag, when each man proceeds to drive all the remaining staples on his section. The posts should be marked to indicate the spacing of the wires, and for this purpose use may be made of a marker board or gage. It takes a man 1 to 1¼ hours to mark the posts for a mile of fence. To reel out the wire a bar is run through the roll and two men carry it between them, but where there is a top board they put the bundle of wire up and roll it along on the fence, steadying it with the bar. On level ground one man can do this alone, but up and down hill two men are required. In stretching the wire it is pulled taut over a number of panels and tacked to several posts near the stretcher before letting go. It is a good plan to have the stretcher right along with or just behind the roll of wire and to stretch it up and secure it to the posts as fast as it is reeled out. It is a good deal of bother to pull up the slack when the reel gets far ahead of the stretching. The wires should be put on the field side of the posts, except on fence which bounds the inside of a curved right of way, when it should be on the track side; although in cases of this kind the wire is sometimes stapled to alternate sides of consecutive posts. On corner posts the wire must, of course, be placed so as to pull against the post. A serviceable and convenient form of wire stretcher is a handspike with a small claw plate screwed fast at one end, for catching the wire behind a barb. The wire is stretched by taking a pry back of a post, and to prevent the handspike from turning when straining on the wire the end holding the claw should be about 4 ins. wide and flattened. In the absence of a stretcher a hold may be had on the wire by giving it a turn once or twice around a handspike or bar. Block and tackle is also used much for a stretcher. Fence wire stretched in cold weather should be drawn up pretty tight, else it will sag in summer; if stretched in warm weather it should be drawn taut but not put under heavy tension, lest it will break when it contracts in winter. In putting up the wires four men can work to advantage: two to roll out or string out the wire, one to use the stretcher and one to tack the wires to just enough of the posts to secure them temporarily. Later one man goes along and nails them solidly to all the posts, driving all the remaining staples.

Labor Data.—The cost of labor in fence construction is quite variable in different localities, even with the same type of fence. The topography of the right of way, and its condition respecting growth of trees or brush; the condition of the ground as affecting the digging of post holes, the experience of the workmen, and sometimes other matters, have a considerable bearing upon the result of each day's labor. The same amount of effort might accomplish much more or a good deal less in one place than in another. Labor data on fence building should therefore be regarded conditionally. With this understanding the following statement, except where otherwise expressed, refers to ordinary work under ordinary conditions. A working day is supposed to be 10 hours. Where an auger or digger can be used effectively a man will dig 100 to 125 post holes 2½ ft. deep, in a day; or 50 with bar and shovel, where there are but few stones. In one day a man will carry and set about 70 posts. A day's labor will carry about 600 16-ft. boards from the side of the track to the fence line on a 100-ft. right of way. If the ground is hilly or rocky or if there are brush or logs in the way it may not carry more than half as many. A day's labor will cut to length and nail on about 90 fence boards, with battens, each board being nailed to three posts. In building wire fence with a top board a day's labor will carry from track to fence line about 450 boards, and it will cut to length and nail on about 160 boards, each board being nailed to



A, Page Fence; B, Lamb Fence; C, Mathews Fence; D, McMullen Fence; E, American Fence; F, Jones Fence; G, Ellwood Fence.

Fig. 427.—Woven Wire Fence.

three posts. A day's labor will reel out, stretch up and nail to posts 12 to 16 ft. apart about 6400 ft. of barbed wire (single wire).

Assuming that one man will dig the holes and carry and set 35 posts in a day, which would be an average record, the time required to build one mile of fence of various kinds is roughly estimated below. No allowance is made for delays in clearing brush or in building around stumps or other obstacles. The work of building a four-board fence, 16-ft. boards, posts 8 ft. apart, without battens, requires about 29½ days' labor; with battens, 36 days; a five-board fence, or a four-board fence with cap board, with battens, 41 days. The labor of building a barbed wire fence four strands high, posts 16 ft. apart, is about 13 days' work; with posts 12 ft. apart, 16 days; with top board and three wires, posts 12 ft. apart, 17 days; with top board and four wires, posts 12 ft. apart, 18 days. For a fence with a different number of wires allow about 8 hours' labor for each wire, more or less as the case may be. Experienced fence men working by contract will build just about 50 per cent more fence in a given time than the same number of ordinary track laborers engaged in the work only a short time each season. Thus, on a certain railroad the average record for the section men was 17½ days' labor per mile of fence built, with top board and three wires, posts 12 ft. apart. The average record for a gang of experienced fence men, working for the same company at the same time, under similar conditions, the same number of hours per day, but for a contract price per rod, was 12 days' labor per mile of fence.

Woven Wire Fence.—The necessity for keeping small animals off the right of way has led to the extensive use of woven wire fence along railroads. The method of construction in most forms of woven wire fence consists in tying together a number of horizontal wires with cross wires, to form a fabric or mesh of some desired shape. The cross wires serve to keep the horizontal wires at proper spacing, and thus woven wire is supposed to permit the use of fewer posts than are required for a fence built with independent wires, but in practice such hardly proves to be the case. The woven fabric does, however, permit the use of lighter horizontal wires for the intermediates than would be serviceable were they stretched up independently; and by using lighter wire a larger number can be afforded, and hence a tighter fence secured. The cross ties in a woven fence add no particular tensile strength to the horizontal wires, but they do serve to prevent the horizontal wires from sagging when part of the same are forced out of the straining line and stretched. Figure 427 is composed of a number of engravings illustrating some of the forms of factory-made woven wire fence in railroad service. Engraving *A* is the Page fence, of "coiled spring" laterals and straight verticals, forming a rectangular mesh. The horizontal wires are of hard steel and the verticals are annealed. The top lateral in the example shown is of No. 7 wire, the bottom lateral No. 9 wire and the nine intermediate laterals of No. 11 wire; the vertical wires are No. 14 and the spacing of the laterals is indicated on the engraving; the vertical wires are spaced about 12 ins. apart. The spiral twist in the lateral wires is produced by coiling the wire around a ¾-in rod and then pulling it out again. The purpose of this twist is to put the fence in tension upon being stretched up and fastened to place, so that it will automatically adjust itself for expansion and contraction due to change of temperature, and enable it to return to its original shape after being run against and stretched by stampeded cattle or other animals. The Lamb fence is similar to the Page fence and is shown as Engraving *B*, the knot or method of attaching the verticals to the laterals being also shown.

Engraving *C* shows the Mathews woven wire fence stretched upon steel posts already described. The top and bottom selvages are straight and the intermediate laterals are bent or depressed at intervals of 12 ins., and into these bends are wrapped the vertical stays, the idea being to keep the latter from slipping out of place. The top and bottom cables are formed of two No. 11 hard steel wires twisted together; the other laterals are of No. 11 hard steel spring wire; and for the vertical stays No. 12 annealed steel wire is used. The vertical stays are wrapped four times around the top and bottom cables. The fence as shown is constructed with barbed wire for the top strand. The steel and sewer-pipe posts are placed two rods apart and a stay rod is driven half way between the posts to act as a stiffener. The wire netting is fastened to the post by cutting a small slot in the post, dropping the strand of wire into it and then closing the slot with a hammer. The Keystone woven wire fence has a mesh similar to that of the Mathews.

Engraving *D* shows four patterns of McMullen woven wire fence, the first section on the left being of the "spiral spring steel" type, in which the horizontal wires are spirally curved to provide for expansion, contraction, etc. The top wire is of No. 7 gage, the intermediates of No. 11 and the bottom wire of No. 9 gage. The cross or tie wires are of No. 12 gage, spaced 24 to the rod. The next section is of the "crimped steel wire" type. The horizontal wires have a special crimp for preserving a "springy quality." The tie or cross wires are of No. 14 gage, with 24 meshes to the rod, the fabric being otherwise made up as in the case of the spiral spring type. The next section to the right is of the "steel wire cable" type. The top cable is of four strands of No. 13 steel wire and the other laterals each of two strands of No. 13 steel wire; with No. 13 cross or tie wires, 24 meshes to the rod. The form shown as the right-hand section of the engraving has a diamond mesh, intended especially for holding hogs and other small animals. The mesh is made in two sizes—2x4 ins. and 3x6 ins. The selvages are of twisted wires of No. 14 or No. 15 gage and the netting strands of No. 15 or No. 16 wire. The netting is made in various widths to suit different purposes.

Engraving *E* shows the 12-bar American woven wire fence in four different styles. The top and bottom wires are No. 9, the intermediate laterals No. 11 and the stay wires No. 12, spaced about 12 ins. apart. For holding the smaller animals the fence is made with an extra stay running in between the regular stays for a few meshes up from the bottom, as shown in the second section from the right. For a cattle fence one or two strands of barbed wire are stretched above the netting, as shown in the two left-hand sections. The Clinton woven wire fence has straight wires with rectangular mesh, the verticals and laterals being electrically welded together. Engraving *G* is an illustration of the Ellwood fence, formed upon twisted lateral strands, with a triangular mesh formed by stays running diagonally. The meshes near the bottom of the fence are smaller than those at the top, so as to take care of the smaller animals. "Hog fence" is a special form of woven wire fence made by nearly all of the woven wire fence manufacturers, in which the bottom portion of the netting for a hight of from 24 to 33 ins. above the ground is formed by closely spaced horizontal wires with numerous stays, so as to secure a small mesh.

Engraving *F* in an illustration of the Jones "locked" fence. The laterals are straight wires spaced as indicated in the engraving, and at intervals these wires are locked to vertical stays by looping the wire through a ring and slipping the stay through the loops of all the laterals. The standard fence of this type has No. 9 lateral wires throughout, with No. 7

hard steel wires for the stays, which are spaced 2 to 3 ft. apart, according to the panel length. These stays are applicable to old as well as to new fences and to either barbed or plain, straight or spiral-spring wire. The stay is applied to wires already attached to the posts by crimping the wires with a special tool, working from top to bottom, and in order to slip the stay through all the wires easily the rings or clamps are first doubled over and after the stay is in position they are spread to lock the wires firmly to the stay.

To prevent old barbed wire from swagging it is quite customary to use stays between the posts. Wooden pickets or slats interlaced with the wires, using staples to secure the latter and preserve the proper spacing, are frequently employed. Besides the Jones stay and method of locking there is another device for a similar purpose known as the Crescent stay. It is long enough to engage two or more wires, as may be desired, and consists of a piece of steel of trough section, $^3/_{64}$ in. thick and about 1½ ins. wide, notched on the edges to engage with the wire. The fence wire is secured to the stay by tying with a wire loop, which is drawn very tight by means of a special tool.

Woven wire fence comes from the manufacturer in rolls of 20, 30 or 40 rods' length, and sometimes in rolls as small as 10 rods, if so ordered. A whole roll is usually stretched at one time. The netting is unrolled flat on the ground, the bottom of the fence next the posts. The end of the fence is then made fast to the starting post, wrapping the strands clear around the post and fastening well with staples both at the extreme end and on the back of the post. The stretcher is then put on at the other end of the roll and the fence pulled up tight to place. The netting is stretched up either by pulling on one wire at a time (the top and bottom wires first) or by clamping the netting between two tongued and grooved pieces bolted together or to a stretcher bar provided with a special clamp for each horizontal wire, and then pulling on the clamping device with block and tackle, ratchet and chain, or other mechanical contrivance. In splicing sections of woven wire together the individual wires of the netting are spliced together, the joint made being similar to or like that made in splicing telegraph wire. In building woven wire fence across a hollow the wire netting is usually stapled to the last post on one side of the hollow and then stretched up at a post on the other side. The netting is brought down to the posts in the hollow by stepping on the bottom selvage and pulling it down to place, slacking off on the stretcher as the fence is depressed from post to post, but keeping a good tension all the while. In stretching over a hill the fence is pulled partly up and then hung up on the highest post on a staple loosely driven. After that it is stretched tightly to place. In stretching woven wire netting up to an end post it is usually necessary to set a straining post behind the end post, temporarily, in case there is nothing else in line with the fence to which the stretching apparatus can be attached. Posts for woven wire fence are usually set 12 to 16 ft. apart, but sometimes as close as 8 ft. apart. The cost of building woven wire fence, posts 12 ft. apart, is in the neighborhood of 20 cents per rod. The average cost for labor in erecting 22 miles of Page woven wire fence, as shown by the reports of the fence gang of a certain railroad, was 17.2 cents per rod. The posts were set an average distance of 17 ft. apart, and 3 to 3½ ft. in the ground. The surface was generally rough and uneven and a great many anchor posts had to be used. The cost stated covered the labor of loading and unloading new material, removing the old fence and disposal of the same, either by piling or burning, and the time consumed in moving the fence gang from one point to another.

Combination barbed and woven wire fences are used a good deal, especially where it is necessary to hold small animals. A committee report to the Roadmasters' and Maintenance of Way Association, in 1902, recommended for a hog-tight or sheep-tight fence in level country, a 26 or 28-in. netting of woven wire (square mesh) at the bottom, with three barbed wires on top. The standard wire fence of the Toledo, Peoria & Western Ry. consists of Keystone woven wire fencing 25 ins. high for the bottom, put on 2 ins. clear of the ground, with three four-point cattle wires spaced at 6 ins., 8 ins. and 10 ins. for the top. The posts are 7 ft. long, set 12 ft. apart and 2 ft. 7 ins. in the ground. Other details are shown in Fig. 427A. The left of the figure shows the braced panel that is standard with this company. The end post is extra heavy, and between this and another post set at a distance of 7½ ft. c. to c., there is a 7-ft. post used horizontally as a strut. The third post is 6½ ft. beyond the second, and is used as a footing for a 7-ft. brace post. The tops of the second and third posts are

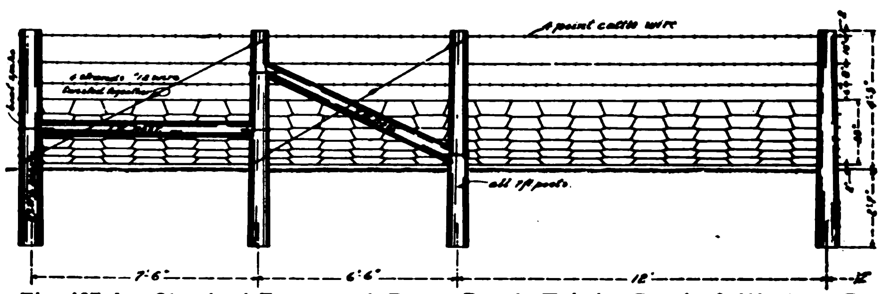


Fig. 427 A.—Standard Fence and Brace Panel, Toledo, Peoria & Western Ry.

then stayed to the end post by four strands of No. 12 wire twisted together. The posts and braces are firmly secured together by boat spikes.

Fence Machines.—Woven wire fence is also made in the field, with machines operated by hand power, and such machines have been used to some extent in railway work. The line wires, which may be either plain or barbed or part of each, are first stretched up alongside the posts, as in building strand wire fence, utilizing old fence wire already in place, if desired, and then the machine is worked along these wires to twist on or "weave in" the cross ties to form the fabric. There are several kinds of these machines, but on general lines the construction consists of an upright iron or wooden frame as high as the fence, on which are arranged a series of tubular spindles, spool carriers and twister wheels turned by a crank and gearing (Fig. 446A). The line wires pass through the spindles, and the spools which carry the cross wires are revolved around the spindles and automatically transferred, first to the upper and then to the lower spindle of each set of two, each time a new row of meshes is formed. Each distinct operation of the machine, as it is moved along, forms a series of meshes from top to bottom of the fence. The base of the machine, about 8x14 ins. in size, is carried upon small wheels which run upon a plank laid down on the ground. The machine builds fence over hilly and uneven ground without trouble. In making vertical turns to follow the lay of the ground the machine makes the meshes at top and bottom of different length, so that the fence fits the ground and does not require so much anchoring in such places as does factory-made fence. The meshes can be made very wide or close enough to turn small chickens, simply by varying the adjustment of the machine, and it can be used to weave numerous kinds of meshes, including ornamental designs. The machine is run by a man and a boy—the man to weave and the boy to fill the spools with wire for the bobbins. Such an outfit can weave 40 to 70 rods of fence in a day, the speed depending upon the size of the mesh. Mr. John Wirley, roadmaster with the Lake Shore & Michigan Southern Ry., has used one of these machines in building right of way fence. The labor cost one year was 33.7 cents per rod of fence, including the taking down of the old fence, setting new posts and weaving the new fence. During another year the average cost was 63.1 cents per rod of fence, including all material and labor. As used on this road a man and a boy have woven 60 to 70 rods of fence per day.

Durability.—Experience has shown that fence wire for railway service should be thickly and uniformly galvanized. Wire in right of way fence is exposed to sulphurous smoke and cinders from locomotives, and parts of the metal which are unprotected or too thinly coated are rapidly corroded. Trouble of this kind has occurred most frequently with woven wire fence, the smallest wires giving out first. In some instances the mesh wires have entirely rusted out in four to five years. Different authorities have laid the fault to inferior galvanizing, due to careless or too rapid work in the manufacturing processes; and to scaling or peeling of the spelter in the process of passing the wires through the weaving machines. The fact of failure under the influences stated has in some instances been made the basis of recommendation for the use of larger wires than are required in fence of ample strength to resist stock. As increase in size of wire increases the cost, and since the matter of failure as between a large and a small wire is only a question of time, wherever the corrosive action is present, the suggestion of larger wire is not altogether satisfactory. Failures of wire fence from corrosion have been most rapid where the quantity of locomotive or bituminous coal smoke has been greatest, but such failures have not been confined to the vicinity of roundhouses and switching yards alone; it has been found to prevail to more or less extent along the entire length of some roads, being most marked where the exposure is greatest, or in places where the smoke is driven to the ground. The inception and progress of the corrosion has been watched closely and found to appear first in spots, in some instances only one or two wires being affected for a considerable distance. This fact would seem to indicate that the galvanizing of the wire was not everywhere uniform.

Gates.—A gate of substantial construction can be easily made by uniting a panel of horizontal boards by vertical pieces or battens at the ends and at the middle, using clinched nails. Preferably there should be double battens—that is, a batten on each side of the panel—at each of the three points, and to hold the gate in shape a diagonal strip may be nailed to the panel, running from the top corner on the free end of the gate to the bottom of the middle batten. In hanging the gate the bottom edge of the top board may rest upon a pin or cross piece between staggered posts. The gate may then slide back half its length and be swung around at a balance on the cross piece. Another way to support such a gate is to hang it upon two track spikes driven into the post, hook upward, one spike coming under the top board and the other spike under the second board from the bottom, to keep the gate from swinging outward at the bottom. In constructing a swing gate the vertical end piece to which the hinges are attached should run up considerably higher than the panel of boards, and the diagonal or brace strip should be run from the top of this vertical piece to the bottom corner of the swinging end of the panel. Figure 428 shows a convenient form of gate which can be improvised with materials obtained on any railroad section. Old switch ties may be utilized for gate posts, and the swinging panel is made of 1x6-in. fence boards of 16 ft. or other available length. The hinge piece is set leaning, so that the gate will rise when opened and swing to the closed position when released. For a top hinge an old fish plate or angle bar spiked to the gate post will suffice, and a piece of old tie bedded in the ground with a dowel pin running into the hinge piece, serves as a bottom hinge. The gate may be held in the closed position by a stop piece and a wooden peg stuck into the gate post, or by some form of latch. To prevent cattle rubbing against a gate several strands of barbed wire may be stretched across it on the field side.

To admit farm machinery, gates should be at least 15 ft. long, and for several reasons swing gates should be arranged to open only on the field side, or away from the track. One of the most important of these reasons is that a gate which swings toward the field has the support of the post when cattle crowd against it from that side, while if it opens toward the track it is held by the fastenings, and if these are faulty or the timber to which they are attached somewhat decayed, the gate is liable to be thrown open from pressure in the manner stated. Another reason is that while a team is standing on the right of way waiting for the gate to be opened it may have to stand dangerously near the track if the gate swings that way; if the gate swings toward the field the team may be driven right up to it before it is opened, and not nearly so much damage is liable to occur should the team become frightened and run into the gate before it has been swung en-

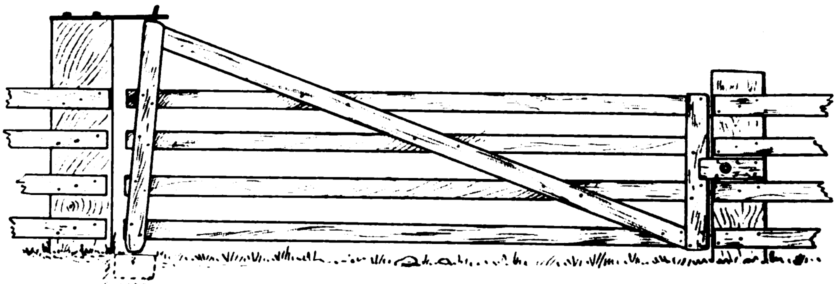

Fig. 428.—Gate for Railroad Fence.

tirely open. It is the duty of section foremen and track-walkers to see that gates opening into the company's right of way are kept closed when not in use.

Fence Crews.—In order to work to advantage in building a fence a gang of at least four men is needed. Where there is much fence to be built it is a better plan to set one or more fence crews at work than to take the section crews off the track to do it. It is customary to pay a contract price per rod or hundred feet of fence built, the company furnishing the material. The gang should be furnished with a box car to carry tools, supplies of wire, nails, staples, etc., and a hand car. Where supplies are not carried in this way it is often inconvenient to get them to the gang just when wanted. Posts and boards should be unloaded in advance of the work. In dropping boards from a car in motion, as in distributing fence material from a slowly-moving train, the trailing end of the board should be dropped first; otherwise there is danger of accident to the men on the car. The safest practice is to forbid dropping long material of any kind from a train in motion, but in unloading fence boards this rule is not always observed. The supply car should be set out at the side-track nearest to the work, and the gang may find it necessary to furnish their own board, as there will sometimes be no other opportunity of getting board within reasonable distance.

Some roads have cars specially fitted up for fence gangs. The fence men's car of the Toledo, Peoria & Western Ry. (Fig. 428A) is 45 ft. long and 8 ft. wide, inside, and has a platform on one end. In this end of the car there is a room 22½ ft. long fitted up for living and sleeping quarters. The side walls are covered with matched and dressed fencing put on horizontally, over which is a layer of building paper, and then 10-in. stock boards and battens up and down. The ceiling is covered with 10-in. stock boards and battens running lengthwise the car. The battens are laid on in fresh paint and nailed every few inches, so that there are no cracks. The flooring consists of matched and dressed fencing crosswise the car, overlaid with paper and then with hard pine flooring running lengthwise. One object in view in the inside finishing was to make the car as nearly vermin-proof as possible. The frames of the bunks are all made of 1-in. gas pipe. There are three sections of beds three berths high, besides a single bed, providing accommodations for 10 men. The beds have movable woven wire springs. There are also a desk fastened to the wall with angle irons and provided with a drawer underneath, a water tank and wash basin, a stove, and four lockers 18x20 ins. by 6 ft. clear hight. Passing from this room through a side door at the left, entrance is made to the hand-car or tool room, which is 9 ft. long, with doors 6 ft. wide on either side. In this room there is a work bench 2 ft. wide and 6 ft. long, with space underneath for coal, nails, fence staples, etc. Ten feet of space in the end of the car is used for a barbed wire bin, which is partitioned off by cross bars fitting in stirrups bolted to angle irons reaching from floor to ceiling. Light is admitted through windows and transoms, some of the windows being specially

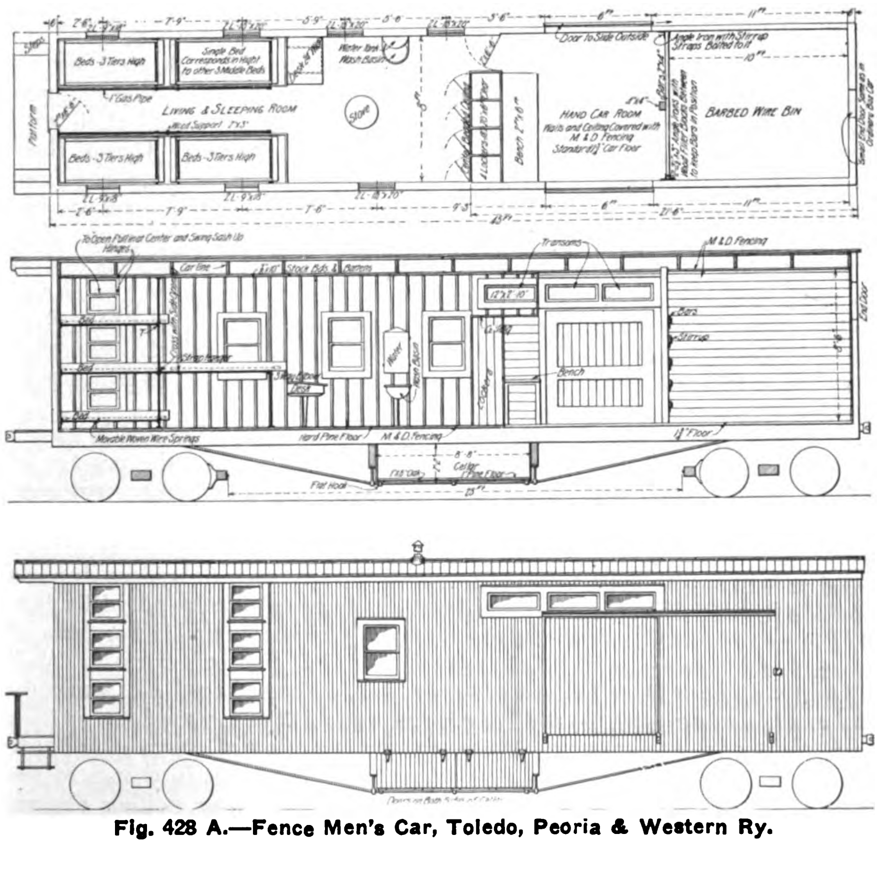

Fig. 428 A.—Fence Men's Car, Toledo, Peoria & Western Ry.

arranged to give ventilation to the sleeping sections, there being a window to every berth. Under the car there is a cellar of good size, with two doors on each side. The fence gang, consisting of five to nine men and a foreman, according to the condition of the fences, is engaged each year from about April 1 until the ground freezes up in the fall, or about eight months.

Fence repairing, like a great many other things on the railroad, usually requires immediate attention, and much of it must be looked after by the section crews. There is some work which can usually be done on fences during winter, when other work is scarce. Wherever the posts are in good condition weak places may be strengthened by nailing on new boards where old ones have been split, or loose wires may be tightened, corner and end posts braced etc., but wherever the work of repairing involves resetting or straightening up of the posts, nothing more than urgent work should be done until after the frost leaves the ground. Staples and 10d. wire nails should habitually be carried on the hand car, so that light or temporary repairs can be attended to when the need is first seen; otherwise such matters are liable to be neglected.

Use of Fence Wires for Telephone Lines.—In sections of the country, particularly in the West and Southwest, where there are long stretches of right of way wire fence with but few or no breaks of consequence, considerable use is made of the wires for telephone circuits, both by private parties and by the railway companies. As the posts insulate the wires from the ground it is only necessary to keep the strands that are used from contact with the other wires and to jump the road crossings, culverts and cattle passes, which can be done by erecting poles and carrying the wire over at a hight sufficient to clear hay wagons or whatever may pass. If a complete metallic circuit is desired the top wire of the fence on both sides of the track is used. In dry weather these wires can be used with good service up to a distance of 100 miles. In Texas the Southern Pacific Co. has a number of wire-fence telephone lines in service, affording communication with section houses situated at a distance from telegraph stations. One of these lines extends from Sierra Blanca to Dalberg, 28 miles, and another from Marfa to Valentine, a distance of 35 miles. In the latter case there are two section houses at "blind sidings" that are served by the telephone line. There is no expense for installation except for a telephone instrument at each point of communication, and a trifle for wire to bridge over gates and other gaps in the fence. In the arid region the working of the system is entirely satisfactory. The telegraph stations being widely separated, this cheap means of communication with isolated section houses in times of emergency is greatly appreciated.

152. Cattle Guards.—A stock guard, commonly called cattle guard, is a barrier of some kind in the track intended to prevent the passage of stock. It is used principally at either side of grade highway crossings, where the track is fenced in, being in principle a means for preserving a continuity in the fence past the track; it is frequently used also at private road crossings with the track and to guard the approach to bridges, tunnels and deep cuts. Like right-of-way fence, cattle guards are required by law, but in no case does the law of any state specify a particular kind or form of guard. Such terms as "sufficient cattle guards," "proper cattle guards," "suitable and sufficient to prevent horses, cattle, sheep, hogs," etc., are common expressions embodied in the language of different state laws on this point. On some roads the building and maintaining of cattle guards are put in charge of the track department and on other roads in charge of the bridge and buildings department, but as a general thing neither department craves the job.

In general, cattle guards may be divided into two types: pit and surface guards; and of the former type there are two kinds—open and covered pits. Practically, there is only one barrier which can certainly prevent domestic animals from traveling the track, and that is an open pit so wide that they cannot jump across it and so deep they cannot jump out in case they get into it. A frightened animal running before a train will not always turn aside, even for a deep pit. A common form of pit guard is an excavation 8 or 10 ft. long (measured with the track), 10 ft. wide and 3 to 6 ft. deep under the track, walled up with framed timbers or masonry. If the excavation serves also for a waterway or open culvert, as is frequently the case, the side walls are omitted; but in any case means should be provided for draining the pit. In the West, where pile structures are common, each wall is usually composed of three piles with a 12x12-in. cap, backed by a bulkhead to retain the roadbed. At an open pit the rails are supported upon stringers direct—usually wooden stringers with the upper corners chamfered away nearly to the base of the rail. The chamfering is necessary in order to prevent animals—particularly hogs and sheep—from walking the stringer astride the rail. It is safe to say that the open pit properly constructed will stop stock. There are, of course, those who will declare they have seen some old cow do the tight-rope act and walk the rail over the pit, but such exhibitions may properly be considered unusual and of infrequent occurrence; and no doubt room could be found for all such rare animals in menageries, where they could make their living easier than by picking it along the track.

Pit Cattle Guards.—While the open pit answers admirably the purpose of a cattle guard it is nevertheless objectionable from almost any other standpoint of the railway company and the public as well. It forms an opening into which a derailed truck will drop and cause a wreck. The stringers constitute a bridge of short span, and if these or any other of the parts are of timber the structure must necessarily be watched against fire as closely as any wooden bridge. The open pit is a constant menace to the lives of people traveling the track after dark. It is necessary, of course, that trainmen, watchmen, and other employees should use the track at all hours; but from the fact that American railroad tracks are, for foot passengers, equivalent to public highways, the majority of people who have been injured by falling into pit cattle guards have been of the common public. Pit guards are objectionable in many ways, also, when looked at from the standpoint of track maintenance. Any break in the continuity of the roadbed, such as at the ends of bridges and at open culverts, always increases the work of maintaining a good surface at that point. It is desirable, therefore, to have as few of these breaks as possible. Low joints are more liable to be neglected at or near planked road crossings than anywhere else; and to place a pit at each side and near the crossing only serves to increase the natural tendency to postpone repairs to the track surface at such points. Where the pit cannot very well be drained, as in a through cut, it will hold the water caught in wet weather, which will soak away into the roadbed and cause the track to settle. The exposure of the roadbed at the opening leads to deep freezing in winter, resulting perhaps in badly heaved track at the pit, which, in connection with a chance low joint at the crossing, puts a considerable stretch of track in bad surface. An open pit on a curve is a bad arrangement, because it leaves a stretch of track of some length without a tie to hold the outer rail against spreading. The best provision against such trouble is to box the stringers into a good-sized timber at their ends, or to hold them together with long bolts, but even then there is still the liability that the rail will spread by crowding the spikes and splitting the stringer.

The danger of spreading could easily be taken care of by notching the stringers at the middle and connecting the rails with a switch rod, but such a rod would be in about the right position to break a person's neck if he should walk into the pit, and it might also serve to catch and hold animals where they would form a dangerous obstruction to trains. Thus it seems almost criminal to place open pits in the track, and their use ought to be illegal. The very fact that the use of such pits (being the best barriers against stock) has not been enforced by law goes to show that they are in disfavor with the public. Moreover, railroad companies have for years been spending large sums of money on guard-rail appliances and ballasted bridge floors, to minimize the chances of serious wreck from derailed wheels; so that, in the light of modern improvements, the open pit cattle guard is out of date, and is fast going into disuse. It should be said, however, that if a pit is to be used at all it ought to be so deep that animals falling into it shall be clear of trains; and there should be placed over it nothing to catch and hold animals. A shallow pit is more objectionable than a deep one, because, while it is about as dangerous for a derailed truck to strike, the likelihood of an animal's making an attempt to cross it is greater than it is with a deep pit. A telltale placed each side of the pit, in the track, might serve as a warning to trainmen or trackmen running along the track after dark, whether or not it would to others. Such a telltale might consist of a few strips of lumber placed diagonally across the track, nailed to the ties—something like a surface cattle guard, say.

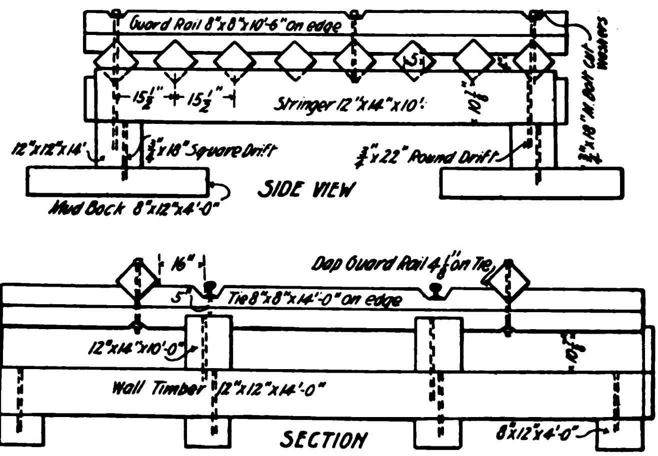

Fig. 428 B—Covered Pit Cattle Guard, Florida East Coast Ry.

The danger to train operation attending the use of open pit cattle guards is in one respect obviated, perhaps, by covering the pit with ties laid across the stringers to form a bridge floor. A timber guard is laid along the ends of the ties, on either side, and bolted to them, to prevent their being bunched when struck by derailed wheels and, except for the rail seats, the upper corners of each tie are chamfered off nearly to the center of the face, so as to present an insecure footing to animals. The pit in this case is usually shallower than the ordinary open pit. Such an arrangement, however, is hardly any improvement on the open pit guard, for if it does not actually destroy the effectiveness of the pit as a cattle guard it introduces a new element of danger to trains. If the pit is so shallow that cattle or other stock can touch the bottom they will step down between the ties and walk across, and if the bottom is beyond their reach they are quite liable to slip and be caught astride the ties when attempting to cross, thus being rendered entirely helpless. Instead of a cattle guard the contrivance then becomes a cattle trap, and if the unfortunate animal is struck in this position the train will almost surely be thrown from the track. There is also some question as to the ability of chamfered ties to carry derailed wheels safely, unless the ties be so closely spaced that they lose some of their effectiveness as a guard. All things considered, then, about the safest pit for train operation is the deep open pit. Hence, for the reasons above stated, the use of a pit cattle guard in any form should be discouraged.

Figure 428B shows a design of covered pit cattle guard that is standard with the Florida East Coast Ry. The ties are 8x8 ins. laid on corner. The guard is intended to be strong enough to carry derailed trucks and is said to be efficient in turning stock. In that part of the country there is no trouble from heaving of the track by frost, so that one of the objectionable features found with such guards in the North is absent. Following is the bill of material: 8 mud blocks, 8x12 ins. x4ft.; 2 wall timbers, 12x12 ins. x14 ft.; 4 wall planks, 3x12 ins. x 10½ ft.; 2 stringers, 12x14 ins. x10 ft.; 2 ballast boards, 3x14 ins. x14 ft.; 8 ties, 8x8 ins. x14 ft.; 2 guard rails, 8x8 ins. x10½ ft.; 4 round drift bolts, ¾ in. x22 ins. (for stringers); 8 square drift bolts, ¾ in. x18 ins. (wall timbers); 6 bolts, ¾ in. x18 ins. (guard rails); 12 cut washers for ¾-in. bolt. The timbers used, including the ties, scale 1805 ft. B. M.

Surface Cattle Guards.—Surface cattle guards are of two kinds, viz.: those intended to present to animals insecurity of footing and another kind intended to inflict pain. A surface guard properly built will turn away horses and ordinary cattle, but of cattle in the habit of roaming through woods there are some that will not stop for a surface guard if there is better grass on the other side. The kind of guard first mentioned usually consists of strips or slats of wood or metal spiked to the ties, either lengthwise or crosswise the track, both inside and outside the rails, and presenting upturned corners or edges. The ballast is usually removed as far as the bottoms of the ties, so that, to stall-fed animals or stock habitually pastured in cleared fields, it has an unfamiliar appearance which is supposed to put them in fear of attempting to cross. These strips or slats should be spaced at such a distance apart that there will either not be room for the hoofs of cattle or horses to slip between them, or else at such distance that when slipping between them there is room for their extrication. The form of surface guard designed to inflict pain is usually made of iron or steel slats, the upper edges of which are serrated or formed into saw teeth, or studded with spike-like projections. In either kind of guard the slats are sometimes spiked directly to the ties and sometimes they are held in end pieces running crosswise the slats and secured to the ties by spiking. As a usual thing the slats run parallel with the rails. A guard formed of slats running crosswise the track is known as the "gridiron" pattern.

As to the relative merits of the various forms of surface guards there is probably but little difference. Guards with wooden slats are the ones most generally used, and are perhaps as efficient as any. They are cheaper in first cost than metal guards and are more cheaply and easily repaired when torn out or damaged by dragging parts of cars or by derailed wheels; on the other hand there is with the wooden guard the disadvantage that it is occasionally subject to destruction by fire. As between the guard which renders footing insecure and that which inflicts pain it would seem that the latter ought to be the more formidable, since it necessarily partakes somewhat of the nature of the other also. The objection is raised, however, that so far as the pain is concerned, such a device is just about as severe on men who may chance to stumble upon it at night as it is upon

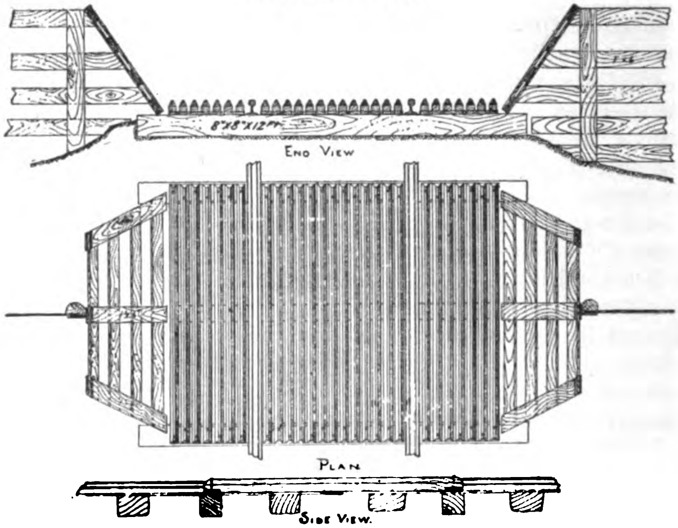

Fig. 429.—Standard Wooden Cattle Guard, Wabash R. R.

beasts; and if a flagman was to fall and strike his knee or elbow upon one of the prongs he would undoubtedly be in poor shape to signal a train.

From the foregoing considerations one might correctly infer that there is in reality no form of cattle guard that gives entire satisfaction. The two essential conditions of a perfect cattle guard—a structure which will safely carry the wheels of a derailed truck and which will form an impassable barrier to stock without entrapping the animals to the peril of trains—are incompatible with each other. The status of the cattle-guard problem is similar to that of the rail joint splice—the seemingly best solution (a welded joint) is either inexpedient or impracticable of application. Under the circumstances, the best practice seems to favor the use of the surface guard, taking advantage of any design or plan conducing to general effectiveness. A common fault with surface guards is that they are not made long enough. Horses will clear an 8-ft. guard at a single jump, and by stepping as far as possible with their front feet cattle will leap the rest of the way over a guard 10 ft. long. If cattle guards were made 15 or 20 ft. long, measured with the track, and well flanked by side fence, there would be but very few animals better domesticated than the Texas steer or the southern "razorback" hog that would attempt to clamber over them. On the Chesapeake & Ohio Ry. it has been found that 12-ft. cattle guards are much more effective than guards 8 ft. long. The Nashville, Chattanooga & St. Louis Ry. has at some places used two 8-ft. guards end to end, making one guard 16 ft. long. A point not to be overlooked in locating a cattle guard is to select a place where there is opportunity for stock to readily turn aside when confronted by the guard.

From all accounts obtainable it adds much to the effectiveness of a surface guard to give it a coat of whitewash occasionally. Many say that a whitewashed wooden slat guard has been known to stop stock where without the white color the stock would pay no heed to it. Others claim that black paint is even better than white. Either color is undoubtedly better than the natural color of the wood, as it gives to the structure the appearance of a distinct object in the track and adds a sort of scarecrow feature which ought to make the general appearance of things so much the more forbidding. An advantage with the white color is that it is conspicuous at night. Some who have tried both colors claim that the most effective scarecrow is to be had by painting the slats alternately white and black.

It may be of service to describe briefly some of the various forms of surface cattle guards in use. Wooden slat guards for single track are sometimes formed by spiking slats to the ties direct, but more usually they are grouped in sections—two sections to cover the space between the rails and a section about 2½ ft. wide to lie outside each rail. On some roads where wing snow plows are used the cattle guards are made wide enough outside the track to permit the side panel of fence to clear the plow with the wings open. It facilitates repairs to have the guard inside the rails in two sections, rather than one, as then the whole guard need not be taken up to repair a broken slat or to make room for tamping one side of the track, in case it gets out of surface. One manner of holding the slats together in sections is by a 1x6-in. cross piece at each end of the section, gained into the under side of the slats, securing each slat to the cross piece by a ½-in. bolt. Another cross piece should be nailed to the under side of the slats at the middle of the section. These details are shown in Fig. 429. If the cattle guard was to exceed 12 ft. in length it would undoubtedly be best to have it made in two sections, lengthwise. Another method of holding the slats together is to separate them at proper intervals by spacing blocks at each end and pass a ⅝-in. bolt across the section, through both slats and spacing blocks. The sections may be held to the track by spiking the cross pieces to the ties or by track spikes driven into the ties with the heads hooking over the edges of the slats, or by lag screws. The use of lag screws permits the guard to be readily taken up. On some roads cattle guards are taken up during the winter season.

Wooden slats are usually triangular in section and are made by ripsawing diagonally across the corners a scantling 3 or 4 ins. square; or, if it is desired that the slat should have vertical sides for a portion of its depth, a stick of oblong section may be ripped diagonally through the middle—as, for instance, a 2x6-in. piece, which might be ripped into two slats, each 2 ins. wide, 4 ins. deep on one side and 2 ins. deep on the other, the bottom half of the slat section then being 2 ins. square and the top half triangular, 2 ins. wide and 2 ins. high. Strips of 1-in. board set edgewise between spacing blocks, with the top edge of the board beveled, and slats of square cross section set on corner into triangular notches sawed into the end cross pieces half the depth of the slat, are also used to a considerable extent. Oak and hard pine are much used for slat material. Figure 429 shows a typical wooden slat cattle guard, with another form of slat that is commonly used. The slats are yellow pine 3x5 ins. x8 ft. long, and the ends of the sections are fastened to 8x8-in. x12-ft. yellow pine pieces laid in place of the ties. As used on the Wabash R. R. a coat of tar is applied hot. A slat guard across the midway of a double track is usually laid on ties placed between the tracks.

Metal Cattle Guards.—Metal surface guards have slats of various forms. The National guard has, in one form, flat metal slats serrated and barbed, set on edge and fitting into slotted cross pieces of triangular section, at the ends and at the middle. Alternate slats are 2½ and 3½ ins. deep and the slats are spaced from 2¾ to 3¾ ins. apart. Another form of this guard has slats of angle iron, with the angle placed uppermost, or like an inverted V. The Kalamazoo cattle guard has triangular slats, alternating with rows of triangular teeth that do not extend quite so high as the triangular slats, the idea being that an animal's hoof will slip down upon the teeth, but a person falling upon the guard would (if he fell across the slats) not strike the teeth. The guard consists of four sections of steel plate stamped into inverted V-shaped ribs alternating with flat surfaces out of which the triangular-shaped teeth or tongues referred to are struck up. The triangular ribs are spaced so far apart that the hoofs of stock cannot reach between two, but must slip down upon the teeth. The ends of the ribs are sloped off by bending down a piece of the metal. The Bush cattle guard has slats of inverted T-irons 2 ins. apart held in slotted pressed steel cross pieces of triangular section. The Merrill-Stevens cattle guard has slats of 1¼x1¼-in. T-irons set at a slant, so as to present an upturned edge. One design of the Standard cattle guard has Z-bar slats set at an incline so as to present an upturned corner. In another style of this cattle guard the slats are angle bars with one leg much longer than the other, and it is laid with the long leg inclined to the ties and overhanging the upturned short leg of the next bar. The bars are arranged in sections with spacing plates and cross bolts, and the ends of the slats are beveled down to prevent dragging things from catching.

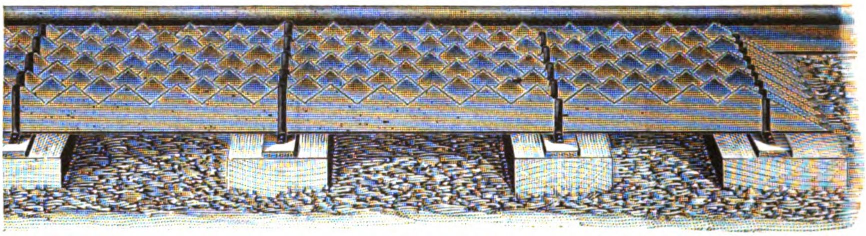

Fig. 430.—The Cook Cattle Guard.

The Cook cattle guard (Fig. 430) consists of serrated steel slats in four interchangeable sections of nine slats each, resting upon metal cross pieces of channel section spiked to the ties. The teeth in adjacent slats are alternated, so that the point of a tooth in one slat is directly opposite the space between two teeth on the adjacent slat, thereby presenting an uneven and unstable footing for stock. The teeth are sufficiently pointed to inflict punishment without cutting deep enough to cause serious injury to animals stepping or falling upon them. The slats are held in position by looped irons or fasteners bolted to the back of the channel cross pieces. For securing these sections to the ties spikes may be driven between any of the slats. A special attachment which may be used in connection with this guard is an intermediate slat for turning hogs and other animals with feet small enough to pass between the main slats. It is lower than the main slats and has small teeth projecting alternately from side to side, after the manner of set in a saw. These auxiliary hog slats are placed between the main slats at the end toward the highway, being fastened by bolts passed up through the cross channels. The chain cattle guard has rows of link-belt chain stretched parallel with the rail over suitable cross pieces at intervals.

The Sheffield cattle guard (Fig. 431) is formed from four sheets of annealed steel plate, each 26 ins. wide, from which 3-in. triangular teeth are struck up 3 ins. apart, in rows 3 ins. between. The sections are spiked flat on the ties without preparation of the latter, and there is no chance for dragging brake gear to catch the plate and tear it out. Being of soft steel the teeth, if bent by accident, can be straightened up by driving with a spike maul. The sections are made in lengths as ordered. The Walhaupter and Positive cattle guards are similar and are formed of buckled plate with folds running crosswise the track and reaching to the bottom of the ties, the pitch of the folds or corrugations corresponding in length to the spacing between the ties. These folds are shaped something like the teeth of a ratchet, and, as laid down in the track, there is an inclined surface running from an upper corner of each tie to a lower corner of the next tie, so that, when an animal steps upon it the hoof will slide into the fold and strike against the ridge or upper corner of the adjacent fold, and thus the leg meets with an obstruction just above the ankle which prevents the animal from stepping forward. The Trackman's cattle guard (Fig. 432) accomplishes its purpose in the same manner, but the folded metal is made in separate pieces, one of which is spiked to each tie. The ties are spaced 12 ins. apart in the clear and the ballast is removed even with their bottoms. The object in making the guard in small pieces is to facilitate removing ties for renewals, to permit lining or surfacing of the track without taking the guard apart, and to avoid the ripping up of a large sheet of metal in case some parts should be torn loose. Iron cattle guards in large sections have been known to tear loose, get under the wheels and cause train wrecks. As will be noticed in the sectional view, there are three different shapes, one being next the highway, another at the opposite end, with several pieces on the intermediate ties that are of the same shape.

The Chicago, Rock Island & Pacific Ry. has in use a number of barbed wire cattle guards designed by Roadmaster J. D. Sullivan. The strands of barbed wire in each section of the guard are stretched over a frame made of two strips running parallel with the rails, with four cross pieces of wood of triangular section, covered with sheet metal. The ends of the section are held together by bolts and the barbed wires are woven back and forth from end to end of the section, on lines parallel with the track. This guard is used on parts of the road in Indian Territory and northern Texas, where the cattle are hard to hold and where other forms of surface guard have failed. The guard was illustrated and described in the Railway and Engineering Review of July 17, 1897. In some quarters it is the practice to cover wooden slat guards with strands of barbed wire stretched over or interlaced between the slats, to frighten the animals away. From the appearance of some such affairs after a dragging brake beam has struck it one would think that it surely would frighten either man or beast, if anything could.

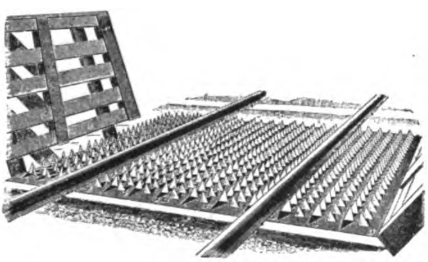

Fig. 431.—Sheffield Cattle Guard.

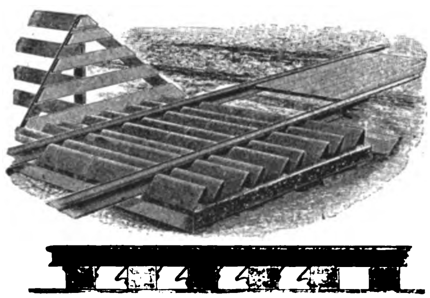

Fig. 432.—Trackman's Cattle Guard.

The Climax cattle guard consists of blocks of vitrified shale clay 24 ins. long, 8½ ins. wide and 4½ ins. high. Each block is formed of two longitudinal triangular ridges molded in shells 1¼ ins. thick and united at the base. The blocks are arranged in rows and held in place by means of a 2-in. wooden cleat around the guard. The end blocks are beveled and slotted for spikes. The complete guard is composed of 40 blocks and weighs about 1200 lbs. There is also a style of cattle guard consisting of rows of drain tile standing vertically on end between the ties and left empty. The top of the tile comes at about the level of the top of rail and each tie is covered with a triangular stick of timber.

Cattle guards are as numerous as Yankee ingenuity has been able to devise, but only a comparatively small number of the inventions in this line have succeeded in being put to use. One idea which inventors seem to persist in working at employs a gate or other barrier which normally lies flat in the track, but is flipped up like a jumping jack in the face of the animal, which is supposed to put the concern in motion by stepping upon a plank or treadle of some kind lying between the ties. Just what would become of such a piece of apparatus if it was flipped up in response to a dragging brake beam may be readily imagined.

The highway or wing fence which is brought across the right of way, and terminated on either side of the cattle guard, should meet the guard with a leaning panel or "apron fence" which is fully as long as the guard; and this panel should be so substantially built that it cannot be hooked down. Animals will jump or "angle" themselves around a short triangular panel or A-fence, which not infrequently constitutes the apron fence of the guard, as shown in Fig. 432. The correct way to build this panel is shown in Fig. 431. The leaning panel should foot at the guard, and it may consist of boards nailed to leaning posts, or the posts may be set plumb and support the panel by brace pieces nailed to the panel battens. At all events there should be post supports at the ends of the panel, and the bottom of the panel should not be fastened to the ties or to the guard, as the jarring of the ties would soon work it loose. All cattle guards should extend squarely across the track, whether the fence joining the guard approaches the track at right angles or diagonally. Leaves, in the fall of the year, and pieces of waste, if allowed to accumulate in a wooden pit or surface guard, make good kindling and increase very much the liability of destruction by fire. But the effectiveness of a surface guard, of either metal or wood, is much better maintained if it is kept cleared of rubbish. Weeds should not be permitted to grow in cattle guards.

The wing fence and the leaning panels at a cattle guard should be whitewashed. Aside from the fact that such treatment may increase the effectiveness of the guard, the white fence is conspicuous at night and assists enginemen to readily locate themselves. The most common mixture for whitewash for railway fences is salt and air-slaked lime, the salt being generally used in the proportion of one tenth the quantity of the lime. It is considered advantageous to permit the lime to slake several days before using it. The Chicago Terminal Transfer R. R. uses white glue and whitewash, and on second application finds that it will last about one year. The mixture consists of 5 lbs. of glue to each barrel of lime. Another mixture that is sometimes used consists of 100 lbs. of cement to each barrel of lime, allowing the lime to slake 30 days before using. Salt and boiled rice mixed with lime is still another mixture that is used for a whitewash. A half bushel of lime is slaked in water and covered to keep in the steam. To this is added 4 quarts of salt dissolved in warm water, and then 3 lbs. of rice ground and boiled to a thin paste, while still boiling hot, is stirred into the whitewash. A mixture that is used on government buildings and light houses consists of ½ bushel of lime, 8 quarts of salt and 3 lbs. of ground rice treated in the foregoing manner, to which are added ½ lb. of Spanish whiting and 1 lb. of glue previously dissolved in water. After adding 5 gals. of hot water the mixture is allowed to stand for a few days covered from dirt. When used it is heated and applied hot. The Grand Rapids & Indiana Ry. uses a locomotive and car equipped with air compressing machinery and spraying devices. This outfit is in service for all whitewashing along the right of way, including fences, cattle guards, etc.

One thing which conduces to the effectiveness of cattle guards is to keep stock from becoming familiar with them, and to do this obstacles may be placed in the way of walking up to the guard and which will make it inconvenient to stand around them. On general principles it is also desirable to prevent stock from standing on or near the track in the vicinity of road crossings. A plan that is sometimes followed with this end in view is to put the cattle guard a little way back from the road and then cover the track and roadbed on the highway side of the guard with some material that will make the footing insecure. The Union Pacific R. R. uses coarsely broken slag in such places. Such may also be used for a "bicycle guard" in towns and cities, where people are inclined to use their wheels on the shoulders of the roadbed or in the midway between tracks. In this case it will usually suffice to merely strew the ground with the lumpy material for some distance from the crossing.

The usual practice is to bring the wing fence up to the middle of the guard or to the highway end of the same, but some careful observers of the behavior of stock in the vicinity of cattle guards claim that the efficiency of the guard is improved by running the fence up to the end of the guard or guard panel which is farthest from the highway crossing; in other words by putting the cattle guard all on the highway side of the wing fence. The explanation is that when cattle are feeding or wandering along the wing fence and headed toward the track, they meet with an obstruction which will direct their attention away from the track instead of presenting an opening into which curiosity might lead them; and also, when cattle standing upon the crossing become frightened by the approach of a train, the guard and side panels, standing out in front of the highway fence, as they do, appear to the animal like a shelter, behind which they will dodge, instead of making a rush for the opening, as they are likely to do where the end of the guard nearest the highway is flush with the wing fence.

153. Bridge Floors.—The bridge floor is where the track and bridge departments meet. Although the construction and maintenance of bridge floors are placed in charge of the bridge department, the rails and fastenings are subject to inspection and repair by the track forces; and as the design of the floor has a great deal to do with the safety of the track, under certain circumstances, the subject may properly be considered in a treatise of this character. The bridge floor may be defined as that portion of the supporting structure which is added to the naked trusses, girders, or trestle bents with their necessary bracing, to support and protect the track and properly distribute the load to the trusses, girders or main supports. The component parts would then include the ties, guard rails, guard timbers, floor beams, and stringers, if the last mentioned are used. As the floor beams and stringers constitute the foundation of the floor, the manner of their arrangement determines very largely the strength of the floor and may logically be considered first.

Floor Beams and Stringers.—The floor of trestle bridges is usually formed of sawed track ties resting across stringers supported by the caps of the trestle bents. This is about the simplest form of bridge floor and the one on which the designs of different railways vary the least. In wooden trestles the spans are usually 12 to 16 ft. and there are usually three stringers placed directly under each rail, or nearly so, a common size of stringer for spans of 16 ft. being 8x16 ins. On some roads only two such stringers are used under each rail. The stringers under each rail are usually spaced from 2 to 4 ins. apart, bolted together through spacing blocks or spools, to maintain air space, and to prevent them from shifting sidewise one of the stringers is bolted to the cap, a long bolt sometimes being used which passes through cap, stringer and tie, and sometimes also through the guard timber. A drift bolt is also frequently used, either being preferable to the practice of spiking pieces of plank on top of the cap, as such will retain moisture and start early decay. In addition to the sets of stringers placed underneath the rails a side or "jack" stringer is sometimes used under or near each end of the ties, to support the ties outside the rail in case of derailment. Owing to the deflection of the main stringers and ties these side stringers are usually considered to carry a portion of the load, the distribution depending, of course, upon the amount of deflection in the main stringers and in the ties. On girder and truss bridges there is a considerable variation with the different roads, in the arrangement of floor beams and stringers, and although in a discussion of the various designs there is room for a great deal to be said, a condensed statement will serve to bring out the principal features of many of these designs. In preparing this I have consulted a very thorough report on "Bridge Floors" by a committee of the Association of Railway Superintendents of Bridges and Buildings in 1897. Some of the illustrations used were selected from a large number contained in that report.

In wooden through truss bridges the distribution of the floor beams may be effected in three different ways: they may be concentrated in sets at the panel points (*A*, Fig. 433); they may be uniformly spaced at short intervals (*B*, Fig. 433), thus permitting the use of smaller stringers; or the ties may bear upon the lower chord of the bridge direct, thus serving as floor beams (*D*, Fig. 433). When the last-mentioned method is resorted

Fig. 434.—Floors for Wooden Deck Trusses.

to ties which come opposite the panel points must be cut off short and supported in some manner upon the adjacent ties. One method of obtaining such support is shown by Engraving D′, Fig. 433. A wrought iron stirrup formed from a bar 4 ins. wide and ½ in. thick supports the tie at each end and is hooked over the tops of the two adjacent ties. The tie is securely held to its proper spacing by bolts and separating spools and an 8x8-in. guard timber is bolted to every tie, which also aids in distributing the load over the ties. When the floor beams are supported directly upon the bottom chord the deflection of the beam under load brings an undue proportion of the load on the inner edge of the chord. One method of alleviating this trouble to some extent is to arrange for carrying a portion of the load upon side stringers, thus reducing the deflection of the beam. By hanging the floor beam below the chord the load may be distributed over the whole width of the chord, the beams can be distributed without interference from the braces or posts at the panel points, and there is effected a gain in headroom over the track equal to the depth of the floor beam plus the depth of the chord. The method of suspending floor beams from the bottom chord in practice on the Boston & Maine R. R. is illustrated by engraving *C*, Fig. 433. With suspended floor beams, however, the lateral bracing of the trusses rests upon the top of the beams, thus necessitating the cutting of the stringers where these members cross. Such cutting or notching necessarily weakens the stringers, and for this reason suspended floor beams are usually distributed uniformly, so as to relieve the stringers of the bending moments which they would necessarily have to undergo if supported on floor beams concentrated at the panel points.

On wooden pony trusses the floor beams may be either supported upon or suspended from the lower chord, but the design of the floor may somewhat affect the manner of bracing the top chord. The top chord is usually braced from the outside by a leaning strut footing into a collar beam suspended from the bottom chord. If the floor beams rest upon the bottom chord the collar beam is independent of the bridge floor and there is consequently no interference. Likewise, if the floor beams are suspended from the chord the collar beam must be made independent of the bridge floor, else the deflection of the floor will carry the collar beam down with it and operate to throw the top chord out of line. One method of avoiding such trouble is to block the collar beam against the under side of the chord so as to be clear of the stringers of the bridge floor. On wooden deck trusses the ties may rest directly upon the top chords (Engraving *E*, Fig. 433), or they may be laid upon stringers supported on floor beams concentrated at the panel points, as in the case with the Southern Pacific bridge shown by Engraving *B*, Fig. 434.

With track supported by columns and I-beams there is the usual arrangement of main and side stringers, as with trestle bridges. With deck plate-girder bridges there are usually two girders under each track, the girders being spaced 6 to 9 ft. centers, the spacing depending largely upon length of span and depth of girder. Engraving *B*, Fig. 435, shows the usual method of construction, the ties acting as floor beams. On widely spaced girders the deflection of the ties under load brings a heavy bearing upon the inner edge of the top flange of the girder, tending to bend the flange and spring the web plate. Engraving *D* shows a method of concentrating the load at the center of the flange, as practiced on the Chicago, Milwaukee & St. Paul Ry. The standard deck girder bridge of the Boston & Maine R. R. (Engraving *A*) has girders spaced at 9 ft. centers with floor beams and iron stringers between, the top of the stringer coming even with the top of the girder, so that the latter acts as a side stringer for supporting the ends of the ties. The lateral bracing is confined to one system, which is placed in the plane of the bottom flanges of the floor beams. The simplest form of floor for through plate girders is shown as Engraving *A*, Fig. 436. The ties act as floor beams and are supported upon the bottom angle or flange of the girder. This method of support has a tendency to weaken the flange, and the lateral bracing and the ties interfere with each other with detrimental effect to the latter. This trouble is overcome by the use of a "shelf angle," which carries the ties clear of the bracing, as shown on the Nashua and Acton bridge, Engraving *E*. In some places plate girders are so closely spaced that the necessary clearance cannot be obtained to use them as a through structure, and the allowable depth will not permit a deck structure. In

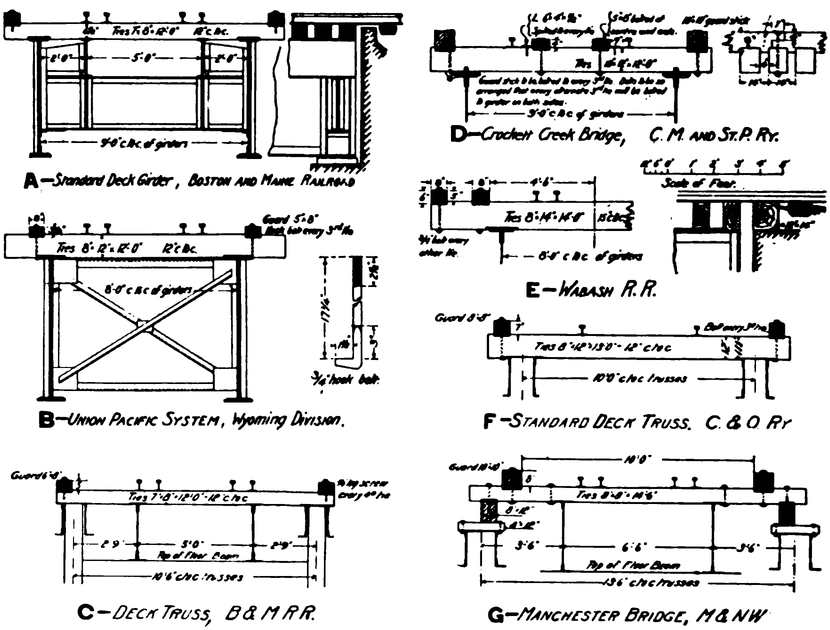

Fig. 435.—Floors for Plate-Girder and Iron Truss Deck Spans.

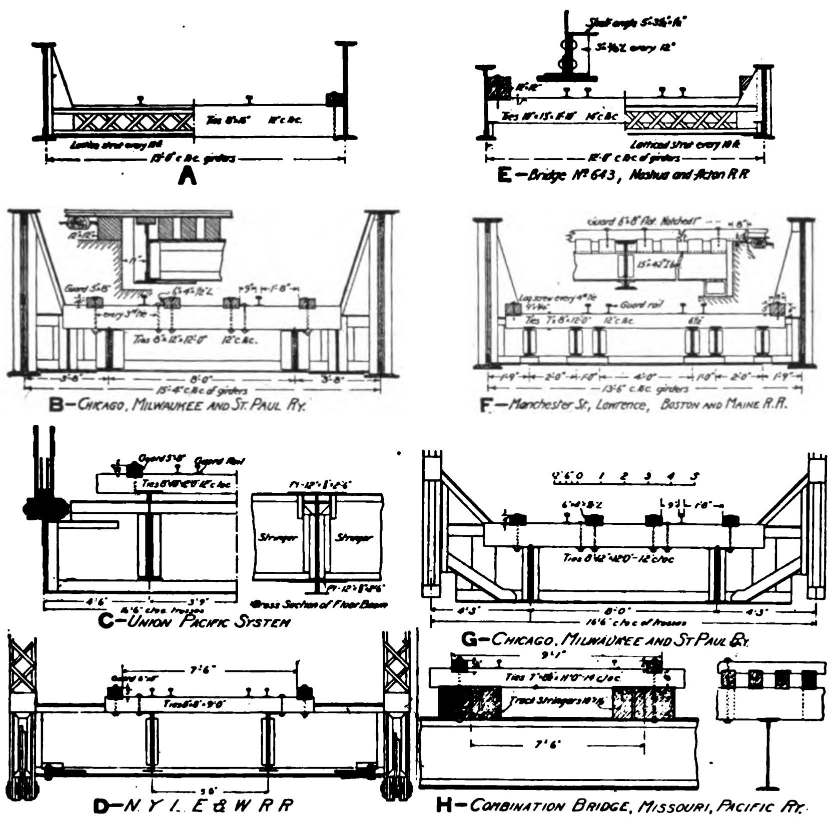

Fig. 436.—Floors for Iron Through Girders and Trusses.

that case the ties can be laid upon shelf angles riveted to the webs of the girders at such a hight that top of rail will come even with the top flanges of the girders. Such is the construction of some of the bridge floors of the Chicago, Milwaukee & St. Paul Ry. In the Chicago, Milwaukee & St. Paul bridge shown as Engraving *B* there are two plate-girder stringers heading against the floor beams, and the ties are arranged as upon a deck girder. The introduction of floor beams and stringers shortens the span of the tie and reduces its size. Engraving *F* shows a method of support with side stringers, in use on the Boston & Maine R. R.

In iron through truss bridges there are usually two iron stringers for each track spaced 5 to 8 ft. apart and headed into the floor beams. In some cases, however, both main and side stringers are used, all of the stringers heading against the floor beams. The floor beams are sometimes hung from the pins at the panel points and sometimes they are riveted to the posts. As a usual thing the stringers heading against the floor beams are supported upon the bottom flange of the floor beam which, being of greater depth than the stringer, extends into the space between the ties and sometimes within a few inches of the top of tie or rail base. In such cases the tie spacing must be modified slightly to make room for the upper flange of the floor beam, but as the interval is not great there is no serious objection. On the Union Pacific bridge shown by Engraving *C*, Fig. 436, the stringers project above the top flange of the floor beam and are connected across the space over the floor beam by a 12x⅜-in plate 2 ft. 6 ins. long. Engraving *H*, Fig. 436, shows a combination wood and iron floor in use on the Missouri Pacific Ry., in which wooden stringers are used upon plate-girder floor beams.

On iron deck trusses the ties may be used as floor beams and rest directly upon the upper chord. As in the case with wooden deck trusses, some bridge engineers object to such practice on the principle that the upper chord of the truss is designed primarily as a compression member, and not as a beam, and that a load bearing upon the chord between panel points subjects that member to an excessive burden, unless it is designed especially heavy for the two duties it must perform. Engraving *F*, Fig. 435, shows this method of support. Engravings *C* and *G* illustrate forms of construction in which iron girder stringers and floor beams are used, the latter being riveted to the posts, and the top chords acting as side stringers. In the form shown by Engraving *G* the lateral bracing is arranged in the plane of the bottom flange of the chord and the top flange of the floor beam, while in Engraving *C*, in which a greater depth of truss is utilized, the bracing is attached to the top flange of the floor beam, some distance below the chord. The latter arrangement is somewhat objectionable, from the fact that the lateral bracing at this point may cause bending of the post. The simplest and perhaps the best form, if the depth can be spared, is to rest the floor beams on the top of the chord at the panel points and head the stringers against the floor beams.

The arrangement of placing the stringers between the floor beams on an iron bridge makes a stiffer floor than is to be had by supporting the stringers on top of the beams. A secure way of making the connection between floor beams and iron stringers which abut against them is to rivet on a pair of vertical angle irons through the web at each end of the stringer and then rivet these angle irons to the web of the floor beam. Where stringers are headed into both sides of a floor beam, as at any of the intermediate panels, the angle connections on both sides of the floor beam may then be riveted to the web of the same, through and through. An efficient way to arrange lateral bracing, where the conditions will permit, is to rivet angle irons to the ends of the floor beams or to the chord members and pass them diagonally under the track stringers, riveting to the bottom flanges of the stringers wherever the two cross.

Wooden stringer pieces are usually two panels or two spans in length and are laid to break joints over the caps or floor beams. A lap stringer is one composed of pieces whose ends overlap each other on the caps or floor beams. Owing to the predisposition of timber to decay where surfaces in contact are exposed to the weather, it is not considered the best practice to have stringer timbers abut squarely, if they meet end to end. Where this rule is observed the stick is cut off slightly out of square at the ends, so that the two pieces abut against each other at the top, or for an inch or two down from the top, but are separated by an air space of $\frac{3}{8}$ or $\frac{1}{2}$ in. at the bottom, where they rest upon the cap or other support and where it is highly desirable to preserve the timber in sound condition as long as possible. Where stringers are packed together in sets they are sometimes spliced at the panel points by pieces of plank about 6 ft. long bolted either upon the outside or between the pieces, thus serving the additional purpose of spacing blocks. To prevent contact between the wood surfaces the splice pieces are separated from the stringer timbers by cast iron washers. On the Elgin, Joliet & Eastern and West Shore roads these splicing planks extend an inch or two below the bottoms of the stringers and are notched over the cap. In addition to this the West Shore road secures each stringer timber to the cap by a drift bolt. It is well to note in passing that iron spools or washers, being non-retentive of moisture, are superior to wood blocks for spacing pieces. Corbels are used to some extent with stringers. The width of the corbel is made the same as that of the stringer, the depth 12 or 14 ins. and the length about 4 ft. The corbel affords the stringer a larger bearing surface than it would get if it rested directly upon the cap, and for this reason there is possible a longer use of the stringer after decay starts at the end than would be the case without it. It also stiffens the stringer and in effect reduces the span. It is used mostly where the span exceeds 16 ft. It is said that in spans of 18 to 20 ft. the use of the corbel will decrease the deflection from 25 to 30 per cent. In iron trestles the longitudinal girders or stringers are sometimes headed against and riveted to the webs of the columns. In some cases where such a connection is made with a column that stands at a batter, the column is bent just below the junction with the stringer, to bring the top part vertical.

As the primary office of the bridge floor is the proper distribution of the load upon the trusses, girders or trestle bents, the foregoing methods of arranging floor beams and stringers may be considered applicable to bridges of all classes, regardless of the character of the immediate support for the track rails. With respect to the immediate support for the track, bridge floors may be divided into two classes: open floors, where the rails are carried upon timber cross ties supported upon stringers or upon the top chords or flanges of the spans; and solid floors, where the ties are underlaid by a tight floor of some kind, the rails resting directly upon the floor covering or upon ties, with or without an intervening layer of ballast. The type of floor in most general use is the open floor, which will be considered first.

Bridge Ties.—The size of tie required for a bridge floor depends upon the manner in which the tie is supported. If the tie is supported by stringers directly under the rails, or nearly so, it supports the rail without appreciable bending moment, and other than this its duty is merely to hold the rails to gage and in line. Under such requirements a tie of ordinary size is sufficient, and the common sizes are 6x8, 7x8 and 8x8 ins., the first and last mentioned being the most common. If, however, the tie is called upon to act as a beam it must be proportioned for the span, and in some cases a large piece of timber may be required. There is also the important difference that ties supported by stringers directly under the rails may safely remain in the track as long as they are sound enough to hold the spikes well, whereas if the stringers come outside the rails the renewing of the ties must be looked after more carefully and the life of the tie is legitimately shortened. Twelve feet is a common length for a bridge tie supported upon stringers. They are frequently used as short as 9 ft. but it is desirable that they should be long enough to permit setting jacks and laying blocking in case a derailed car should come to a stop on the bridge. On double-track bridge floors a long tie (22½ to 24 ft.) running under both tracks is sometimes used, but this arrangement meets with the objection that in renewing ties both tracks must be disturbed simultaneously. It is therefore considered better practice to use independent sets of ties for the two tracks. Ties 12 ft. long will usually close the gap between the tracks on a double-track bridge. On trestles the ties should extend out far enough to cover the caps, so that in case a derailed car should fall off the trestle it will not strike a cap and knock out a bent. White oak, yellow pine and fir are the woods most used in this country for bridge ties and floor timbers.

The ties in a bridge floor must be made secure against being moved out of line and also against being spread apart or "bunched" under derailed wheels. The proper alignment of the ties may be maintained by dapping them over the stringer or by drift-bolting a portion of the ties to the stringer, if the latter be wood; or by securing them to the stringer with hook bolts (Engraving *B*, Fig. 435), if the stringer be of iron or steel. Bolts and nuts are also commonly used for securing ties to wooden stringers. It is also quite largely the practice, where the stringers come directly under the rails, or nearly so, to lay the ties on flat, except every third or fourth tie, which is turned edgewise and dapped over the stringer to bring its top level with the other ties; and sometimes ties of extra depth are provided for this purpose, in case all of the ties are laid on edge. Another method somewhat in vogue with ties laid upon built girders is to notch each tie over a projection of the web plate through the upper flange of the girder, as shown in Engraving *D*, Fig. 435, and Engraving *B*, Fig. 436. For holding the ties in line it is usually thought to be sufficient to dap them over the stringers or girders ½ in., but in certain localities the use of bolts or hook bolts in addition is recommended as a means of preventing the ties from being blown off the bridge by heavy wind or lifted off by high water. A long "deck bolt" passed through the cap and a tie, on the center line of the track, at each bent, is sometimes used. Ties laid upon plate girders may be brought to an

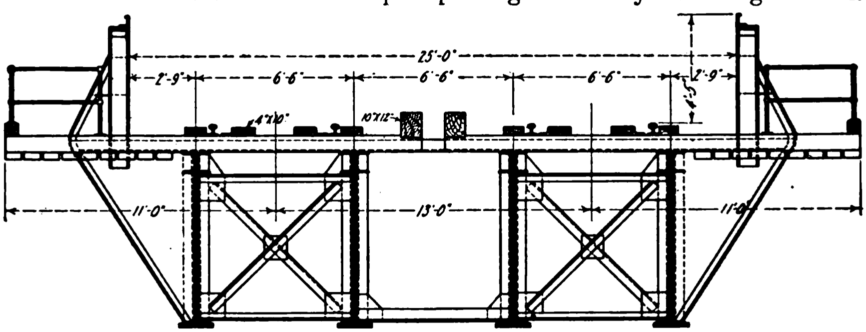

Fig. 437.—Cross Section of Floor at Hand Car Refuge, Boone Viaduct, C. & N. W. Ry.

even bearing for the rail by notching deeper into those which come at the middle portion of the span, to allow for the extra thickness of cover plates. In order to provide a smooth bearing surface for the ties—that is, one without rivet heads—and to avoid the necessity for dapping the ties to allow for varying thickness of the girder flange, it is now quite extensively the practice to dispense with cover plates altogether for the top flange of plate girders. The necessary strength is then provided by a "double flange," consisting of two lines of angles on each side of the web, with perhaps side plates besides. The plate girders shown sectionally in Fig. 437 are built this way.

Ties are made secure against bunching under derailed wheels by spacing at close intervals and dapping the guard timbers 1 to 1½ ins. over them, so as to have a joggle or blocking between each two ties. The clear spacing between ties is made as little as 4 ins. in some cases, but more generally about 6 ins. A space as small as 4 ins. is liable to catch a workman's boot and it leaves a weak joggle on the guard timber for holding the ties to their spacings. The guard timber is bolted to every third or fourth tie (in rare cases to every tie), preferably over the side stringer, in case such is used. A long bolt can then be passed through the guard timber, tie and stringer. In order to prevent the bolt from splitting the tie it is the practice with some to let the tie project 4 to 6 ins. beyond the outside of the guard timber For fastening guard timbers to the ties both bolts and lag screws are used, but in oak timber it is found that the thread of lag screws is rapidly eaten away, so that the bolt and nut proves to be a much more reliable fastening for such timber. In yellow pine timber, however, such is not the case, and lag screws are frequently removed and used the second time. The best practice seems to favor putting the bolts into the timber from underneath, so that the nut comes on the upper side, in plain view, and where it can be readily attended to in case it should work loose. With nuts put on above the timber, however, the hole through the wood cannot be so well protected from water as when the nut is put on from below. To prevent the head of a lag screw or bolt from projecting above the timber it is sometimes countersunk into the timber by the use of a cup-shaped washer. To prevent the bolt from dropping out, in case the nut on the upper end should work off, some make it a practice to bend the bolt slightly before it is driven into position. This trouble is overcome, however, by the use of a slotted washer. This is a cast washer of the ordinary form with a slot extending radially from one side of the hole, so that after the nut has been screwed home a nail can be driven through the slot and against the side of the nut, thus serving as an efficient nut lock.

Guard timbers are usually spliced over a tie with a scarf or half-and-half joint, with at least a 6-in. lap, as shown by Engraving *D*, Fig. 435; or sometimes the two pieces are butted together squarely and bolted through adjacent ties, as shown in Engraving *B*, Fig. 434. In usual practice the pieces of the guard timber are made to break joints with the stringers—that is, the middle of the stick comes over the bent or floor beam and the pieces are halved together at the middle of the panel. Another idea is to have the joints in the guard timbers on opposite sides of the floor come staggered. Guard timbers vary in size from 6x8 ins. to 12x12 ins., the smaller size being most frequently in use. A ¾-in. bolt is the size commonly used. The hight or projection of the guard timber above the level of the top of rail must be governed by the reach of the snow plows, in case the timber comes within clearing distance. The guard timber is sometimes placed within 9 ins. of the outside of rail, but more frequently the distance is much greater. The question as to the proper distance between guard timber and rail is taken up in connection with the subject of bridge guard rails.

On bridges of considerable length a string of planks or boards should be spiked to the ties for a footway. Trackmen and other employees must travel the bridge and the public will, and it is well therefore to make the walking safe. The walk is especially convenient for flagmen running to or from their trains, and it is most serviceable when the ties are covered with frozen sleet. If it is feared that stock might reach the bridge and use the walk, it should be omitted for some distance from the end of the bridge. On a double-track floor the walk comes between the tracks. On long trestles refuge platforms large enough to receive a hand car should be provided every 1000 ft., or ¼ mile at the farthest. Such platforms may be built by planking over long bridge ties extending out past the guard timber, over a bent, and bracketed against the bent. Figure 437 shows the general arrangement of hand car refuges on the Boone Viaduct of the Chicago & Northwestern Ry. This viaduct is 2685 ft. long and 185 ft. high at the highest point, and on each side of the viaduct there are four refuge platforms at an average distance of 537 ft. apart, arranged with a substantial railing, as shown. The brace which appears in the figure is for the support of the bridge railing, which is necessarily broken at the platforms.

If the track on the bridge is curved the running rails should be spiked to every tie; but on straight line there is no necessity for spiking more than half of the ties; i. e., alternate ties. To get the rails in proper alignment they should not be permanently spiked until after the guard timbers have been laid and bolted complete. As the grain of bridge ties does not always run parallel with the sawed faces, they should be bored for the spikes with a ⅜ or $^7/_{16}$-in. auger, to prevent splitting. No splice bars should be slot-spiked on bridge ties, because the ties cannot be moved by creeping rails and are therefore liable to be split by pressure against the spikes.

Tie plates are quite extensively used on bridge ties, particularly where the latter are of pine timber, and hard pine is now one of the standard timbers for bridge ties. They are also used on oak ties in some cases where the traffic is particularly heavy or where the bridge is on a curve. In point of economy it may in many instances be found advisable to use plates on bridge ties where they may not be needed on the adjoining grade ties. The first cost of the former exceeds that of the latter, and the cost of renewal is also higher.

End Construction.—The point at which the most trouble usually arises in maintaining track to surface at bridges is at the line which technically divides the bridge and the track departments, namely, at the abutment or the end bent. If the abutment be of stone or other firm foundation, the surface of the track approaching it must be well maintained, because a rough spot at such a place is more severe as a cause of jarring trains than elsewhere, owing to the different sustaining properties of the two materials

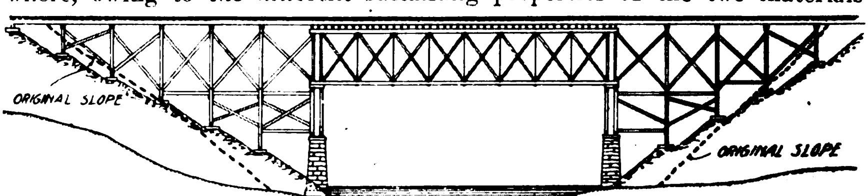

Fig. 438.

lying adjacent to each other; and if the abutment lies askew to the direction of the track the jarring due to uneven surface becomes much aggravated. If the end of the bridge be on timber, as at the end of a pile or framed-bent trestle, the effect of a low place in the track approaching the structure will be to create a heavy pounding force as the passing wheels suddenly mount the higher track at the proper level. Such pounding will settle the end bent if it be not very firmly supported. The importance of a bent of the full sustaining power at this point is therefore apparent. A fault too frequently met with is the want of some inclosure to hold the roadbed and ballast from being washed or crowded away from the end of the bridge, thus weakening the support for the track where it is most needed. But good end construction will not avail if the track immediately adjoining is not kept in good surface, neither can good surface be maintained where there is poor end construction. The question of maintaining smooth track at the ends of bridges, therefore, involves matters which concern both the bridge and the track departments.

With trestle bridges adjoining an embankment the earth usually slopes away for some distance under the trestle, or past the first two or three bents. A substantial bulkhead must therefore be provided to retain the ballast and roadbed at the point where the bridge floor joins the grade. Such a bulkhead is usually formed by spiking 3 or 4-in. planks to wing piles driven some distance out from the bent and slightly in rear of the line of piles in the bent. As it is desirable that an air space of 3 or 4 ins. should be maintained behind the cap and at the ends of the stringers, the bulkhead is separated from the end bent by furring strips spiked to the backs of the bent piles below the cap. The bulkhead should begin about 2 ins. below the base of rail and extend well into the bank, below the tops of the piles, so there will be no liability that material will be washed from under the bulkhead in time of high water or from the wash of surface drainage during a heavy storm. The outer edge of the bulkhead should conform to the slope of the embankment, and a brace is usually run along each sloping edge, from top to bottom, and to this the ends of the bulkhead planks are spiked. To re-enforce the end bent against the pressure of the earth at the back of the bulkhead, struts are run from the cap to the second bent, preferably to the ground line. Where the embankment joins a waterway and is liable to scour, a winged bulkhead, extending into the solid earth beneath the embankment, is made by spiking planks to the back side of wing piles set to give the face of the embankment a flare. In low bulkheads 4-in. sheet piling is sometimes substituted for horizontal planking.

Fig. 439.—Terrace Retaining Walls, Tennessee Central Ry.

Where trestles are built over steep slopes considerable trouble is frequently experienced in maintaining the footings. On newly made embankments the footings, unless very carefully prepared, will settle, and even when built on the natural ground the excavations for the foundations of the bents may leave the slopes between them so steep that they will not stand. A plan that has sometimes been followed with good satisfaction, both on steep natural surfaces and on new embankments, is to terrace the end slope in a manner to reduce the general inclination and permit the slopes between the foundations to be built to the angle of repose of the material. A diagram of such construction is shown in Fig. 438, in which the original slope is indicated by the broken line. In building such terraces the work of excavation is started at the top and the surplus material is cast over the ends and sides and worked toward the foot of the embankment. In planning work of this kind it is desirable to make the general slope easy enough to permit berms or footings $3\frac{1}{2}$ or 4 ft. wide, and still retain the natural slope of the material between the bents. Where this cannot be done it is sometimes the practice to face up the slope with a stepped dry rubble wall, to retain the loose filling and afford footings for the trestle sills. Some extensive dry walls of this kind (Fig. 439) were built in the construction of the Tennessee Central Ry., the general slope over the walls being $1\frac{1}{2}$ to 1. If the embankment or slope is composed of material like clay, with a tendency to slide, it is generally considered that the wisest plan to follow is to avoid excavating into the slope at all, but to build piers at the top and bottom of the slope, to grade, or a pier at the bottom and a pile foundation at the top, and bridge the space between top and toe of the slope with a single span. In locating a line through country where the topography is favorable to the scheme, some engineers aim to close the gaps at the ravines either wholly by embankment or wholly by trestle, so that the problem of building the latter over the slopes of newly made embankments does not arise.

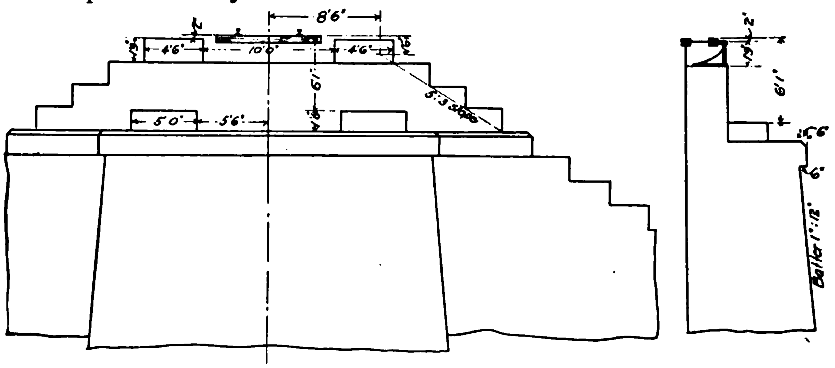

Fig. 440.—Arrangement of Parapets and Cast Iron Bulkhead, C., B. & Q. Ry.

On new embankments adjoining steel bridges the Chicago, Burlington & Quincy Ry. uses temporary spans supported upon piling driven into the bank. In order to avoid the construction of heavy abutments with wing walls to retain high embankments, the standard practice on this road is to place piers at the banks of the stream, with shore spans of plate girders supported temporarily at the bank ends upon timber blocking laid upon a foundation of piling. This pile foundation is located part way up the end slope of the embankment, and the piles are driven through the filling into the solid earth below the original surface. At the ends of the plate-girder shore spans temporary I-beam spans 16 or 17 ft. long are used, the bank end of each being supported upon a pile bent driven into the top of the embankment. After the embankment has settled a masonry abutment is built at the end of the plate-girder shore span, the short I-beam span is removed and the embankment is filled in behind the new masonry.

It is always important that the ballast under the first grade tie be retained in some substantial manner, and at the ends of bridges resting upon masonry the proper arrangement of the parapet requires careful attention. One method is to place a stick of timber, called a wall plate, on the parapet to support the rail, as shown in the Wabash bridge floor, Engraving *E*, Fig. 435. The objection to this practice is that the ballast lies against the timber, causing it to rot out quickly, and, besides, if the timber is not held rigidly in place by some means it will keep working its way over the edge of the parapet and permitting the ballast behind it to give way and settle under the adjacent ties. On the Boston & Maine R. R. the parapet stone at the top is narrowed down to about 8 ins. in width and extends within $1\frac{1}{2}$ ins. of the base of rail, so that the space between the last bridge tie and the first grade tie need not be uncommonly wide. This parapet (Engraving *A*, Figs. 434 and 435) serves to retain the roadbed and hold the ballast from being shoved out of place by the grade ties, so that the bridge floor and the track on the grade are separated by a distinct line without the intervention of anything which can decay or which is liable to be disturbed. In through bridges the end floor beam is usually dispensed with and the stringers supported upon the masonry direct. In some cases this arrangement permits of a closer spacing between the last bridge tie and the first tie on the ballast.

For masonry abutments cast iron bulkheads are used to good advantage, being durable and narrow, thus permitting close spacing between the last bridge tie and the first tie on the ballast. The standard bulkhead of the Chicago, Burlington & Quincy Ry. is a cast iron plate 21 ins. high and $\frac{5}{8}$ in. thick, bolted to brackets made fast in the masonry on the land side of the plate. On the backing, in rear of the bridge seats (Fig. 440), there are two parapets of masonry $4\frac{1}{2}$ ft. long and 1 ft. 9 ins. high, serving as enclosures at the ends of the bulkhead. The space between these parapets is 10 ft. in the clear and the bulkhead is made to fit into this space. The plate or face of the bulkhead is in two sections, each 5 ft. long, bolted to brackets at the ends of the bulkhead and to a third bracket in common, at the middle. The brackets are secured to the masonry by 1-in. stone bolts, two being used on each bracket, or six for the bulkhead. The plate is ribbed, bottom and top, the bottom rib being $4\frac{1}{2}$ ins. wide and the top rib, forming the top edge of the bulkhead, $3\frac{3}{4}$ ins. wide,

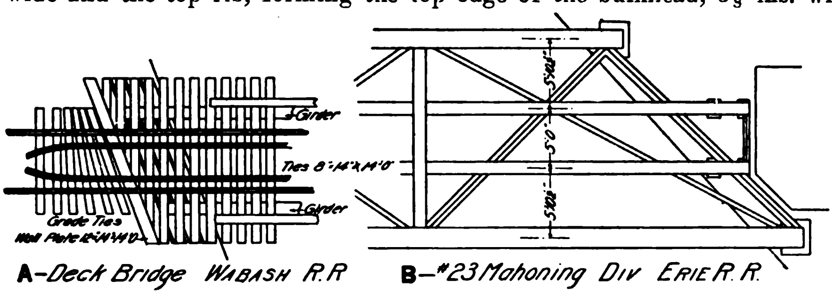

Fig. 441.—End Construction for Skew Bridges.

thus occupying but little room between the ties, so that a suitably narrow spacing may be had, as above noted. The top rib comes 2 ins. below the base of rail, so that a tie may be laid as close to the bulkhead as is desirable. At double-track bridges the arrangement is simply duplicated, two bulkheads being arranged with a common parapet between them. Figure 208 also shows a sectional view of this bulkhead.

At the ends of skew bridges the stringers should be arranged to meet the roadbed squarely (Engraving *B*, Fig. 441). The necessary support for the end of the extended stringer is usually afforded by a buttress at the back side of the masonry pier or abutment. Where this cannot be had, or is not provided, one of the stringers is sometimes extended past the masonry to meet the other squarely and is rested upon a mud sill. A few ties must then be supported partly upon the bridge floor and partly upon the embankment, and it nearly always happens that the projecting stringer or mud sill must be raised and blocked up occasionally to bring the track to surface; and besides, either piece of timber will rot out rapidly. The practice of ending the bridge floor at a skew and fanning out the ties on the roadbed (Engraving *A*, Fig. 441) to meet it is never satisfactory, since on one side of the track the ends of the ties must be spaced too close for efficient tamping and on the bridge floor the ties must be placed either askew to the rails or the last three or four ties must be cut short and joined into the wall plate (Engraving *A*), thus supporting only one of the rails. If the bridge ties are laid parallel to the parapet, or askew to the rails, both ends of the tie do not receive the load at the same time, and as a result the ties tend to jump and wear out rapidly. Since in passing from ballasted track to a bridge floor there is a change in rigidity of support, both wheels of an axle should pass the dividing line simultaneously, and hence the end of the bridge floor should be squared up with the track. In skew trestles the end bent can be built square or a square bent may be built immediately in rear of it to support the ends of the floor stringers. When a skew bridge is rebuilt upon old abutments the additional masonry necessary for supporting the ends of the floor stringers to bring them square may be laid upon the old bank by digging down and giving the new masonry a base of suitable size.

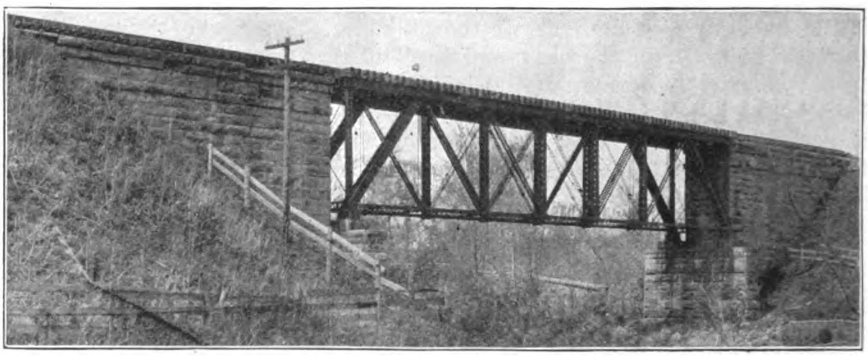

Fig. 442.—"T" Type of Bridge Abutment (Dismal Creek, Ill. Cent. R. R.).

With the "T" abutment style of end construction, examples of which may be seen on a number of roads, wing walls for retaining the embankment are dispensed with and the track adjacent to the bridge floor is very firmly supported. This type of abutment consists of a narrow masonry pier (Fig. 442) longitudinal with the track, extending back full depth into the embankment, from toe to top of the end slope, which lies at the natural angle of repose, so that no retaining wall is needed. The construction of such abutments is usually in connection with deck spans, the bridge seats being arranged upon a cross wall at the end of the abutment pier, as shown in the figure—hence the term "T-abutment." High abutment piers of this kind have sometimes been built as narrow as 7 ft. thick, except at the top, which is corbeled out to a width of 12 ft. or more to support and retain the ballast for the track.

The "T" abutment shown in the Fig. 442 is 9 ft. thick, and to replace the three top courses of stone, which had begun to disintegrate after long service, the whole top was remodeled by building a concrete coping to retain the ballast, on plans shown by Fig. 443. In beginning the work the ballast was removed from the top of the old masonry and the track was temporarily supported on timber stringers. The three top courses of the old masonry were then removed and the concrete coping was deposited in sections 6 ft. long. To firmly bind the sections together, two old rails were embedded longitudinally in the concrete, as shown. The top of the concrete coping is finished out to retain 18 ins. of ballast under the bottoms of the ties. To afford drainage the concrete bed is crowned 3 ins. in the center, and 4-in. tile drains projecting one inch from the face of the masonry serve to carry away the water collected. The concrete coping protects the body of the pier against further injury from seepage, and the corbeling of concrete protects the face of the masonry from dripping water. This style of coping has also been applied on this road to new "T" abutments built of concrete from the bottom up, to take the place of trestle approaches to some of the bridges rebuilt.

As bearing upon some of the questions hitherto discussed, reference may be made to the recommendations of a committee report to the Association of Railway Superintendents of Bridges and Buildings in 1897, as follows: "(1) Ties 12 ft. long, spaced 6 ins. apart in the clear, supported directly under the rails and near the ends; (2) suitable inside guard rails and spacers at ends of ties; (3) squaring the floor at the ends of skew bridges; (4) connecting bridge floor with approach by the method shown [Engraving *A*, Fig. 435]; (5) making the floor independent for each of the two tracks of a double-track bridge." The last recommendation (5) refers to the use of two sets of ties for the two tracks, the ends of both sets at the dividing line being supported in common upon a single stringer placed midway between the tracks and serving as a side stringer for both sets of ties. The ends of the two sets of ties meeting upon this middle stringer are covered by a single guard timber lag-screwed to the ties of both sets.

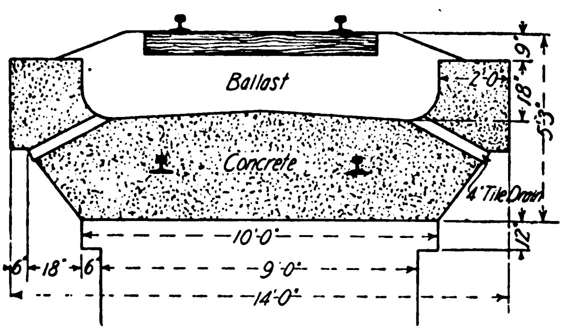

Fig. 443.—Cross Section of "T" Abutment and Concrete Coping, Ill. Cent. R. R.

As the bents of trestle bridges will settle occasionally, the floors of such bridges have to be surfaced to keep the track in smooth condition. Evidently the readiest method of doing such work is to raise and block up the stringers, and on pile bents no other convenient method is available. On the Savannah, Florida & Western Ry. (Atlantic Coast Line) a double cap is used, one over the other. In case of settlement the surfacing is done between these caps. The upper cap is raised by driving a wedge between the two and the shim used runs the length of the cap and is nailed in place. If the bent has settled unevenly at the two sides, however, such method of surfacing will not bring the track back into line. It frequently happens that the slight settling of one side of a trestle bent will throw the track out of line without dropping it much out of surface, especially if the bent be a high one; for it is easily seen that a small settlement at one side of a high bent must throw over the top much faster than the track will settle. If the bent be a framed one the simplest remedy is to jack up the end of the sill at the settled side of the bent and block it to place, when it will usually be found that the track will return to its proper alignment and surface. In the case of uneven settlement in a bridge pier the stringer would have to be moved sidewise, in addition to the work of blocking, in order to bring the track into both line and surface; or, in cases, perhaps, the track could be put in line more easily by pulling the spikes from the rails and respiking them to proper alignment. The most frequent source of trouble in this direction is found with bridge floors supported at the ends upon timber or cribbed foundations, for such are especially subject to settlement. Such settlement is all the more augmented if the end of the bridge comes at a high fill, because the settling of the fill leaves the end of the bridge high; and a train meeting the end of the bridge must be suddenly boosted, as it were, the reaction from which comes upon the end support in the nature of a tremendous blow. This state of things can be helped a good deal by easing off gradually the fall in the track from a point some distance clear of the end of the bridge. Owing to the tendency of track at the ends of bridges to get into rough surface it is a good plan to use 60-ft. rails at such places, so as to remove the first joint on the grade to a good distance from the end of the bridge floor.

Such work as raising stringers at ends of bridges and lining track on bridges is ordinarily done by a bridge gang, but in case the bridge men are slow in getting around the section crew should look to it; and then, whenever the end of the bridge floor is raised, the track for some distance on the fill beyond must generally be raised also, so that the section crew is needed in any event. No slope should be permitted in a bridge floor at the end, to compromise with a settled embankment. The end bent in a pile trestle is sometimes given an extra number of piles—say six, altogether, if the regular number in the other bents is four— in order that it may better withstand the hammering from the trains at this point. The piles in an end bent should, if possible, be long enough to reach down through the embankment and drive to a firm bearing in the solid ground beneath. Where the embankment is new it is sometimes the practice to extend the floor of the trestle temporarily over the embankment one span beyond the end bent and rest it upon mud sills, the extra span to be taken out after settlement has ceased. The wall plate supporting the rails over a masonry abutment is sometimes blocked up at the ends, to give elasticity and cushion the blow due to the sudden transition from earth to masonry support.

Curve Elevation on Bridges.—Where a bridge is located on a curve or on the run-off of a simple curve there arises the question of the method of elevating the outer rail. Among bridge men there is a wide range of opinion on the best method to pursue, owing to which, and to the different styles of bridge floor supports, a number of methods are in service, as follows: (1) By shimming under the outer rail, upon the tie; (2) by the use of tapered or wedge-shaped ties; (3) by shimming or blocking under the ties; (4) by a cushion tie; (5) by raising the outer stringer; (6) by increasing the depth of the outer stringer; (7) by tilting the trestle bent or pair of girders; (8) by inclining the cap.

Shimming under the outer rail is done by spiking a piece of plank to the top of the tie. The shim is placed longitudinally with the tie and is made long enough to carry the guard rail. This method is open to the objection that the track spike loses some of its holding power and the shims are liable to be split or badly cut up by derailed wheels, thus leaving the track in dangerous condition. By this method also the rails do not stand on the same plane and there is an improper inclination of the rails to the wheels, which leads to irregular wear. Wedge-shaped or taper-sawed ties answer quite well for a slight amount of elevation in the outer rail, but an elevation of 4 or 5 ins. requires a very deep stick at one end, thus calling for large timber, which in some localities is scarce. Extra labor is required in sawing the ties, and unless the timber is large enough to furnish two ties in one stick there is considerable waste of material; so that, either from waste of material or from the usual practice of mill men, who, in computing the amount of lumber in the tie, assume the tie to run its whole length at the size of the larger end, tapered ties are much more expensive than common ties. There is also the further objection that in notching the ties for use at the middle portion of a long plate girder, the material which must be cut out to allow for the extra thickness of cover plate must necessarily weaken the tie at the small end and leave it in danger of breaking off in case of derailment. There is also some extra expense attaching to the necessity of having to keep on hand a stock of ties sawed at differing tapers to suit the different bridges on the line.

Elevation of the outer rail by shimming or blocking under the ties may be accomplished in three ways. A tapered block may be used between the tie and the outer girder or stringer, the block being fastened to the tie by bolts or lag screws and the tie dapped over the block and the inner stringer. In dapping the tie over the inner stringer the notch in the tie must be cut to a bevel, owing to the inclination of the tie to the top surface of the stringer, and on a plate girder with a number of cover plates at the center the additional depth of cutting required seriously weakens the tie for service against derailment; and if the grain of the wood does not run with the tie the tie will usually split off at the end, starting from the shoulder of the dap. The most approved method is by the use of two blocks of different thickness under each tie, or one over each girder or stringer. The tie is dapped over the blocks an inch or half inch and the blocks are dapped over the stringers or girders, so that any extra cutting, to allow for extra heavy cover plates at the middle of the span, is made in the blocks and not in the ties. The method of shimming under the ties is done by building upon the outer girder or stringer by laying a longitudinal timber or plank.

A cushion tie is in reality a long, tapering shim extending under both rails. It is made the same width as the tie, or preferably an inch wider, so as to project a half inch over the tie on each side and prevent water from getting between the two. It is about 3 ins. thick at the smaller end and is secured to the tie by means of bolts or lag screws. The objections against the cushion tie are that, being thin at the small end, it is easily warped out of shape by the sun or split by the spikes; and, as usually made, the horizontal joint between it and the tie holds water which rapidly rots out both the tie and its cushion covering. The shallow cushion piece is also somewhat insecure against being torn out by derailed wheels.

The elevation of the outer rail by raising the outer stringer may be accomplished either by a cushion cap or blocking, or by corbeling the stringer. A cushion cap is a stick of timber tapered to the desired inclination of the rails and drift-bolted to the top of the main cap, under the stringers. In order to hold the stringers in line the cushion cap is dapped under the stringers. The principal objections to this method are that the dap under the stringer, and the joint between the cushion cap and main cap will hold water to rapidly rot out the timber; and the stringers do not stand vertically on edge. A similar method that is in practice to some extent is to use a tapering block under the outer stringer and then adz down the top of the cap to an inclination in the same plane, for the inner stringer. Another method, that is seldom if ever employed, is to lower the inner stringer by notching the cap. On the Savannah, Florida & Western Ry., where a double cap is used, elevation is obtained by placing blocks between the two caps. The use of a corbel under the outer stringer gives results similar to the use of blocking under the tie and seems to find favor. Where the corbel method is standard it is generally used under both inner and outer stringers, the outer one being enough thicker than the inner one to give the proper inclination for the ties. Wherever side or jack stringers are in use it would seem that the most desirable way to obtain the elevation would be by some method having to do with the support for the stringers, so that the tops of all the stringers could be placed in the same plane. The elevation may be built in the stringers or girders by increasing the depth of the outer stringer or girder. The objection to this method is that the ties must be dapped at a bevel, and in case of girders having several cover plates in the middle of the span, the increased amount of dapping made necessary cuts deeply into the tie and seriously weakens it for withstanding derailment.

The next method to be considered consists in tilting the trestle bents or the pair of stringers or girders supporting the ties. A trestle bent may be tilted by raising and blocking the end of the sill. This tilting of the bent inclines the cap and gives inclination to the track. The objection to this method is that the middle or "track" posts (which otherwise would be plumb posts) are inclined, and with slowly-moving trains, which do not develop much centrifugal force, the load does not act through the axis of the trestle, with the result that an undue proportion of the load is thrown upon the posts under the inner rail, with three of the posts acting as batter posts and leaning toward the inside of the curve, with only the inside post to oppose this action, and that with its batter reduced. As a result the bracing must stand a heavy racking stress. The seriousness of the latter objection disappears to some extent where the middle posts of the bent are set at a batter instead of vertical. The same objections apply to a leaning bent on a horizontal sill; that is, a bent built by framing the outer posts longer but with the axis of the system of posts inclined. The method of obtaining elevation in the outer rail by tilting up the pair of stringers or girders under the rails, by blocking under the outer girder, is objectionable from the fact that at slow speed the load acts vertically on the tilted girder, thus introducing a sidewise component for which the girder was not designed.

The last mentioned arrangement (8) for obtaining curve elevation on trestles, namely by inclining the cap, is much in favor and is extensively practiced. In applying this method to framed bents the sill is laid horizontal and the posts stand in the usual manner, the cap being inclined by lengthening the posts on the outer side. If the bent is more than one deck high, only the top deck or top story is framed with an inclined cap. In pile bents the piles are cut off at the proper hight to receive the cap at the desired inclination, the cap being sometimes framed on to the piles and sometimes dapped over and drift-bolted to them. It is to be noticed that by this method of inclining the track the elevation of the curve cannot be changed without resorting to one of the other methods above mentioned.

The stringers for supporting curved track on bridges or trestles are sometimes sprung to the curve. In one instance which might be cited as an example, a five-deck trestle 77 ft. high was located on a 6-deg. curve. The length of span was 15 ft. c. to c. of bents, and the stringers, three in number for each side of the track, were 8x16 ins. in size and 30 ft. long, laid to break joints over the caps and sprung to the curve. To strengthen a curved trestle against heavy stresses from centrifugal force the bents should be securely cross braced.

Bridge Guard Rails.—A question of first importance in the design of a bridge floor is the arrangement of the guard rails. If a derailed truck gets badly slewed on a bridge there is much danger of a serious wreck, both of the train and the bridge, especially a through bridge or one on which the trains run between the trusses. It is highly desirable, then, that means be provided to restrain the derailed wheels and keep the truck as nearly parallel with the track as is possible while passing over the bridge floor. The proper position for bridge guard rails is inside the track and not outside, for this reason: When all the wheels of a truck leave the rails and swing askew to the track, the wheels on the front axle almost always take the lead in guiding the truck, and of these two wheels the one running in the track takes the advance. If inside guard rails be in use the wheel which must run against the guard rail is the one in the advance; moreover, the side of the wheel which brings up against the guard rail is the inside, the portion of the wheel in contact with the guard rail being the guard side of the flange. On the other hand, if the guard rails are placed outside the track there is no guard rail in position for the leading wheel to meet, and its mate, the lagging wheel, which is outside the track, brings up against the guard rail. It is then to be noticed that with outside guard rails the portion of the wheel which comes in contact with the guard rail when the truck is slewed is the outside of the wheel or the corner of the tread. Now it must be clear that any obstruction to the leading wheel has a tendency to swing the truck in line with the track; but if the lagging wheel meets with obstruction the action is directly the reverse, the tendency being to slew the truck all the more. An inside guard rail retards the leading wheel of the front axle, which makes contact by a rounded edge (back side of the flange), so that the tendency of the wheel is to sheer off; moreover, the wheel is guarded the full depth of the rail. An outside guard rail retards the lagging wheel of the front pair, which, meeting the guard rail with the sharp corner of the tread, has a tendency to cut in and climb over; and all the more so because the wheel, being lifted to a hight equal to the depth of the flange (or the tendency being such), cannot be guarded so deeply. The action with inside guard rails is therefore to assist the derailed truck to swing back parallel with the track, whereas the effect of outside guard rails is to do the reverse.

The guard which meets all requirements most satisfactorily is an ordinary rail placed inside each running rail, about 8 ins. in the clear. The usual arrangement is to spike such guard rails to the ties (alternate ties) in the ordinary manner, and when such is the case the rails should be spliced on the service side with fish plates, putting the bolts through from the service side, so that the nuts cannot interfere with, or be reached by, the wheels in case of derailment. Old rails worn out in service are as good as any for this purpose, but a rail should not be used which presents a slivered or ragged head to the service side, because derailed wheels are liable to bite into the roughened edge and mount the rail. Preferably the guard rails should be the same hight as the running rails, but rails of ordinary section, even if not quite as high as the main rails, are satisfactory. In order to present a smooth service side, without spikes or bolt heads to interfere with derailed wheels, it is the practice on some roads to splice the rails together and turn them on side, using the flange of the rail as the service side of the guard. One method of holding the guard rail in this position is to bolt it to cast iron chairs, which in turn are bolted to the ties. On the Elgin, Joliet & Eastern Ry. the guard rails are turned on side and laid directly upon the ties, being fastened by bolts passing through the web of the rail and the tie.

As a wheel will readily bite into and mount a low timber there is not room to put effective timber guards inside the rails, unless the timber has metal protection on the service side. Such protection is sometimes afforded by facing the service side of the timber with a flat bar of iron laid with the top edge flush with the upper corner of the timber. A better arrangement is to face the service corner of the timber with an angle iron. Angle irons are sometimes used for inside guards in lieu of rails, the horizontal leg of the angle extending inward, toward the middle of the track, and bolted to the ties. In some cases the vertical leg of the angle is backed by a timber laid on flat over the horizontal leg and bolted to the ties through the portion which overlaps the horizontal leg. In other cases the horizontal leg of the angle is turned toward the running rail, as in Fig. 437, so as to form the bottom of a channel for the derailed wheels, the angle then being bolted to the timber backing through the vertical leg. Inside guard rails are all the better if they extend as high as the running rails, but they should not extend higher. A suitable size of timber for an inside guard would then be 5 x 8 or 6 x 8 ins., the stick laid on flat and dapped over the ties. The floor of the Boone viaduct, on the Chicago & Northwestern Ry. (Fig. 437), consists of yellow pine ties 12 ft. long and 8 ins. square in section, laid directly upon the plate girders and spaced 12 ins. c. to c. On each side of each rail there is spiked a 4x10-in. plank, those in the track being faced on the service side with a 6x4½-in. angle iron. At the ends of the ties there is a 10x12-in. yellow pine timber guard laid on edge and bolted to the ties. On the outside of the bridge these timbers are broken at the hand-car refuge platforms, so that they do not appear in the figure. On roads where snow plows are used timber guards that are much higher than the rail cannot, for obvious reasons, be laid near the latter. Where such conditions exist it is therefore possible to hold derailed wheels nearer to the running rails with inside guard rails than with outside ones.

In general practice inside guard rails are extended from 60 to 150 ft. beyond the end of the bridge and gradually deflected to meet in the middle of the track. The ends of the rails are usually made to abut against a terminal or point piece, which sometimes consists of a cast block running to a point, and sometimes an old frog point is spliced to the guard rails. To prevent anything from catching upon the terminal piece the point is beveled down or turned down into the ballast between two ties. On the Lake Shore & Michigan Southern Ry. the two rails run together and turn down into the ballast between two ties, being bolted together at the ends through a cast filler block. If the approach to the bridge be on a curve the safest plan is to extend the guard rails all the way around it before bringing them to a point; or to run them to a point, say 60 ft. ahead of the bridge, and then lay a single rail in the middle of the track the rest of the way around the curve. The purpose of deflecting the guard rails to the middle of the track is, of course, to catch derailed wheels and gradually guide them close to the running rails, and into line with the track. In order that the guard rail may have sufficient support or backing to properly perform its function, the inside of the rail throughout its curved portion should be well braced. Concerning the efficacy of this arrangement for general service there is some difference of opinion. In almost all cases where the derailed wheels are not far from the running rails the arrangement accomplishes its purpose, although one occasionally hears of an instance where the wheels refuse to be constrained and jump over the guard rail. Such is quite likely to be the case where the derailed wheels on one side are running off the ties, as it would be easier for the wheels on the ties to mount the guard rail than it would be for the guard rail to draw the other wheels back onto the ties. One can readily understand how such a result might obtain where the ballast is not filled in against the ends of the ties. For this reason it would seem that the use of a set of long ties, or switch ties, extending the length of the deflection in the guard rails would be an important aid in bringing derailed wheels into position to travel safely over the bridge, and a third guard rail, laid in the middle of the track, might come into play in any case where the wheel jumps over the deflected guard rail.

In remote cases derailed wheels are diverted by more than half the track gage, and then the deflection of the inside guard rails works a result exactly the opposite of that intended, for if the inside wheels catch the guard rails past the center of the track the truck will be thrown still farther away, and cases of this kind are on record where the car has been thrown into the end post of the bridge, knocking it down and wrecking the bridge. To avoid such consequences it has been proposed that snubbing posts in the form of a cluster of piles be erected in advance of and in line with the bridge post, to break up any cars which are so badly out of line as to strike the bridge post, and thus wreck the train before the bridge is reached. At a number of through bridges on the Grand Trunk Ry. there is a wall of cut stone masonry about 3 ft. thick, 6 ft. high and 30 ft. long, in front of and in line with each truss to protect it from injury by derailed cars. Another plan in practice is the use of a pair of flared guard rails placed outside the running rails just in advance of the guard point, so as to catch the truck and deflect it into position to take the right side of the inside guard rails. These outside advance guard rails are laid upon switch ties and braced, the leaving ends (opposite the guard point) being about 8 ins. clear of the running rails, and then flaring to a distance of about 5 ft. from the running rails at the entering end. Engraving *E,* Fig. 444, shows the arrangement, except that timbers are used for guard pieces instead of rails. The device illustrated is known as the Childe-Latimer bridge guard. The guard timbers flare out to a distance of 7 ft. from the center of the track or to a distance apart which corresponds to the distance between the bridge trusses. The large posts set in the ground to back up the ends of the flaring timbers are 16x16 ins., 12 ft. long, the top standing 4 ft. above top of rail. When timbers are used for these flaring guard pieces the upper corner on the service side of each should be sheathed with an angle iron to prevent derailed wheels from biting into it. These timbers should not be smaller than 10x10 or 12x12 ins. From the leaving end of the advance guards there should be outside guard rails parallel with the running rails, extending toward the bridge, to prevent the wheels from dropping off the ties until they reach a point where the deflected inside guards come close enough to the running rails to hold them on.

The fact that derailed wheels will sometimes take the wrong side of guard rails deflected to the center of the track has induced some to abandon the practice of deflecting the rails at all, but to lay them parallel with the running rails their whole length. Such is the practice on the Michigan Central R. R., and in addition a third inside guard rail is laid in the middle of the track. Each guard rail is turned down into the ballast, at each end, so as not to catch anything loose hanging from the cars. The idea which here obtains is that the safest plan is not to attempt to change the position of the derailed truck from that in which it first strikes the guard rails, and that any arrangement which will prevent it from swinging into a worse position while crossing the bridge is a sufficient protection. The middle guard rail serves to keep the inside wheels from getting past the middle of the track while on the bridge, but if they are already past the middle of the track before it reaches the bridge the guard rails do not operate to make the condition of things worse, as is sometimes the case where the guard rails are deflected to the middle of the track, as above explained. It may be well to remark that on through bridges with trusses standing widely apart this principle is undoubtedly the safest to follow out in practice; but on narrow bridges the advantage is with the two-line pointed guard, for if the derailed wheels have passed the center line of the track the car would strike a truss in any case, as also it might with the three-line guard if the wheels have nearly, if not quite, reached the center line; but in that case two-lines of guard rails converging to the center might draw the derailed car out of reach of the truss. On deck bridges the advantage would seem to lie with the three-line guard, without question, and a peculiar advantage in any case is that the three lines of rails may serve to carry badly slewed wheels, broken trucks, sliding car bodies, etc., clear of the ties, with less liability of bunching the latter than would be the case where the middle of the track is open.

The three-line straight bridge guard in use on the Michigan Central R. R. was designed by Mr. O. F. Jordan, formerly roadmaster with that road, and is known by his name. It consists of three lines of rails equally spaced between the main rails and parallel to the same throughout. The turned-down ends are inserted through a ½-in. iron or steel plate covering the space between the main rails and spiked to the ties. As first constructed, there was a rail on the under side of the ties (making four rails in all) bolted through and through with the middle guard rail, but this under rail is no longer used. Some other roads which use the Jordan bridge guard are the Lake Erie & Detroit River Ry., and the Toronto, Hamilton & Buffalo Ry. At one time the Chicago, Milwaukee & St. Paul Ry. used a bridge guard designed on a similar principle. It consisted of two T-rails, laid 10 ins. inside the main rails, and a 5x6-in. oak timber laid on flat in the middle of the track and dapped over the ties 1 in. The top of this timber was capped with a 6-in. channel iron inverted and bolted through and through at every fourth tie. The center guard ended at the ends of the bridge and was beveled down to prevent anything dragging under a train from catching, but the rail guards extended 150 ft. beyond the ends of the bridge. Besides the three guards in the track there were the usual timber guards near the ends of the ties. In course of time the use of the center timber guard was abandoned. A noteworthy feature of bridge floor design that is standard with this road, as touching the subject now in view, is to have no bolt heads or other projections where they will catch derailed wheels or parts of a car or its running gear that may be dragging.

It is quite commonly the practice to dispense with guard rails inside the track and depend upon guard timbers outside the rails. When such is the case the guards should be placed close enough to the rail—say 8 or 10 ins. from the rail in the clear—to serve as well as possible the purpose of a guard rail and prevent derailed trucks from becoming badly slewed in the track. If ties as long as 12 ft. are used the timber guard dapped over the ties near their ends, to keep them from bunching, is not close enough to the rail to be of service in holding derailed wheels on the floor, since the truck is already slewed so badly by the time the wheel strikes the guard timber that it cannot be turned back into line with the track, and consequently trouble is likely to ensue. Hence, if guard timbers are to be depended upon to hold the wheels on the floor they should be placed close to the rails, and beyond the ends of the bridge the timbers should be gradually flared out a sufficient distance from the rail to catch badly derailed trucks and deflect them into line with the track. These flaring guard ends should be laid upon switch ties placed in the track on the approach to the bridge floor. Owing to the tendency of derailed wheels to bite into timber, a low timber guard outside the rails, without inside guard rails, becomes an element of danger and actually worse than no guard at all in case of derailment, because of its action in retarding the wrong corner of the derailed truck and the liability of the wheel to mount it. For this reason the upper corner on the service side of the guard timber should be faced with an angle iron. If such protection is not provided the timber guard should never be less than 8 ins. high above the ties, but it is best to provide the metal protection for timber of any size. On some bridges of the Boston & Albany R. R. 10x12-in. hard pine guard timbers set $2\frac{1}{2}$ ft. from the rails are used, without inside guard rails. At the end of the bridge there is a flared approach consisting of rails laid to turn derailed wheels inside the line of guard timbers. The bridge guard of the Grand Trunk Ry. consists of a T-rail laid outside each main rail, at a distance of 12 or 15 ins., and well flared out beyond the ends of the bridge. Guard timbers should be securely bolted to every third or fourth tie, but if they are not dapped over the ties they should be bolted to every tie. If inside guard rails are used the outside guard timber is not needed, and it should then be placed so far from the rail that derailed wheels cannot reach it so long as they are held by the inside guard rails. At this distance from the rail it can perform its true function equally well, which is to keep the ties properly spaced and prevent them from spreading and bunching in event of a derailment. A piece of timber of square cross section is preferable to an oblong section for guard rails, owing to the fact that a choice of four sides is had for either the line side or the upper face of the timber.

In connection with inside guard rails a replacing device is sometimes used. The arrangement consists in laying the guard rails close inside the running rails and placing an inclined plane or "elevating casting" each side of each running rail at the point where the flared opening at the heel of the deflected portion of the guard rails draws to a close. The inclined planes are cast blocks, similar to the filler blocks of a frog, and each running rail with its guard rail and the incline castings are bolted together through and through, like a bolted frog. The incline castings gradually bring the wheels up to a hight even with top of rail, where they are constrained by the guard to take the rails again. One of the best known rerailing devices is the Latimer bridge guard, shown as Engraving *D*, Fig. 444. The Childe-Latimer bridge guard, shown as Engraving *E*, is a later improvement. In addition to the rerailing device and inside guard rails deflected to a point piece in the middle of the track there are outside flare guards in advance of the guard point, to steer derailed wheels to the right side of the guard point, as already explained.

While some claim much for a rerailing device at the end of a bridge others think that it may not be needed, and in cases may actually make matters all the worse for the derailed truck. Thus, for instance, it is claimed that a set of wheels which can be brought over by the guard rail and held until they reach the replacer will, in all probability, cross the bridge in safety, because the guard rail must do its important work before the replacer is reached; i. e., it must get the truck swung pretty well in line with the track. Now many think that when this much has been accomplished the chances of further trouble on the bridge are so slight that it would not be advisable to attempt to better the situation by taking further risk; for it must be admitted that to attempt to replace wheels on the rails at high speed with any form of rerailing device is doing it at the hazard of jumping the truck into a worse position than it had before. At high speed the truck would necessarily be swung with considerable momentum; and when the wheels have been raised out of the rut between the running rail and guard rail, it is difficult to tell how far the truck might swing. It does look a little like a case of not "leaving good enough alone." Such replacing devices when used should not be on the bridge, as the shock which might come upon the structure should the device fail to replace the wheels on the rails might cause dangerous stresses. It would be better to place it two or three rail lengths in advance of the bridge.

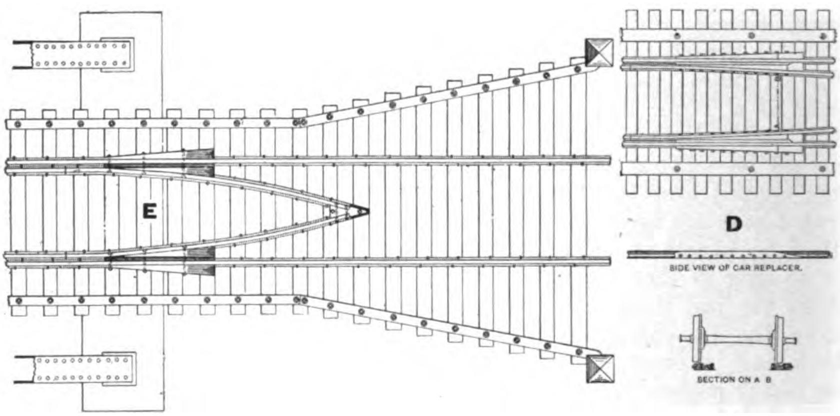

Fig. 444.—Latimer (D) and Childe-Latimer (E) Bridge Guards.

Wherever the supports of an overhead structure stand at the side of a track, as at crossings on separated grades, they should be protected against dislodgment by derailed cars. This may be done by laying guard rails in the track as on a bridge floor. Such guard rails are usually run to a point in the middle of the track, 50 or 100 ft. in advance of the columns or other supports, after the ordinary manner with bridge floor guards, but if the supports to be protected stand on only one side of the track, only one guard rail is usually laid, that being, of course, near the rail that is on the opposite side of the track from the object to be protected. In addition to the guard rail protection it is customary to build a masonry pier parallel to the track to surround the supporting columns to a hight of 4 ft. or more. Such piers or walls usually perform no service in supporting the overhead structure, being placed simply to encompass the column supports and fill intervening space in a manner to guard the supporting columns against shock or displacement by derailed cars. In some of the track elevation subways in Chicago concrete protection walls are built around the columns supporting the overhead bridges. An example of such construction on the Chicago & Western Indiana R. R. is illustrated in Fig. 445. The foundation for the wall is 4 ft. 4½ ins. wide and 14 ins. deep, extending to a level 2 ins. below that of top of tie. The wall built thereon is 3½ ft. thick at the base, tapering to a thickness of 1 ft. 9 ins. at a hight of 4 ft. 1½ ins. above the base, above which the wall has a uniform thickness of 1 ft. 9 ins. The hight of the wall above the foundation is 10 ft. The ends of the wall are prow-shaped, the top receding 7 ft. from the bottom, on the extreme edge, which is 6 ins. wide. Some of the protection walls in this subway are 243 ft. long and are provided with arched retreats through the wall at four different places, the opening being 3 ft. wide and 5½ ft. high.

Fire Protection.—As wooden bridges are liable to take fire from passing trains or from fires which spread over the right of way, the question of providing means for fighting such fires, or for protecting the structure against taking fire from trains, readily suggests itself. At wooden bridges or trestles it is customary to place barrels of water for service in case of fire, and at iron bridges at least one barrel is needed to protect the bridge floor. The barrels at the ends of bridges are usually sunk into the embankment, to insure that they will not be tipped over by mischievous persons. To prevent freezing during winter the water is salted. Where the weather becomes only moderately cold two buckets of salt to each barrel is sufficient, but in some parts of the Northwest where extremely cold weather is prolonged, one third to a half barrel of

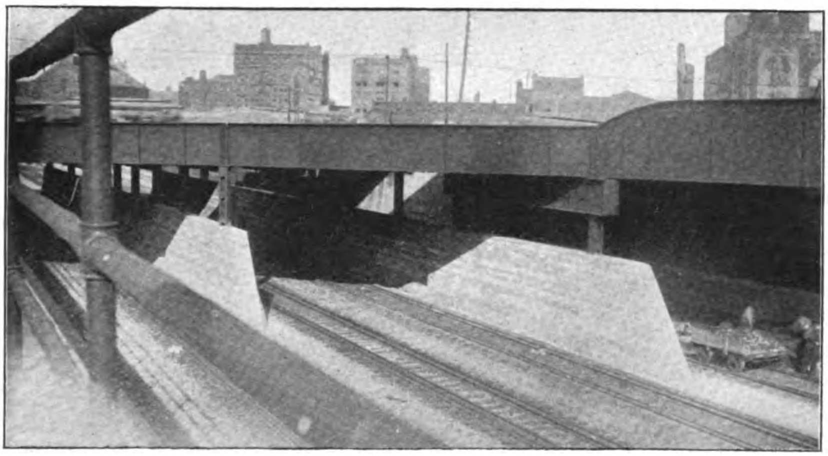

Fig. 445.—Concrete Protection Walls, for Bridge Supports, C. & W. I. R. R.

salt is used to each barrel of water, and even then the water on top will sometimes freeze into slush. On some roads a stick of wood is stood upright in the center of the barrel, projecting a few inches above the top, to prevent the barrel from bursting in case the water freezes into ice, but plenty of salt will usually keep the water in condition for use. In practice it is found to be necessary to renew the salt every fall, and, as might be expected, the use of salt requires frequent renewing of the iron hoops on the barrels. The barrels should be provided with heavy covers chained to the side, and a water bucket should be sunk in each barrel for use in case of fire. Whenever water is added to the barrels the condition of these buckets should be examined, for a coal oil can or tin pail with the bottom eaten out with rust or a wooden bucket with the hoops eaten off is a poor weapon for fighting fire. On long bridges or trestles it is customary to have water barrels stationed at frequent intervals, usually on the trestle caps or on a platform extending beyond the ends of the ties. The section men are required to keep these barrels filled, so that they will not be checked by the sun and become leaky. At bridges where water is not handy the water barrels, if numerous, should be filled periodically by hose from a tank car or from the tender of the work train, as the cost of trucking water by the section crew is too great.

Concerning systems of watching wooden bridges against fire there is no generally uniform practice. On some roads no regular bridge watchmen are employed and, aside from the chance that the section crews may pass over the bridges once or twice a day, they receive no particular attention. In other cases watchmen are employed during the dry season of the year to pass over each bridge after the passage of a train, keeping close watch for fire. In case there are a number of wooden bridges within a distance of a few miles the watchman is given a velocipede hand car and is required to look after all of the bridges within the limits of the beat he is able to ride over between trains, within a reasonable time after the passage of the trains. In watching bridges the watchman should not pass the bridge sooner than 15 minutes after the passage of a train, since fire starting from sparks might smolder or not get sufficiently

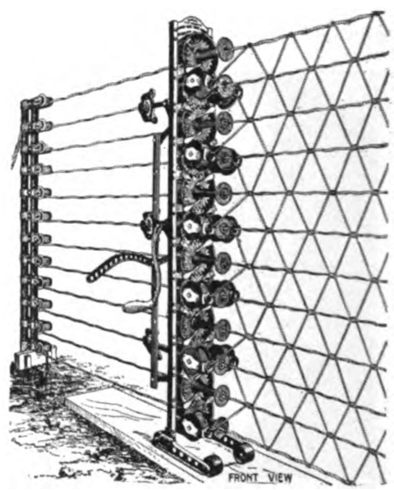

Fig. 446A—Kitselman Woven Wire Fence Machine.

started to attract notice until after a few minutes from the time it begins. In other cases important wooden bridges, particularly long ones, are placed in charge of a watchman who patrols the bridge after the passage of each train, at all times of the year. Oak bridge ties are not liable to take fire except during extremely dry weather, and even then it is seldom that the fire will spread and burn the tie to the danger point. Nevertheless it is a good plan to have water barrels at all bridges—whether of wood or of iron—if there are wooden ties in an open floor.

It is quite frequently the case that means for protecting wooden bridges from fire are provided in the construction of the bridge floor. One method is to cover the ties with galvanized sheet iron, making a close fit with the rails by upturning the edges of the sheets. Another method quite extensively in use on wooden trestle bridges is to cover the stringers and caps with galvanized sheet iron. Such protection keeps the fire from the vital parts of the floor and protects the parts covered, even though fire may burn some of the ties. On the Louisville & Nashville R. R. the galvanized iron used is No. 20 Birmingham gage and is put on the caps in strips 25 ins. wide and 7 ft. 9 ins. long. The strips overlap 6 ins. and are riveted together with flat-head, soft iron, tinned rivets $^5/_{16}$ in. in diameter and $\frac{3}{8}$ in. long, placed in the center of the lap, $2\frac{1}{2}$ ins.

apart. Each set of stringers is made up of three 7x14-in. pieces and is covered with strips of galvanized iron 33 ins. wide. In either case the iron is turned down 5 ins. over each edge of the timber, at an angle of 45 deg., so that anything which falls upon the stringers or caps, when it slides off, will fall clear of the trestle bent. Such a covering also protects the timber from the weather and is sometimes applied to the upper chord pieces of wooden trusses. The Southern Pacific wooden deck truss shown as Engraving *B,* Fig. 434, is so protected. The top of the top chord, under the floor beams, is covered with No. 24 galvanized iron turned down 3 ins. over the edge of the timber and tacked.

In the case of a wooden truss deck bridge adequate protection from fire cannot be had without covering the structure. One method in practice on some of the southern roads is to fit planks between the ties, forming troughs, and then to close the ends of the troughs by fitting pieces of boards between the ties. The space between the ties, and for a depth of about an inch over the tops of the ties, is then filled with gravel or sand. Gravel is said to answer the purpose best, because it does not wash out through the cracks between the tie and the plank. The use of gravel or sand has the effect of rotting out the ties much sooner than would be the case with ties in an open floor. On the Boston & Maine R. R. wooden deck trusses are tightly roofed over with two layers of ⅞-in. boards laid at a pitch of 1 in. to the foot, as shown by Engraving *A,* Fig. 434. The floor beams are laid directly upon the top chord and, being spaced only 2 ft. 7½ ins. centers, heavy stringers are not needed. The roof boards are butted at the ridge and covered with a strip of galvanized iron 18 ins. wide. The ties are "saddled" or cut out on the under side so as to fit over the peak of the roof. The tie remains 4 ins. thick in the middle, which is supported by a ridge stringer 6x12 ins. in section. The roof boards are painted and sanded as a protection against fire. By another method, in service on the Philadelphia & Reading Ry., the ties or the stringers are not disturbed. The stringers are covered with sheet metal, which is turned down over the edge of the piece, and roof boards are butted against the stringer, near its upper corners, so that the sheet metal covering laps the joint. Outside the stringers the roof boards slope beyond the floor beams and between the stringers the roof boards form a valley. A covering for Howe truss deck bridges that is used on the Chicago, Milwaukee & St. Paul Ry. consists of roof boards outside the stringers and galvanized sheet iron troughs between the ties. The details are explained by the legends in Fig. 446.

Of late years considerable attention has been given to the question of protecting iron bridges from corrosion by the brine which drips from refrigerator cars. The increasing amount of traffic in such cars has enforced upon bridge men a problem requiring serious study, and the only solution seems to lie in completely covering the bridge. On the Cleveland, Cincinnati, Chicago & St. Louis Ry. the stringers and chord pieces of iron deck bridges are protected from brine by painted beveled blocks, fitted closely between the ties, so as to cover the parts exposed.

Bridge Floors Over Streets.—The elevation of tracks over streets in cities has developed a number of special designs for solid bridge floors. The conditions imposed usually require that the bridge floor shall be tight, to prevent anything dropping from the cars into the street, and the desire to reduce to the lowest practicable limit the hight of the embankment filling, considered in connection with the headway requirements, calls for a shallow floor. The track in such cases is usually carried by through plate girders, and a very common type of floor is had by using I-beams for floor beams, between the girders, resting them either directly upon the lower flange of the girder, or upon hangers attached to the web plate; then covering the I-beams with floor plates or with longitudinal rail plates, to which the rail is secured by means of bolts and clips. The guard rails usually consist of angle irons riveted to place and the floor plate is tarred and graveled, so as to shed water. The Chicago, Burlington & Quincy Ry. floor for street viaducts is formed upon 15-in. I-beams spaced $14^{11}/_{32}$ ins. apart from center to center, and resting directly upon the lower flange of plate girders spaced 13 ft. apart. The I-beams are covered with a $^5/_{16}$-in. floor plate and the rails are secured by bolts and clips to longitudinal rail plates 20 ins. wide and $\frac{1}{2}$ in. thick riveted directly to the I-beams. A $5 \times 3\frac{1}{2} \times \frac{1}{2}$-in. angle iron is riveted to the rail plate, 9 ins. clear of the rail, on either side, to serve as a guard

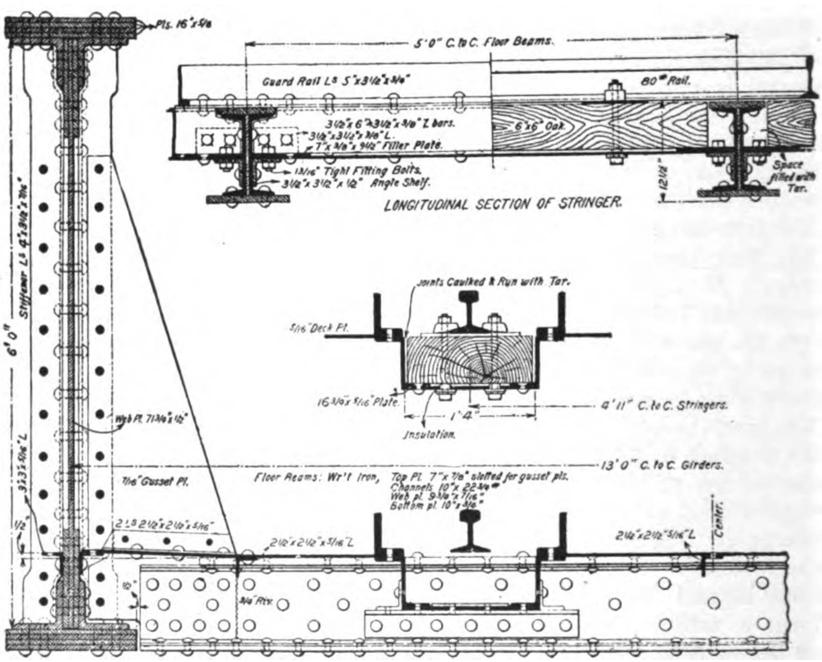

Fig. 447.—Floor for Street Viaduct, Chicago & Northwestern Ry.

rail. The floor of street viaducts on the St. Charles Air Line is made of 12-in. I-beams spaced 12 ins. centers, and covered with a $\frac{3}{8}$-in. plate. The rails are carried on special short plates laid on the floor plate, and a Z-bar is riveted to the floor plate, each side of each rail, to serve as a guard rail. The plates under the rails vary in thickness from $\frac{1}{8}$ in. at the center of span to $\frac{1}{2}$ in. at the end of the bridge, half of the camber being taken out by these plates. The floor plate is not laid directly upon the I-beams but upon filler plates or strips 3 to 5 ins. wide, varying from a thickness of $\frac{5}{8}$ in. in the middle of the track to $\frac{3}{8}$ in. under the rails and nothing at the plate girder, so that the floor has a transverse slope each way from the middle of the track and a longitudinal slope each way from the middle of the span. The floor beams (12-in. I-beams) are attached to the web plate by hangers and are suspended above and just clear of the lower flange of the girder.

The standard floor for street viaducts on the Chicago, Rock Island & Pacific Ry. has 12-in. I-beams attached to oblique hangers, so that the bottom of the beam is even with the bottom of the girder. The hanger plate is 9 ins. wide and $\frac{1}{2}$ in. thick and stands at an angle of 45 deg., being bracketed against the web plate and across the edge of the lower flange of the girder. The I-beams are spaced $13^7/_{16}$ ins. center to center and covered with a $^5/_{16}$-in. floor plate. Longitudinal rail plates $\frac{3}{4}$ in. thick are laid upon the floor plate, to which the rail is secured by bolts and clips, the bolts reaching through the floor plate. A 6x4x$\frac{1}{2}$-in. angle iron laid on flat and riveted to the rail plate outside each rail, 9 ins. in the clear, serves as a guard rail. The floor plate is tarred and covered with finely crushed screened rock, and then with a layer of gravel about 3 ins. deep, to deaden the sound of trains passing over the bridge. On viaducts over other roads or where the subway does not carry street traffic the floor plate is omitted and the floor remains open, the rail plate in that case coming directly upon the floor beams. The floor system for street viaducts on the Chicago, Milwaukee & St. Paul Ry. is built upon 12-in. 45-lb. I-beams spaced 15 ins. centers. The I-beams rest directly upon the bottom flange of the plate girders and are riveted thereto. On tangent the plate girders are spaced 13 ft. centers. The I-beams are covered with a $^5/_{16}$-in. floor plate and the rails are carried in 10-in. channels laid upon the floor plate. The bearing for the rail is a cushion of oak timber $1\frac{5}{8}$ ins. thick, laid in the channel and covered with a $\frac{1}{4}$-in. steel plate upon which the rail bears directly. The rail is secured by $\frac{7}{8}$-in. U-bolts and clips at intervals of 30 ins., the legs of the U-bolt extending through floor plate, channel, the oak cushion and its cover plate. The U-bolt straddles a cast saddle block bearing against the under side of the floor plate. On curves the superelevation of the outer rail is obtained by increasing the thickness of the cushion timber in the channel. The application of a coating of asphalt composition to the floor plate of these bridges, to protect it against corrosion from salt water drippings from refrigerator cars, did not prove a successful experiment The difficulty with the asphalt was that it cracked and peeled off, leaving the metal unprotected.

The standard floor for street viaducts on the Chicago & Northwestern Ry. is shown in Fig. 447. The floor beams are built of two 10-in. channels spaced $\frac{1}{2}$ in. apart, with top and bottom plates. The floor beams are spaced 5 ft. apart and are connected with the girder by gusset plates which project 2 ft. and go between the channels of the floor beams. There is a filling piece between the channels, extending from gusset to gusset, thus giving a thick web. The bottom of the floor beam comes even with the bottom of, and stands entirely clear of, the lower flange of the plate girder; and, being riveted to the gusset plate, the load is carried directly to the web plate of the girder. The track stringers are made of two Z-bars riveted to a $16\frac{3}{4}$x$^5/_{16}$-in. plate, forming a channel, into which is fitted an oak block 16 ins. wide and 6 to 7 ins. thick, forming a cushion for the rail, the arrangement being similar to the Chicago, Milwaukee & St. Paul device, above described, except that in the latter case the channel rests upon the top of the floor beam instead of butting against it as in this case. There is a camber of one inch in the girders, for drainage, and the variation in the thickness of the block levels the rail. A 5-in. angle iron is riveted to the top of the Z-bar channel, on each side of the rail, to strengthen the channel and to act as a guard rail. The cushion block is covered with a rail plate and the rail is secured by clips and bolts, the latter reaching through cushion block and bottom plate, as shown. The rail is carried just clear of the floor beams. The floor beams are covered with a $^5/_{16}$-in. plate, which is stiffened with

$2\frac{1}{2}$x$2\frac{1}{2}$x$^5/_{16}$-in. angles on the under side. The floor plate is then covered with a coat of gravel roofing to protect the metal. The purpose of the cushion block in the bridge floors here mentioned is to deaden the sound of trains passing over the bridge.

In some cases a solid floor is secured by the substitution of buckled plates for I-beams. Thus, some of the bridge floors on the Chicago, Rock Island & Pacific Ry. were built up of plates and angles into a continuous corrugated surface with rectangular troughs running crosswise the track, suspended directly from the web plate of the girders by hangers. The rails are attached by bolts and clips to longitudinal rail plates 18 ins. wide and $\frac{1}{2}$ in. thick resting directly upon the ridges between the troughs. Inside guard rails (T-rails) are secured to the rail plate and a 4x$3\frac{1}{2}$x$\frac{1}{2}$-in. angle iron is laid outside the running rail and secured to the rail plate. The buckled plate floor of the Illinois Central R. R. is shown in Fig. 448. It is formed of channels having a 5x$\frac{3}{4}$-in. base and $4\frac{1}{2}$x$\frac{3}{8}$-in. legs, alter-

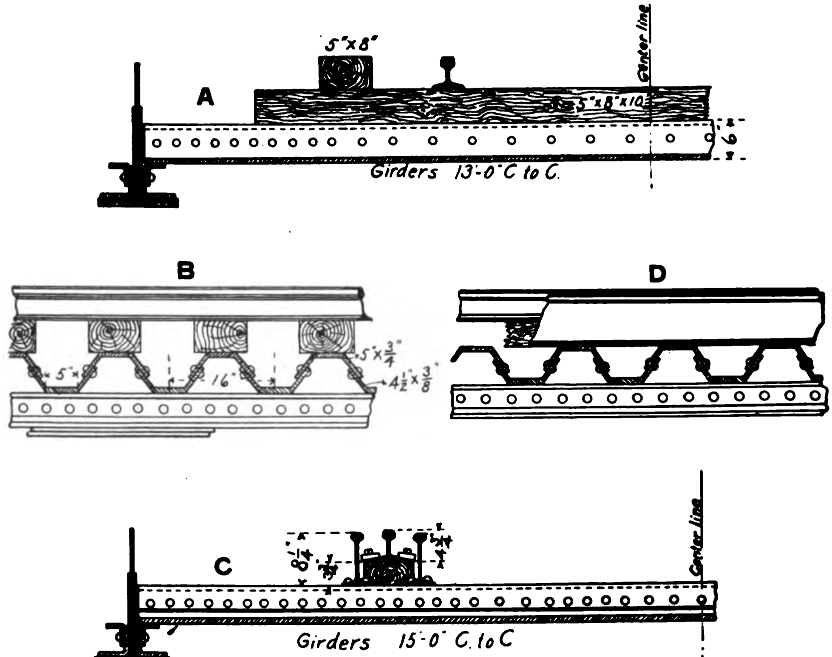

Fig. 448.—Buckled Plate Bridge Floor, Illinois Central R. R.

nately inverted and riveted together, forming a corrugated surface 6 ins. deep. The channels rest upon a shelf angle riveted to the girder over the vertical leg of the bottom flange angle, as shown. The floor for girders spaced 13 ft. centers is shown as Engraving *A*, Engraving *B* being a section of the floor parallel to the track. The ties are 5x8 ins. x 10 ft. long, laid upon the ridges between the troughs, and are held in place by 5x8-in. guard timbers. It was first the practice to place the ties in the troughs, the tie being small enough to fit into the trough and high enough to support the rail just clear of the top of the trough. Later it was intended to raise the tie about $1\frac{1}{2}$ ins. and fill the space around the tie with asphaltic concrete. In order to obtain access to the troughs for cleaning and painting, however, it was finally decided to place the ties on the ridges between the troughs, as shown. Engraving *C* shows the form of floor where the girders are 15 ft. apart and Engraving *D* is a section of this floor parallel to the track. Two 8¼-in. deck beams are riveted to the ridges between the troughs and spaced sufficiently far apart to receive an oak timber cushion for the rail. The cushion is supported by the lower flanges of the deck beams and the rail is secured by bolts and clips. On the Chicago, Madison & Northern line of the Illinois Central R. R. a buckled plate floor is used having troughs 12 ins. deep. The track ties are 6 ins. thick and 10½ ins. wide and are laid in the troughs and supported upon shelf angles placed along the sides of the trough about 7 ins. from the bottom, so that the tie projects 1 in. above the top of the trough. Guard timbers, 10x12 ins. or 12x12 ins., are dapped over the ends of the ties and bolted to them, thus forming a very substantial floor on which the ties cannot be bunched.

Ballasted Bridge Floors.—The most improved type of bridge floor is the ballasted floor, or the "ballasted-top" bridge, as it is sometimes called. The advantages in this type of floor construction are conceded by both bridge engineers and trackmen. From the point of view of the bridge men, the trains pass over the ballasted floor without so much shock to the bridge as is the case when the track is laid upon stringers, owing to the ability of the ballast to take up or receive the vibration from the trains. The weight of the ballast also increases the percentage of dead to live load, thus decreasing the deflection and vibration in the bridge structure proper. From the standpoint of the trackman there is everything in favor of the ballasted floor, both in regard to the question of safety and to facility of maintaining the track in serviceable condition. A derailed truck will travel as safely over such a floor as at any point on the grade; and as continuity of roadbed conditions is preserved over the bridge, the work of maintaining the track in surface and alignment is nowise different from ordinary methods in practice for raising track and throwing it to line upon the roadbed. The ballasted floor is an outgrowth of the long-time practice of covering open culverts with timbers or old rails and filling in over such covering with ballast to support the track, thus doing away with many of the objectionable features of such openings.

The modern improvement in ballasted floors consists of a solid metal covering over the stringers, floor beams, or girders, overlaid with ballast to support the track. The ballasted floor for deck bridges on the Michigan Central R. R. is formed by laying I-beams about 12 ins. apart directly upon the upper chord or upper flange and covering the I-beams with a floor plate. The floor plate is covered with a layer of asphaltum and weep holes are left at intervals for drainage. A curb consisting of a 3½x7-in. angle iron on end is riveted to the side edges of the floor to retain the ballast. The ballast (gravel) is placed upon the asphaltum covering of the floor plate and the track is surfaced in the ordinary manner. On the Chesapeake & Ohio Ry. old rails laid workwise side by side are used for the flooring of plate-girder deck bridges. The rails are spaced 6 ins. apart centers, the rivets in the top flanges of the girders being spaced to come between the rails, the openings being left to drain the water out of the ballast, which is broken stone. On double-track bridges the pieces of rails in the floor are 23 ft. 5 ins. long, extending the whole width of the bridge. The rails are secured to the bridge laterally by an angle iron at their ends which is bolted to a side extension of the top cover plate of each girder. This extension projects out 15 ins. beyond the web plate, and the angle iron against which the rails abut is secured to it with ¾-in. bolts. To retain the ballast and finish up the side of the bridge floor a ⅜x10-in. plate standing edgewise is riveted to each outside angle iron.

More frequently the covering for the ballasted bridge floor consists of buckled plates made by uniting channels, plates, angle bars, or Z-bars in such a manner as to form the corrugated surface. A number of such forms are shown in Fig. 449. Engraving *A* shows diagrammatically a section of floor with troughs having flaring sides, or of trapezoidal section, being formed of channels alternately inverted. This type of construction, known as the "Lindsay" floor, is in use on the Illinois Central R. R., as already noted. Engraving *B* shows the Francis & Dawley floor, in use on the New York, New Haven & Hartford R. R., particularly as a floor for street viaducts in Providence, R. I., and Boston, Mass. The bottom of the trough is formed of channels, the sides of angle bars and the ridge is united by a plate. The advantage of this form of construction is that the cap plate provides a means of spacing the troughs exactly to any desired distance center to center. The depth may also be varied easily by varying the length of the angle leg. Engraving *E* shows a trough of similar shape formed by Z-bars and plates. Engravings *D* and *F* show sections of floors with troughs of rectangular section, the former being composed of plates and angle bars and the latter of channels and plates. If the ties are to be placed in the troughs the top angle bars in *D* and the top channels in *F* should be placed inside the vertical plates of the ridges, but where ballast is to be used the arrangement is best as

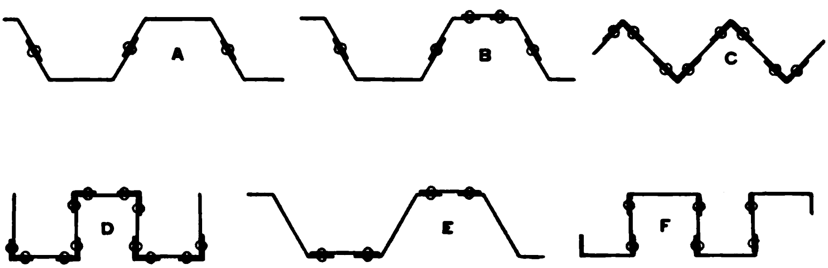

Fig. 449.—Forms of Buckled Plate for Bridge Floors.

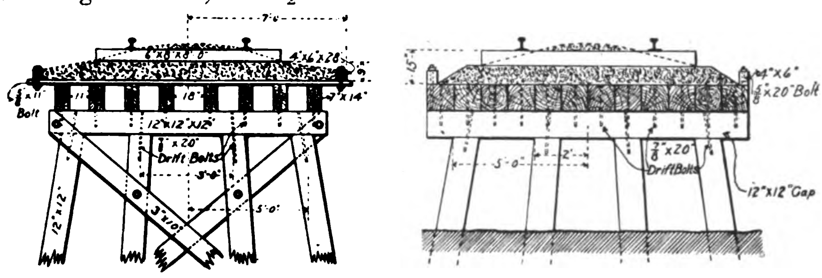
shown, with the angles or channels capping the joints in the corners, to keep out water. In *D*, however, the top plates of the ridges might perhaps better be placed over the angle legs, as in Sketch *B*, the arrangement otherwise remaining as shown. Engraving *C* shows a section of floor with triangular-shaped troughs, being formed of angle bars and plates. This type of floor is in service on the Pittsburg, Ft. Wayne & Chicago Ry., in street viaducts in Chicago. As made on that road the top angle comes between the plates instead of capping them. Crushed stone ballast is used and the base of rail is 6½ ins. above the apex between the troughs. It is remarkable that the noise of trains passing over these bridges is not nearly as loud as the rumble that is heard from the solid plate or buckled floors where the rails are supported directly upon the metal.

Troughs with flat bottoms may be supported directly upon the flanges of the bridge girders, either at the ends of the trough or at intermediate points, but triangular flooring (Engraving *C*) is sustained at the ends of the troughs by angle lugs riveted to the web plate of the girder. Forms *A*, *B*, *C* and *F* are without seam or rivets in the bottom of the floor, so that tight riveting or calking to prevent leakage is not required. The joints are also better protected against corrosion. Drainage is usually provided by a weep hole in the bottom of each trough near each end, which drips into a gutter consisting of a channel running longitudinally under the floor, being suspended from hangers riveted to the troughs.

These gutters empty into down spouts leading to the pavement gutters or to the sewers.

The protection of steel plate in ballasted bridge floors from rapid corrosion is attended with considerable difficulty, as periodically the ballast must be dug out to uncover the metal for repainting or recoating. Consideration of this fact has resulted in the use of creosoted timber flooring for steel bridges on some roads. On some of the plate-girder bridges of the Chicago & Alton Ry. the floor for retaining the ballast consists of 6x8-in. creosoted timber laid on flat, side by side, across the top flanges of the girders. The ballast is 6 ins. deep under the ties. In order to carry the bed of ballast unbroken over the ends of the deck girder bridges, the abutment parapet is built up even with the top of the girder and the opening between the end of the girder and the parapet is bridged over by a metal plate. For drainage purposes some of the plate-girder bridges stand on a grade of 1 per cent, the difference of elevation in the ends of the bridge being evened up in the track by the difference in the depth of the ballast. On track-elevation viaducts where a shallow floor is required the creosoted flooring is only $3\frac{1}{2}$ ins. thick. The floor of the track-elevation bridges over street subways that is used by the Atchison, Topeka & Santa Fe Ry. consists of 12-in. 55-lb I-beams resting directly upon the bottom flanges of the plate girders, and spaced 16 ins. centers, covered with creosoted planks laid longitudinally with the bridge. The planks are dressed to a thickness of $2\frac{1}{4}$ ins. and are tongued and grooved. At the sides of the floor the planks, covering a width of about 18 ins., are laid to slope toward the center of the bridge. On the New York Central & Hudson River R. R. old bridge floor beams $16\frac{1}{2}$ ins. deep, covered with 4-in. plank, have been used in ballasted-top culverts of $13\frac{1}{2}$ ft. span. The Chicago, Burlington & Quincy Ry. is experimenting with a floor of reinforced concrete slabs 4 ft. wide, measured along the track, and $8\frac{1}{2}$ ins. thick.



HOUSTON & TEXAS CENTRAL RY. SOUTHERN PACIFIC RY.

Fig. 450.—Ballasted-Top Wooden Trestles.

Ballasted floors are also quite commonly in use on wooden trestles. The stringers may be planked over, as in the Houston & Texas Central ballasted floor, shown in Fig. 450, or the stringers may be laid touching side by side, as in the Southern Pacific ballasted floor, shown in the same figure. In the floor of the Houston & Texas Central Ry. there are eight 7x14-in stringers 28 ft. long, laid to break joints across the 14-ft. spans of the trestle. Across the stringers are placed 2x12-in. x 14-ft. flooring planks, along the outer edges of which are bolted 4x6-in. x 28-ft. curb pieces to confine the ballast. The track construction is ordinary and 9 ins. of gravel ballast is used underneath the ties. The tops of the ties, between the rails, are covered with ballast, as a means of protection against fire. In building new trestles creosoted lumber is used, both for the substructure and the superstructure, and, as such, it is regarded as very durable. It is found that expenses for repairs and renewals to trestles fall off very perceptibly as soon as the flooring and ballast are put on, and increased security is afforded the structure against catching fire from engines. The planks and stringers are separably removable and the track is worked by the regular section forces in the usual manner. In the floor of the Southern Pacific Co. the depth of stringer varies with the span, running from a depth of 6 ins. for a culvert span of 4 ft., to 12 ins. for a clear span of 14 ft. The piles are so driven that their center lines if prolonged would meet at a common point vertically over the center of the track, 25 ft. above top of rail.

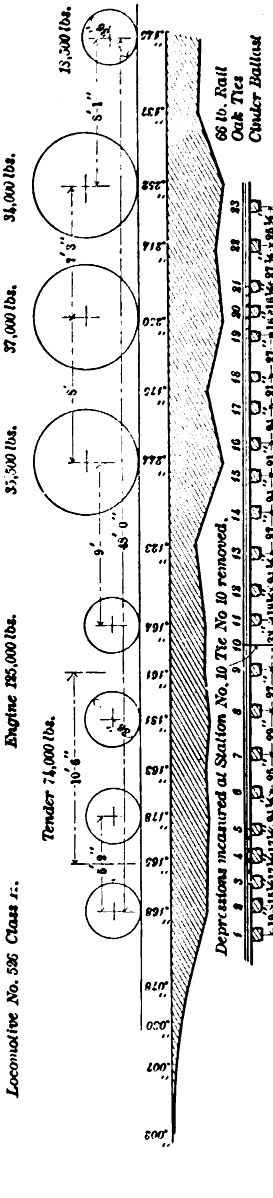


Fig. 452.—Experiments in Track Deflection (For Strain Diagram See Fig. 525).

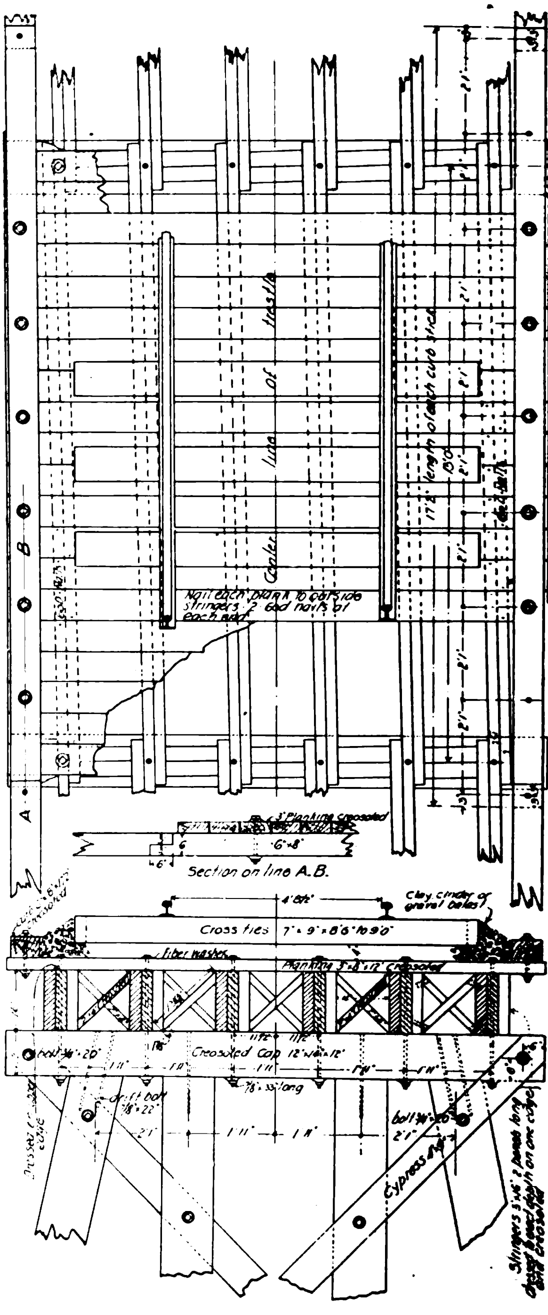

Fig. 451.—Ballasted Trestle Floor, Louisville & Nashville R. R.

The ballasted floor for timber trestles on the Louisville & Nashville R. R. has six stringers, each of which is made up of two 3x16-in. pieces dressed on one edge to exact depth and spiked together. The timber is creosoted, and the idea in building the stringer of two pieces is that they will take the chemical treatment more thoroughly than a solid 6x16-in. stick. The stringer pieces are two panels long and are laid to break joints and to lap by on the caps, as illustrated in Fig. 451. By this arrangement it is unnecessary to cut sticks at the ends that might be too long if required to meet on the caps. It is objectionable to cut timber or to mortise it for framing after it has been creosoted. Each stringer piece is held at the center by a long bolt passing through the floor and cap. The floor can be strengthened by putting in additional stringers without disturbing the ballast or existing stringers. Creosoted yellow pine trestles constructed on these plans were in sound condition after 24 years of service, and apparently good for a much longer life, having, since they were built, been strengthened by additional stringers in the manner stated, to enable them to carry heavier rolling stock.

Elevated Railway Floors.—As an elevated railway is essentially a trestle the type of floor for such bears a general resemblance to the floors of ordinary railway trestles. The floor in general use has plate-girder or lattice-girder stringers spaced 5 to 6 ft. centers and headed into the bents. The ties are laid directly upon the stringers and secured thereto by hook bolts. A guard timber, usually about 6x6 ins., is placed inside each rail, about 4 ins. clear of the gage line, and a 6x8-in. guard timber, laid on edge, is placed outside each rail about 8 ins. in the clear. Some of the elevated railways in New York have the inside guard timbers protected on the upper corner by a strip of iron. It is usually considered, however, that where a timber guard stands close to the rail metal protection is not needed, as a wheel cannot bite into timber unless it can strike it or meet it at a considerable angle. On elevated roads there is hardly room between the main rails and the guard timbers for the wheels to slew around to do this. The superelevation on curves, which rarely exceeds 3 ins., owing to the slow speed, is obtained by taper ties. The inside guard timbers are omitted on curves, and an inside T-rail guard is bolted to the inner rail of the curve, with cast separator blocks, maintaining a flangeway of about 2½ ins. It is usual, also, to back up the running rails and guard rail with braces. The track construction of the Union Elevated Ry. in Brooklyn has stringers or girders spaced 6 ft. apart. The ties are 8 ft. 3 ins. long and 7 ins. deep. The outer guard timber is 7x8 ins. in section, laid on edge, with the inner side 11 ins. from the gage line of the rail. The inner guard is 6x6 ins., spaced 6 ins. clear of the rail. The floor is secured to the stringers by hook bolts passing through the outer guard timber and tie. In the old system of track construction on this road the outer guard timber was 6x8 ins. in section, spaced 6½ ins. from the gage line of the rail and the inner guard timber was spaced 3½ ins. clear of the gage line. The floor of the Northwestern and Loop Elevated railways in Chicago has 6x8-in. ties 8 ft. long laid directly upon girders spaced 5 ft. centers. The ties are laid on flat and spaced 14 ins. centers, and hook bolts are used. The inner guard timber is 6x6 ins., laid 4 ins. clear of the gage line of the rail and the outer guard timber is 6x8 ins. in section, laid on edge and spaced 9¾ ins. from the gage line of the rail. Thus the wheel runs between two timbers, in a rut which is 13¾ ins. wide. The conductor rail is laid 20¼ ins. from the gage line of the running rail, on one side of each track, in the midway, and is lag-screwed to an insulating block which stands 1 in. clear of the outer guard timber. The space between the tracks is covered with four planks 8 ins. wide, laid 1 in. apart, to serve as a walk. On the Boston Elevated Ry. the outer guard timbers (6x9 ins., laid on edge and dapped over the ties) stand $10\frac{1}{2}$ ins. from the gage line of the rail, which is of 85-lb. Am. Soc. C. E. section The inside guard timbers (6x6 ins.) stand 4 ins. clear of the gage line. The near side of the head of the conductor rail stands 19 ins. from the gage line and the top of this rail is $11\frac{1}{2}$ ins. above top of tie. The conductor rails for both tracks are in the midway, with the feeder box, covered by a walk 34 ins. wide, between them. On sharp curves a 100-lb. T-rail is used for a guard rail, being considerably higher than the 85-lb. traction rail. Vulcanized yellow pine ties and tie plates are generally used in the floors of elevated railways.

154. Snow Fence.—In districts where the snowfall is not deep the principal difficulty with snow, if at all, is from drifting into the cuts, shallow cuts, as a rule, giving the most trouble. The cuts subject to drifting are those which lie across the direction of the wind, the snow which is carried being dropped into the eddy formed by the wind blowing over the top of the cut. A snow fence is an obstruction erected for piling up drifting snow, and it is used principally at cuts. If ground room is to be had it is placed across the direction of the prevailing winds, a sufficient distance back from the cut, on the windward side, to prevent the accumulated snowbank from extending into the cut. Where hard winds frequently blow from different quarters during the winter season it is sometimes necessary to have snow fence on both sides of the cut. The drifting snow is piled up on both sides of the fence. As the fence checks the velocity of the wind and turns it on an upward course it lets go of some of its entrained snow on the windward side, and that which is carried over drops into the eddy on the lee side or track side. As this side of the fence is shielded from the wind it is usually the case that the larger drift is formed on that side. On the windward side snow banks that slope 1 in 5 to 1 in 3, according to the velocity of the wind, are ordinary, while on the leeward side slopes of 1 in 17 to 1 in 8 are ordinary. As a general thing, deep cuts through mounds which rise abruptly need no protection, because after the wind blows the side of the hill bare but little snow will be carried to or over the cut. The force of the wind usually splits and the snow from the surrounding level is carried mostly around such a hill instead of over the top of it; and, from the upward currents caused by the hill, the snow which is blown over is usually carried high in the air, out of reach of the cut. But when the ground is level or gently sloping back from the cut for some distance, the snow which comes drifting hugs the ground closely and drops readily into the cut.

Stationary Fence.—The most common form of snow fence is an ordinary board fence, the boards in some cases being nailed to the posts horizontally, while in other cases the boards are placed upright and nailed to scantlings stretched between the posts. So far as results are concerned the merits of the two kinds are about equal. In cultivated or settled districts, where the right of way must be fenced at the place, the fence is usually made to serve both purposes—both a snow fence and a line fence. In this case the fence must be substantially built, and in any case the posts should be firmly set in the ground. If used only for snow, however, the posts need not be set nearer than 15 ft. 3 ins. for 16-ft. boards. The boards should be nailed on the windward side of the posts, overlapping, so that they may be easily taken off in case the fence is to be moved. In order to make it difficult for tramps and other persons to tear off boards the middle post of each panel is sometimes set on the opposite side of the boards from the end posts. Fence boards 1x6 ins. in size are commonly used, spaced 1½ to 6 ins. apart, and in some cases the boards are nailed on touching, so as to make the fence tight. Although it is not necessary to make a tight fence in order to pile up the snow, it is, in one way, at least, the most effective. Where the fence is made tight, eddy currents form on the windward side, and the snow will not pile up against it until the bank reaches the hight of the fence. The tight fence is therefore not so soon buried in the snow or drifted under. It is not necessary that the bottom board should touch the ground; in fact, as a measure of fire protection it should be placed about 1 ft. above the ground. If the first snowfall does not fill the gap the obstruction which the top boards offer to the wind will cause the snow to form a heap in the becalmed zone behind the fence, and accumulations to the front slope of this heap will gradually reach the lower board. In some cases the men fill this gap by throwing snow there before drifting begins.

As with line fence, so in building snow fence, there are, to be found here and there in practice, a considerable number of ways of making up the panels and bracing the same. At some of its badly exposed cuts the Intercolonial Ry. builds a fence 12 ft. high with upright boards touching edge to edge. Trial with boards spaced 1 in. apart and 2 ins. apart was not as satisfactory as the plan of putting them on close together. The round cedar posts stand 8¼ ft. apart centers and 8½ ft. high, and rest upon round cedar sills 8 ins. in diam. and 12 ft. long placed crosswise the direction of the fence and secured at the ends by stakes driven into the ground and by heaps of stones. The post is boxed into the side of the sill at the center, and spiked, and is knee-braced by two 3x5-in. x 10-ft. flattened cedar pieces let into the sides of the post and sill 1½ ins. and spiked. The 1-in. spruce boards are nailed to three 3x5-in. flattened cedar girts let into the posts and spaced 3½ ft. apart centers, the bottom one being 12 or 15 ins. from the ground. Another style of snow fence that is built for a fixed position, though not frequently found, is a stake and rider structure of poles or split rails. The fence is built by driving two stakes into the ground to cross each other, X-style, about 4 ft. from the ground. Into the crotch of these stakes a leaning pole or rail 16 to 20 ft. long is laid, with one end resting upon the ground. About 4 ft. from the first set of crossed stakes another set is driven to straddle the incline pole or rail and into this second crotch another pole is laid, inclined like the first and lying over it. The fence is extended by repeating the process. In lieu of poles, slabs from a saw mill, if available, serve the purpose even better. In Europe wire netting is sometimes used for snow fence. The posts are set permanently and the netting is put up at the beginning of each winter and taken down in the spring.

One of the most permanent forms of snow fence construction is a stone wall. In Europe stone wall snow fences are used to a considerable extent, being built to replace wooden fences as soon as experience has shown their proper position. On the Italian Meridional Ry. substantial stone walls 13 ft. high and 6 ft. 11 ins. wide on base, the sides battered 1 in 5, are doing service as snow fence. Walls 9 ft. 10 ins. high and lower are laid up dry with rubble stones, with a rounded concrete cap 19.6 ins. wide and 11.8 ins. deep. Walls higher than this are of dry-laid rubble except for a binding course of concrete 11.8 ins. thick, extending through the wall at the middle point of its hight, and a concrete cap of the dimensions stated. On some of the Hungarian railways there are stone wall snow fences 16½ ft. high placed 131 ft. from the edge of the cut. In this country stone walls are occasionally built for snow fences. The Union Pacific R. R. has dry rubble stone snow fence, about 5 ft. high, in a number of places.

On the Cape Cod division of the New York, New Haven & Hartford R. R. a stockade snow fence is made by setting old ties on end, in a ditch 2 ft. deep. By banking up at the ground line when the ties begin to rot off, the fence can be made to last 12 to 14 years, with good satisfaction. In this locality, where the ground is generally sandy, a day's labor will dig the ditch and put up about 25 ft. of this old-tie snow fence. The Minneapolis, St. Paul & Sault Ste. Marie Ry. and some other roads make use of the same kind of snow fence.

The effective hight of a snow fence is the hight of the structure above the ground less the depth of the fall of snow. The required hight therefore depends upon the ordinary depth of snowfall, for one thing, and upon the lay of the land for another. The hight of snow fence in service varies from 4½ ft., the ordinary hight of right-of-way fence, to 12 or 14 ft. where the drifting is bad. A hight of 7 or 8 ft. is ordinary. In any case the posts of snow fence should be longer than ordinary fence posts, so that additions to the hight of the fence may be made by nailing on more boards, if necessary. The direction of the fence should be somewhat across the path of the prevailing winds during winter time. In case, then, the wind strikes the cut at a slight angle, the fence, to be most effective, should be broken up into sections placed some distance apart, but parallel, and overlapping slightly when seen from the direction of the wind. At the end of the cut the fence should be extended beyond and turned toward the track, so as to guard the mouth of the cut against a quartering wind.

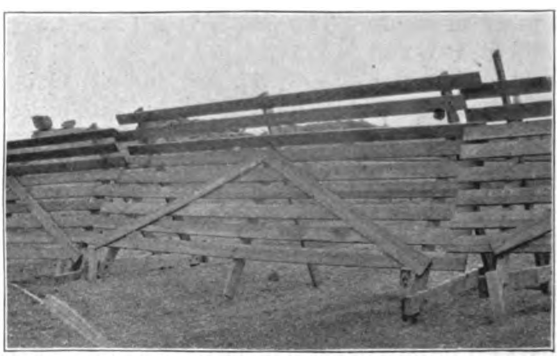

Fig. 453.—Standard Snow Fence, Union Pacific R. R.

The distance the fence should be placed from the cut depends upon local conditions, but usually 60 or 75 ft., or about 15 ft. away for every foot in hight of fence. It is well when placing snow fence at a cut for the first time to use a temporary or portable structure, or to build the fence only temporarily, nailing the boards to the posts rather loosely. After observing carefully the way the snow drifts for a few winters, it is possible that the fence may then be placed to better advantage, when it may be built permanently. If the fence is too near the cut the leeward snow bank will extend into the cut, and may cause the snow to drift deeper than it would without any fence at all; because in that case the cut would simply drift full, while with a snow fence too near, it might drift level with the top of the snow bank on the lee side of the fence. If the fence is too far away the current of wind deflected upward at the fence will drop before it reaches the cut, and whatever snow it carries will fall into the cut. The proper hight of the fence, as well as its distance from the cut and its direction, is also best determined experimentally, from observation extending over several winters. Fence that must be built too close to a cut for the best results should be higher and tighter than one that can be placed to best advantage.

With a view to the expediency of changing the direction of snow fence or its distance from the cut after experience with the local conditions may have shown such a change to be necessary, many roads have adopted a style of construction which admits of removal at only slight expense for labor and without doing material damage to the fence. Such fences are usually built in separate leaning panels with back braces in lieu of posts. An example of such construction is the standard snow fence of the Union Pacific R. R., shown in Fig. 453. It is about 7 ft. high and consists of diagonally braced panels of 1x6-in. boards, each leaning against three back braces (2x6 ins.), with three boards at the top nailed to the projecting ends of the back braces and leaning to windward. The panel posts and back braces are bolted together at the top and tied at the bottom by a plank bolted on, and spiked to stakes driven firmly into the ground. If the fence is placed when the ground is frozen the legs may be fastened with wire staples to drift bolts used as stakes. Where the wind blows unusually hard the fence is weighted down by piling stones upon the tie pieces. The pur-

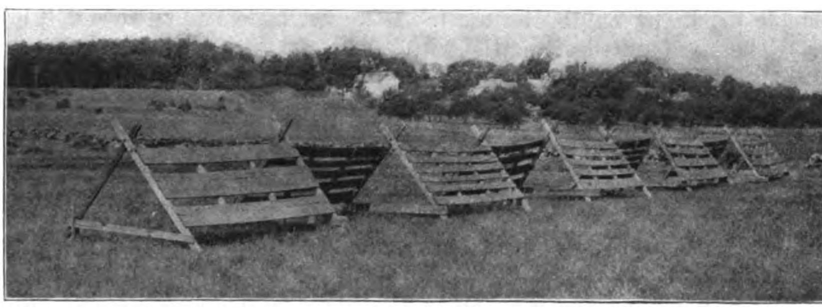

Fig. 454.—Portable Snow Fence, Boston & Maine R. R.

pose of the top projection to windward is to give the snow a back flurry and heap it up in front of the fence as much as possible. In setting up these fences on some roads it is the practice to leave 2-ft. spaces between the panels, thus to some extent economizing in the use of lumber.

Portable Snow Fence.—In regions of heavy snowfall and long continued winds a single line of snow fence is not usually found to be sufficient, for as soon as the snow bank which forms between the fence and track becomes as high as the fence, the fence then ceases to be of service. Where the winds have a good sweep it is frequently the case, therefore, that two or more lines of fence are needed, the second line being parallel with the first and generally about 100 ft. farther away from the cut. If the land bounding the right of way is waste land the second line of fence is usually made permanent, like the first, but if the land is cultivated a portable fence, in panel sections, is usually brought into service and put up temporarily during the winter. Again, the right of way on some roads is not wide enough to permit the building of even one permanent snow fence at a desirable distance from the cut to be protected, and in such cases it is usual to rely upon portable fences set up on private property temporarily during the winter season. A common form of portable panel is made by nailing 1x6-in. boards 16 ft. long to 2x4-in. x8-ft. scantlings, at each end and at the middle. The panel is held to position by 2x4-in. braces leaning against the panel posts and spiked or bolted to stakes driven into the ground. As the panels have to be handled over a good deal they ought to be strengthened with battens at the ends and middle.

A form of fence for portable use or for use permanently on rocky ground, where the expense for digging post holes would be a matter of some consideration, is shown in Fig. 454. This fence is simple in construction and is used on a number of roads. It consists of separate panels formed by spiking inch boards to 2x4-in., 2x6-in. or 4x4-in. scantlings, for end pieces and stiffeners. Alternate panels are then placed so as to lean against each other, or to and from the wind, in the manner shown. The end pieces of adjacent panels are crossed at the tops and bolted together and tied by a strip spiked across the legs at the bottom. The two end panels are maintained in position by a brace piece bolted to the top of the end piece and tied across the bottom by a strip, as in the case of the intermediate panels. On some roads a back brace is also used at the middle of each panel. To take the fence down it is only necessary to knock loose the tie pieces spiked to the bottoms of the legs and unbolt the end pieces at the top. Another scheme for a portable snow fence, that has been used on the Chicago & Northwestern Ry., is to build separate panels of boards and wire them fast to the posts of the wire fences during the winter season.

The Pittsburg & Western Ry. (Baltimore & Ohio R. R. system) builds portable panels by nailing boards to A-frames made from two old bridge ties. These are united at the top with a bolt and tied across the bottom by nailing on a strip 5 ft. long. At one time the Chicago & Eastern Illinois R. R. used a portable snow fence made entirely of 1x6-in. fence boards. The panels were 16 ft. long and seven boards high, spaced 1 in., 2 ins. and 3 ins. apart, with battens 8 ins. from the ends of the panel and a bracing cleat running between diagonally opposite corners on each side of the panel. At each panel point in the fence the two panels were headed into and hung upon a braced standard placed at right angles to the fence. This standard consisted of two upright boards 4 ft. 8 ins. long and 3 ins. apart, nailed at the bottom to the middle of a horizontal board 8 ft. long, and knee-braced to the ends of the same. In setting up the fence the ends of two adjacent panels were inserted between the two upright pieces of the supporting standard, lapping by each other, the bottom board of the panel and the one next the top being cut off at the batten where they came in the way of the horizontal piece of the standard and the top ends of the knee braces where they were spiked across the two upright pieces of the standard. Each panel was supported at the under edge of the top board, resting upon the two knee braces where they crossed the 3-in. space between the upright pieces, 6 ins. from the top of the standard; and at the under edge of the board next the bottom, resting upon the horizontal piece of the standard. When portable fence is removed from the fields in the spring it should be carefully piled or stood up in a leaning position, and to protect it from fire the grass should be kept from growing around the piles or stacks. In dry regions a layer of dirt is sometimes spread over the top of the pile of panels to protect against fire.

The number of lines of snow fence required depends upon the quantity of the snow, for the second fence (from the cut) serves to catch and hold snow which would be sure to drift against the first fence. At some points on the Union Pacific R. R. the snow fences are as many as five and six lines deep, one in advance of the other, at distances of 75 to 200 ft. apart. In several places on this road snow fence is placed at a much lower level than the track. At one point there are three lines of snow fence on a steep side hill, lower than the track, which is in a side-hill cut. Such protection is necessary where the sweep of the prevailing winds up these side hills is sufficient to carry snow up into the cuts.

The same result that may be obtained by the use of two or more lines of snow fence may be accomplished by using portable fence on top of the snow bank formed at one fence, or even by the use of a portable fence alone. As soon as the accumulation of snow attains a hight level with the top of the fence the practical utility of the latter ceases, and the furrow in which the fence stands, between the windward and leeward drifts, becomes rapidly filled up. Before the fence becomes buried, however, it is taken up and placed upon the summit of the leeward drift, when it again becomes effective. By transferring the fence to the top of the new leeward drift each time that the drifts each side of the same cease to increase in hight or volume, the repetition of the process will in time form a bank so high that the wind will be carried past the cut before falling to the surface level. It is also frequently the practice, where repeated storms have filled the fences, to build walls of snow as substitutes for portable fences, the snow being taken from the track side of the wall and heaped up to a hight of 4 ft. or more. In a hard wind snow walls, unless protected in some manner, will be blown away. Such protection may be arranged by topping out the wall with a fence board nailed to two stakes driven into the snow. Snow walls will sometimes endure several days of thawing weather after the surface snow has melted away, and remain to do service in the next storm. A good deal of labor is required to build them, however, and they should be regarded only as an expedient, when portable fence is not quickly available. In some parts of Europe where land is more closely utilized than in this country, the width of the right of way is very narrow and the permanent snow fence must be built at the edge of the cut. In a case of this kind the whole of the drift has to be put on the windward side of the fence. Such is the case with some of the snow fences on the Paris, Lyons & Mediterranean Ry., in France, and in some instances portable fence is relied upon altogether. Before the snow starts drifting a wall of snow is built at the proper distance from the track, the snow being taken from an excavation on the track side of the wall. As soon as a drift has formed in front of this obstruction a wooden screen about 5 ft. high is planted on top of the drift by driving boards endwise into the snow. When a new drift is formed as high as the top of the screen the boards are pulled up and set upon the summit of the new drift, the operation being repeated as often as the screen is drifted full. A temporary fence may also be built by laying up a wall of old ties, rail fence fashion, and such a scheme is frequently resorted to where lumber is not on hand. This fence can be put up quickly by the section men, and by picking out the soundest of the ties it may be made to last two or three winters. On rocky ground, where stakes cannot be driven the old-fashioned rail fence or worm fence can be used.

Hedge Fence.—If the nature of the soil and other conditions are favorable it is a good plan to set out along snow fence a hedge of evergreens, stub pines, or of such indigenous trees as grow bushy near the ground. Common balsam or cedar is good, where it will grow and thrive. By the time the board fence is decayed the trees will generally have grown sufficiently high to form a most efficient snow fence, which will need no repairs except, perhaps, an occasional trimming. In some localities where there has been difficulty in getting plants to grow, willows have been found to be the best. For the purpose of a snow fence it is generally recommended that the hedge should be planted in three or four rows about 8 ft. apart, the trees in one row staggered with those of the next row. The row nearest the cut should be at such distance as has been found proper for structural snow fence.

Comparatively speaking, hedge snow fence has received but scant attention in this country. Only a few roads have tried them, and on some of these the experiments have been disappointing. According to some authorities these failures have been due to a wrong adaptation in some respect, such as the selection of a plant not suitable to the soil or for the purpose of a snow fence, or to a wrong method of cultivation, or lack of watchfulness in trimming and protecting from fire. Along the Chicago, Milwaukee & St. Paul Ry. in southern Wisconsin cedar hedges planted on the right-of-way line at many of the cuts have attained a hight of 12 to 16 ft. Some of these hedges have been permitted to grow too high, and the foliage is so sparse near the ground that low board fences are necessary to prevent the winds from carrying the snow under. For the decoration of its station grounds and for snow fences at cuts and at other places where drifting snow might be bothersome the Philadelphia & Reading Ry. has made extensive use of the shrub California privet (Ligustrum ovalifolium). These plants are raised in the company's own nursery and set out when two years old, about 10 ins. apart. The first year they are not trimmed any further than that which they receive at the time of planting, but the next year they are trimmed in January or February, again in July, and again in the winter. The trimming is easily performed, as the wood is not hard like the Osage orange, which is used quite generally for hedge fence. As a hedge plant the privet is one of the most beautiful, as the leaves remain until late in the winter and it is an early thriver. It is trimmed to a hight of 6 or 8 ft. the growth is dense from the ground up, and its effect on the landscape is decidedly beautifying. For some time about 30,000 of these shrubs were raised each year for planting in exposed places for snow breaks. For hedge snow fence on the Intercolonial and Northern Pacific roads, see §219.

The most extensive use of hedges and tree plantations for snow fence has been in Russia, where such means of protection was adopted as early as 1865. On the Moscow-Nijni-Novgorod Ry., particularly, this kind of snow fence has been systematically experimented with and studied, and the results achieved have been highly satisfactory. In the north, northwest and western districts the trees planted are mainly coniferous—firs and pines—but occasionally white firs mixed with birch in the proportion of one to four. On 16 lines of railway, trees of these kinds are being cultivated, and on only three of these lines (which are in the south and center of Russia, where it is difficult to acclimatize conifers) have the results been unsatisfactory. With these exceptions coniferous trees, if planted at the proper distance from the track, give the desired protection. On the road named (where the right of way is 350 ft. wide) the trees are set on the boundary line, 175 ft. from the track. In the majority of cases the fences are formed of two or three rows of trees, but frequently there is only one row, and sometimes as many as six and even ten rows. As a general thing these plantations begin to be useful after seven to ten years of growth. Saplings transplanted from nurseries have given better results than those taken direct from the forest.

The culture of the conifers is usually undertaken by the railways themselves, a small nursery being attached to each roadmaster's district. It is rarely the case that large nursery grounds are maintained or that special services are called in to supervise the cultivation of the saplings, or that trees are purchased from outside. The aim is to have the nurseries so widely distributed that the plants needed at any point will not be longer than 24 hours in transit. In the majority of cases the firs appear to be the most suitable species, but in some parts white Siberian or Polish pines are preferred, and in sandy soil the pines flourish best. The pruning of the conifers is commenced when they have attained a hight of about 28 ins., being usually attended to in the autumn. The purpose of this early pruning is principally to keep the trees at a uniform hight and to thicken the branches and develop the foliage close to the ground. As the trees increase in size the front of the fence is trimmed to slope toward the bottom, like the side of a battered wall. Where the snow drifts are usually of moderate size the trees are trimmed to a hight of about 4½ ft., but for heavy duty the hight is not less than 9 or 10 ft., while on some lines the trees are allowed to grow to full hight, as in the forest. The cost of a mile of fence set with conifers ranges from $40 to $275, according to the number of lines of trees and the conditions peculiar to the location.

On the steppes of central and southern Russia, where conifers do not thrive, the experiments with leafy trees for snow breaks have been very numerous and frequently have been carried out on an important scale. In these trials the degree of success has not been uniformly so good as in the experience with conifers in the North and West. Black and tartar maple, elm, ash, hawthorn, willow, osier, sorrel thorn, mulberry and red alder are some of the trees used. As the trees during the winter are leafless and open they fill up with snow, and if close to the track afford no protection. In any case a large number of rows of trees is required to stop the snow, various authorities putting it at 15 to 32 rows, set close together and a good distance from the track, the first row to be not nearer than 70 to 100 ft., according to the local topography. Where the number of rows is comparatively small the best results are obtained by alternating the rows of trees with rows of bushes, always having bushes in the outside rows. White, yellow and German acacia, wild olive and honeysuckle are some of the bushes employed. On the St. Petersburg-Warsaw line a combination of willow and birch is fairly satisfactory, but they afford less protection than conifers. On other lines 10 rows of white acacia, in one instance, and 20 rows of red alder, in another, have also proven satisfactory. On the Hungarian State railways three rows of wild roses, the plants staggered in the different rows and trimmed to a hight of 6½ ft., have given good protection, and acacias have done fairly well.

In shallow cuts of 3 or 4 ft. or less depth it sometimes pays better to grade down the banks than to build and maintain snow fences. By running the slope back 60 or 70 ft. on each side of the track, or even 1 in 10 for the heavier work, the wind will drop and blow the cut clear. If there are hollows near such cuts the work may be cheaply done with plow and scraper. Material near the track may be loaded and used to fill in bridges or be wasted on embankments. Snow fence is sometimes made by heaping up earth, and if the material may be had by excavating for a slope ditch it would seem that the plan ought to pay. The Union Pacific R. R. has followed quite extensively the plan of grading back shallow cuts on easy slopes and piling the dirt up at the proper distance to form snow breaks. In other instances dirt or rock taken from deeper cuts that have been excavated to ordinary lines has been disposed of in the same manner. Some of the roads in the northern part of the Mississippi valley have used sod walls 4 or 5 ft. high for snow fence.

In a flat country some attention should be paid to the hight of the track above the surrounding level. As long as the rails are higher than the snow on the ground immediately to the windward the track will be blown clear while snow is drifting, but as soon as the depth of the snow exceeds the hight of the rails above the general level the track is then virtually in a cut, which will drift level full in short order as soon as the wind starts blowing; and a depth of a few inches of fine, closely compacted drifted snow is a greater hindrance to traction than several times that depth of snow which falls in place. On prairie land where hard snow storms are to be expected the hight of the roadbed should therefore be such that the rails will stand above snow of the ordinary depth on the surrounding level For sake of illustration, suppose that on the plains in some certain locality the depth of snow to be expected with more or less regularity is 2½ ft. on the level. It is not at all necessary to assume that snow of that depth would fall during one storm. Allowing 5 ins. for depth of rail, 7 ins. for depth of tie and 8 ins. for depth of ballast, we get 20 ins. from sub-grade to top of rail, leaving 10 ins. as the hight of the embankment which is necessary to put top of rail even with the top of the layer of snow. In such a case it ought to be more than 10 ins.—say 15 or 16 ins.—so as to allow for snow thrown to the side of the rail by engine pilots and snow flangers. As already explained, the speed of snow plows on open track should be such that the snow will be thrown well clear of the shoulders and not heaped up at the side of the track. A ridge of snow at the side of the track is just as detrimental in the way of stopping drifted snow as though the track stood in an earth cut of the same depth.

In Russia, where there is much level country and where the accumulations of snow during the long winters are a serious difficulty to contend with, this question of providing against snow drifts over slightly elevated embankments was long ago investigated in a thorough manner and settled by government authority. In the schedule of conditions for the construction of new lines, as laid down by the ministry of ways of communication, is a stipulation requiring that the hight of embankments in places exposed to snow accumulations shall not be less than 25.2 ins. (0.3 sagene), except when passing from cuttings to embankments. With the usual allowances for ballast this requirement places the rail head 3 ft. 2 ins. to 3½ ft. above the ground level, but on some of the railways where the fall of snow is excessive the managements, from their own choice, prefer to make the embankments even higher than the government requirements, in order to obtain desired protection from drifting snow.

Certain abnormal conditions of location or of the winds have in cases suggested the trial of odd arrangements in snow fence. When the direction of a wind is straight through a cut it will blow the track clear, but when it strikes at a small angle the formation of long drifts diagonally across the track may sometimes occur. One can imagine how the winds might pick up enough snow between the track and the fence to form drifts of good size once it is blown down into the cut, or the wind might veer so far from the prevailing direction as to blow between diagonal fences set to overlap in the path of the prevailing winds. Again, when snow-bearing wind blows into a curved cut the change of direction may reduce the velocity and cause it to drop its snow in the artificial calm to windward, forming long and narrow drifts on the track. And then, the direction of a cut may be such that the prevailing winds come at a small angle, and if they change around considerably some of the snow behind the fences may be blown into the cut. On the Concord and White Mountains divisions of the Boston & Maine R. R. wing fences have been tried in some of the cuts to meet such conditions. At certain points where the track runs due north and south, or nearly so, the prevailing winds (northeast) blow into the cuts in a quartering direction. A few days after a storm has cleared off the wind may veer into the other quarter (northwest) and blow into the cut from the opposite side. The arrangement for protecting such cuts consists in running short wing fences or panels down the slopes of the cut, as far as the ditch, at an angle of about 45 deg. with the track. The panels of wing fence are separated by intervals of 60 to 90 ft., and are placed alternately on either side of the track, the idea being that when disposed in this manner they stand at right angles to a quartering wind blowing from either side of the cut. These fences, although tried for a long time, have been rather disappointing. When the wind blows in certain directions long bars of hard snow 2 to 4 ft. deep will form on the track, running from the panels of fence like windrows, so to speak. Sometimes these drifts are almost as solidly compacted as ice and it is a hard pull for engines to get through. These fences, which are often referred to in discussions on snow fence, were illustrated in the Railway and Engineering Review of Nov. 4, 1899.

As any obstruction which will form a calm in the wind currents will cause the formation of a snow drift, it is seen that buildings and other structures to the windward may cause the track to be obstructed in much the same manner that drifts are deposited behind snow fence. The following instructions issued in anticipation of trouble arising in this way are found among the rules for location and construction of the Northern Pacific Ry.: "In regions swept by strong winds, where the snowfall is liable to be great and drifting to occur, all structures will be put on that side of the track opposite the prevailing winds. Usually this will be the southerly side, and station buildings, water stations, switch stands, and every kind of structure that can cause the formation of drifts, will be put on that side. Sidings and spur tracks should be put on the same side, where practicable." On some other roads track and bridge men and other employees are instructed to pile no ties, timbers or other material on the windward side of the track so close that drifts formed behind the piles might extend to the track.

There are some situations other than those mentioned hitherto which require protection by snow fence, such as turntable pits at exposed points, and round about the mouth of a tunnel, to prevent snow from blocking the entrance or the cut leading up to it. At the east end of the Aspen tunnel, on the Union Pacific R. R., there are three lines of snow fence running around the side of the mountain, above the entrance to the tunnel. In desert regions, such as are found in the southwestern part of this country, the sand drifts and forms into heaps in a manner very similar to that of drifting snow, but is more dangerous to train operation, and fences have to be built to keep the track from being covered by sand. Such fence is built on the same principle as a snow fence. On some roads running near the seashore the same conditions prevail. Along some portions of the Trans-Siberian Ry. drifting sand gives a great deal of trouble, and in such places a line of shrubs is planted, wherever they can be made to grow As a further protection a strip of wild oats is sown along both sides of the track. The Southern Pacific Co. has a special standard section for roadbed requiring protection against damage by sand storms. The track is filled in with sand to a level 1 in. above the tops of the ties and in cuttings this level is extended out 4 ft. beyond the ends of the ties. On embankment the shoulder is filled up to the same level and carried out 3 ft 8½ ins. from the rail. For the protection of slopes, to keep the sand from blowing away, rock, heavy subsoil or brush with butts well embedded and branches about flush with the face of the slope, is used. Where stone of the proper size can be obtained they are placed on lines 3 ft. 8½ ins. from the rails, on embankments. The use of a layer of cinders or of clayey soil, and the planting of Bermuda grass and other vegetation for the protection of sand slopes from the wind are elsewhere referred to.

155. Snow Sheds.—In mountain regions where the snowfall is heavy and deep drifts and snow slips are liable to occur, such as in deep cuts and along side-hill slopes, the track must be protected by snow sheds. Such structures are formed over the track by framed bents of heavy timbers covered with planks on top and at the sides. On side-hill where snow slides are liable to occur the up-hill side of the shed is built to form part of a slope extending from the hillside over the top of the shed. In case unusual trouble is looked for in this direction the space behind the shed is filled in with a heavy masonry wall (Fig. 457) or rock cribbing and the crib is covered with timber or earth filling, to form a firm slope on the up-hill side of the shed. In some cases the bents are anchored to the rock with long tie rods. In addition to this heavy V-shaped or diagonal stone-filled cribs are sometimes constructed higher up on the mountain side, to split the slide or to turn it aside.

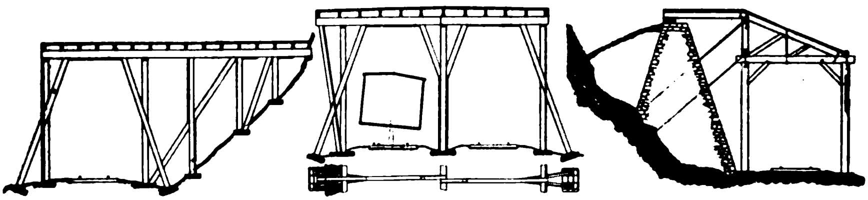

Fig. 455. Fig. 456. Fig. 457.
Types of Snow Sheds, Central Pacific R. R. (S. P. Co.).

On the Central Pacific line of the Southern Pacific Co. there are 36 miles of snow sheds. Of this 28.49 miles of shed is continuous, being broken only over bridges. Sheds of the latest design measure on the inside 20 ft. high from top of rail and 16 ft. across from post to post. The bents are constructed of 8x10-in. posts, 8x16-in. beams and 5x10-in. braces. The bents are placed 6 to 8 ft. apart, according to the quantity of snow, which in some places frequently lies 25 ft. deep. The roof planking is 3 and 4 ins. thick and the side boards $1\frac{1}{2}$ and 2 ins. thick. In the latest structures the roofing is redwood and the remaining lumber mountain pine. Figures 455 to 458, inclusive, illustrate types of construction, Fig. 456 showing the arrangement where there is a side-track. To admit light and air a narrow opening is left in the side planking near the top, as indicated in Figs. 457 and 458. Figure 459 shows types of strong crib construction that are used on the Denver & Rio Grande R. R. At a place on the Southern Pacific road in northern California a shed was at one time constructed in a troublesome side cutting to carry sliding earth and rock over the track.

The Canadian Pacific Ry. is another line that encounters very deep snow. At Hector, in the Kicking Horse River pass, near the summit of

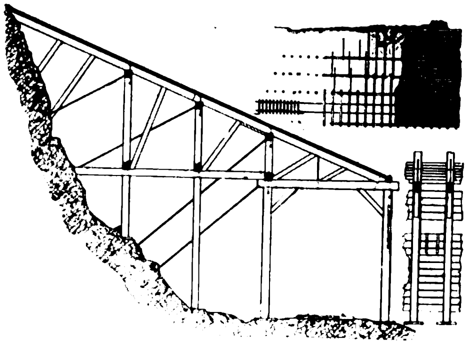

Fig. 458.—Snow Shed, Cent. Pac. R. R.

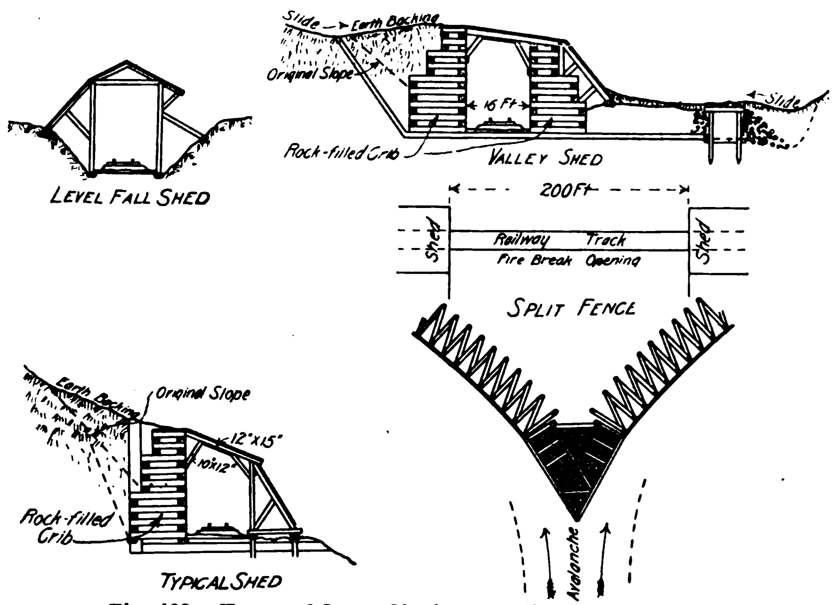

Fig. 460.—Types of Snow Sheds, Canadian Pacific Ry.

the road in the Rocky mountains, snow falls in every month during some years. Records kept by the watchman at this point for a number of years show an average annual snowfall of 27 ft. 4 ins., the minimum being 23 ft. and the maximum fall during any year 41 ft. In the Selkirk range, to the west, the snowfall is even more remarkable, the average for a number of years at the station at Glacier House, B. C., being 31 ft., and in a single year 43 ft. 8½ ins. In the Rocky mountains the snow is generally handled with rotary plows, without serious difficulty, but in the Selkirks, where avalanches are of frequent occurrence, bringing down immense masses of snow mingled with rocks, mud, tree trunks and other debris, machinery is powerless to keep the road open and many miles of snow sheds are necessary. Points that are not liable to be covered by avalanches or deep drifts are left unprotected and are kept open by the rotaries.

Types of snow-shed construction on this road are illustrated in Fig. 460. The so-called "level-fall" shed is placed at points where the road must be protected from drifts but where avalanches are not expected. The "typical" shed is built at points along the sides of valleys where avalanches can come from one direction only. The "valley" shed is employed in the bottoms of valleys where avalanches may descend from either side. In narrow valleys avalanches do not always stop in the bottom, but frequently sweep some distance up the opposite side, doing damage from an unexpected direction. Cases are on record where laborers on the track have been killed by not heeding an avalanche sweeping down the opposite side of a valley which they supposed was so far below that the avalanche could never get up to them. In the heaviest work the bents are built of 12x15-in. Oregon pine timbers securely braced and drift-bolted together, and are spaced about 5 ft. centers. Wherever the lay of the land is favorable, the ground above the shed is cleared and graded up, with the object of giving the avalanche an upward turn and shoot it across the track without striking the shed with full force. Glance and split fences, built as cribworks of logs, are also used, in places, along the mountain side, to turn the avalanches into ravines, where they will pass under the track, or to split up the avalanche and break its force. Avalanches of dry snow descend with great velocity (greater than that of wet snow) and the currents of air set up by the swift motion of the huge mass often do more damage to railroad property than the avalanche itself, as they may extend over a wide area. These currents are locally known as "snow flurries," and are sometimes attended with the force of a cyclone, snapping off the trunks of full-grown trees. These "flurries" have been known to sweep away bridges which were not touched by the avalanche of snow passing underneath. One bridge on this road was swept away six times in this manner, and was finally replaced by a masonry arch, which has been able to stand firm.

To guard snow sheds against fire several systematic measures have been adopted. Where it is necessary to protect a long stretch of track it is the practice of the Canadian Pacific Ry. to break the shed into comparatively short sections, with open spaces of 200 ft. between them. To protect these openings V-shaped "split fences" of heavy cribwork (Fig. 460) are built on the hillside above, to deflect the avalanche to the right and left and cause it to pass over the sheds. These open spaces also serve as ventilation openings, to quickly clear the sheds of smoke, which in winter, when all the small openings are covered with snow, would otherwise be slow to escape. At some of the sheds there are also systems of piping with hose attachments, or sluices, leading water from high streams above the tops of the sheds, where the watchman can use it in case of fire. At many places there is an extra or "open-air" track outside the shed to carry the traffic in summer, the object being to reduce the fire risk, avoid the smoke and give passengers the benefit of the mountain scenery. The Central Pacific line has special trains equipped with water tanks, fire pumps, hose, etc., for fighting fire in the snow sheds. These trains are held in readiness, with crews ready to go at a moment's notice. The worst fires to contend with are forest fires, which sometimes burn down long stretches of shed in spite of all efforts of the fire crews. Another means of fire protection in the construction of the shed itself is to side up the structure at intervals with galvanized iron in place of planking, and this road has also movable or telescopic sections of shed 50 ft. long, at intervals, which are run inside the stationary shed during the summer season, leaving gaps in the structure. These movable sections stand on wheels, on a track of 16 ft. 8 ins. gage.

Some of the European railways, particularly the Arlberg line of the Austrian State Ry., have gone to great expense to protect the track against avalanches. One method is to erect a series of walls or piers of various kinds on the slopes above the line, to reduce the speed of moving bodies of snow, break them up and divert them into separate portions, which checks their momentum and scatters the tremendous force of the original mass. The Arlberg line builds thick cemented stone walls in some places, and in other cases a double line of old rails is driven into the ground and filled in between with logs and poles. The two rows of rails stand 3 ft. apart and the rails, which are 3 ft. apart in each row, stand 7 ft. out of the ground. Rock-filled log cribs are also used, as in this country. It has been found that the most effective way of preventing danger from avalanches is to place the means of protection where the avalanches are formed, and the most satisfactory method is to set out trees on the slopes to prevent the snow from getting started. The Arlberg line has not only taken up the work of planting trees on an extensive scale, but has also adopted the policy of acquiring existing forest and wooded slopes along the line, in order to prevent removal of the timber prematurely. The old timber is cut down and used in protective works and young trees are planted to take its place. In reafforesting slopes where the timber has been felled irrationally, both pines and deciduous trees are planted. At some points on the Hungarian State Railways it has been found necessary to extend the arches of tunnels for some distance into the approach cuts, in order to protect them from deep snowfalls and sliding snow. These arches are of masonry construction, of the same curvature as the tunnel lining, and by filling over the top with stones they are made strong enough to withstand sliding earth and rock.

Where a snow slide crosses open track it will fill up the side-hill cutting occupied by the track and pack it very hard with snow, rocks, tree trunks and other debris which a snow plow cannot clear away. In some cases snow slides have been known to fill up one side of a valley, covering the track with such a large pile of debris that it was necessary to build a detour track to get the traffic past. An avalanche at Ophir, Colo., on the Rio Grande Southern R. R., Feb. 20 1897, cut over 10 acres of timber 10 ins. to 2 ft. in diameter and struck the depot, which was built of strongly

Fig. 460 A.—Avalanche at Ophir, Colo., Rio Grande Southern R. R.

framed bridge timber. One end of the building was carried completely away and the remainder was shoved 15 ft. and buried up in a mass of snow rocks, trees, etc., six large tree trunks being driven entirely through it. Four loaded box cars were carried 600 ft. from the track. The avalanche traveled $1\frac{1}{2}$ miles from the top of the mountain, nearly a third of the distance being through timber. It took 30 men and four locomotives 38 hours to dig the track out and pull timber and rocks out of the way. Figure 460A shows one of the engines pulling trees off the track.

156. Fire Guards.—Destructive fires started by sparks from locomotives often run over large areas, especially through the stubble of grain fields in the prairie states. It is therefore incumbent upon the railway companies to take some means for guarding the abutting property from fire, as far as possible, wherever the conditions are threatening. A fire guard is made by plowing several furrows, usually four or five, parallel with the track, at such a distance from the track that sparks will not be blown beyond them, generally from 100 to 150 ft., but sometimes 200 ft. This distance ordinarily brings them off the right of way; but as they are made for the benefit of the people living along the line no well-disposed person objects to the use of his land for such purpose. It is a good plan to burn over the ground between these furrows and the track. When no wind is blowing or, better, when a light quartering wind is blowing toward the track, the section crew should set fire to and burn off the windward side, keeping watch near the furrows and the track. Wind will carry the fire along quite rapidly, and, coming from almost any direction, will usually favor either one side or the other of the track. If it is blowing parallel with the track and not too hard, both sides may be burned at the same time If no wind at all is blowing fires may be kept going at several places, so as to get over the ground more rapidly. In places where much anxiety is felt regarding fires a second line of furrows is made beyond the first and the ground burned over between them. The ground between the first line of furrows and the track need not then be burned over. The plowing of fire-guard furrows is frequently let by contract, and continuous furrows as long as 70 miles have been plowed, a six-horse team making about 25 miles per day with one furrow in hard prairie soil. It will usually take less time to watch and burn over the dry grass, etc., around wooden bridges and other track structures than will be spent in running to put out fires every time they get started.

157. Bumping Posts.—Obstructions to prevent cars from being pushed off the ends of spur or stub tracks are of two kinds: viz., wheel stops and bumping posts. Too frequently, such devices are badly used, and often the damage caused by their presence is much greater than would be the cost of pulling a car onto the track occasionally. Nevertheless, to provide for conditions which sometimes make it a necessity, such, for instance as when there is a failure of brakes to act (when there is such a failure in fact), slippery rails, grade in the track either way, mischievous boys, etc., it should be used. The logical idea is that the post should come into service only in event of the failure of a brake chain or through some other uncertainty, and that it should not be put to "general use," as is frequently the case. In a spur where the track is level and there is room beyond the end of the track it is not worth while to go to much expense in putting in a bumping post, because there is not really any need of it; and the stronger the bumping post is made on such track the harder will some juvenile trainman send cars against it and try to knock it out, just for amusement. There is not quite so much sport in pushing or running a car off the end of a spur track as there is in sending it against a bumping post, and as a usual thing trainmen are more careful in handling cars on tracks without bumping posts than they are where bumping posts are provided. Where there is room beyond the end of the track, so that no particular damage will be done by cars which may be run off the end of it, it is largely the practice to dispense with bumping posts. In order to facilitate the work of hauling the cars on again it is the practice with some roads to spread the rails apart, about a foot wider than the gage, at the end of the track, and to lay a plank inside the flaring end of each rail to receive the wheel as it drops from the rails. In pulling the car ahead the convergence of the flaring rails serves to bring the wheels readily onto the track again. Where cars have to be thrown up grade into a spur, by a "flying switch," a bumping post is needed, because the car must be given a good start and it is not always so easy to judge of the proper speed required. Where the grade of the spur descends from the main track there is no necessity for throwing cars into it at much speed, but to provide against the contingency of the brakes being let off standing cars there should be some kind of stop to hold them; likewise, when coupling cars on such a spur, sometimes the starting of a car cannot well be avoided.

About the best all-round stop for out of doors, where there is plenty of room, is to cover the last 15 or 20 ft. of the track to a depth of 2 ft. with cinders, gravel or sand. Cinders is the best material, because it does not freeze hard in winter. This arrangement will stop cars at considerable speed, it is easy on the cars and is comparatively inexpensive. The standard car stop of the Southern Pacific Co. is a heap of earth or sand retained on three sides by a plank box 10 ft. square and 22 ins. high. This box is open on the side where the track enters, and is formed by spiking 3-in. plank of durable timber to the inside of 6x8-in. posts 5 ft. long, set at the corners of the box. The rails extend about half way through the heap. This is the type of buffer used for permanent spurs at principal stations. At points where something better looking is required there is a heap of earth or cinders walled in on sides and rear with concrete. The stop shown in Fig. 461 is 12 ft. wide over side walls, and 11 ft. long. The walls are 9 ins. thick and the heap of earth, which in this case happens to be adobe sand, is 3 ft. high above top of rail. The standard buffer for temporary spurs and for use at unimportant stations is a truncated pyramid of earth 15 ft. square on base, 5 ft. square on top and 3 ft. high, the track running into the heap about 5 ft. The earth buffer of the Chicago & Northwestern Ry. is a heap of cinders or dirt a rail's length beyond the end of the track. Between the end of the track and the heap there is a

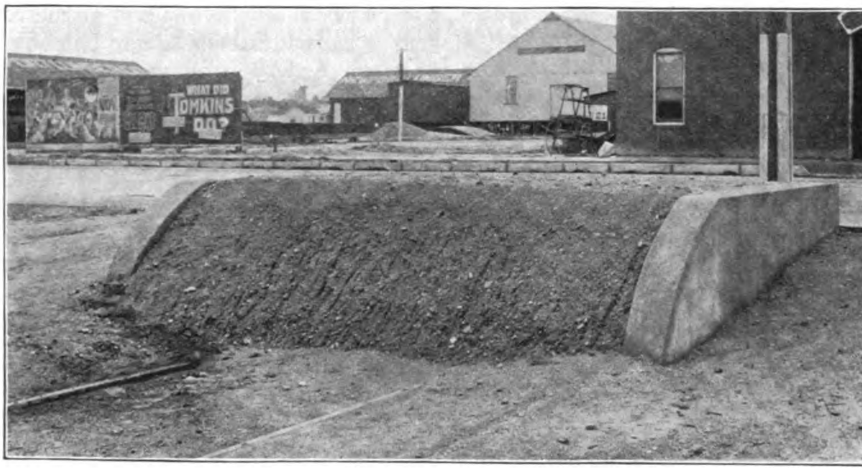

Fig. 461.—Earth Car Stop, Southern Pacific Co.

bed of cross ties laid touching side by side, and on these ties there are two guard rails about 5½ ft. apart, or just far enough outside the line of the traffic rails to let the wheels drop off at the end. When a car is pushed off the end of the track the wheels go bumping over the ties for a distance of 30 ft. before reaching the dirt heap, and the guard rails prevent the truck from slewing; they also serve to hold it in line when the car is being hauled on the stub ends of the rails again. On some roads a large stick of timber is set in the ground at the end of the track, for a bumping post, and the back side of this post is planked up to retain a long heap of earth thrown up as a backing for the post.

Ordinary wheel stops or chocks are not supposed to be hit hard, and are used only as a sort of reminder that the end of the track is there. One form is a casting bolted or clamped to the rail head. In another form the ends of the last rails of the spur are bent upward for a foot or so at about the same curve as the wheel tread; in another, the ends of the rails are bent upward squarely and a 12x12-in. stick of timber is put across in front of the bent-up ends and bolted down to the rails with U-bolts, for the wheels to strike against. In still another style the end of each rail is curved upward 12 or 15 ins. high and backed by a stick of timber or braced piece footing into a longitudinal timber under the ties. A very simple wheel stop is made by laying a piece of 6x8-in. timber across the rails and backing it up by two posts driven or set in the ground, at either side of the track, the top of the posts projecting out of the ground just high enough to hold the cross timber. In order to prevent the timber from being carried away it is chained to the posts.

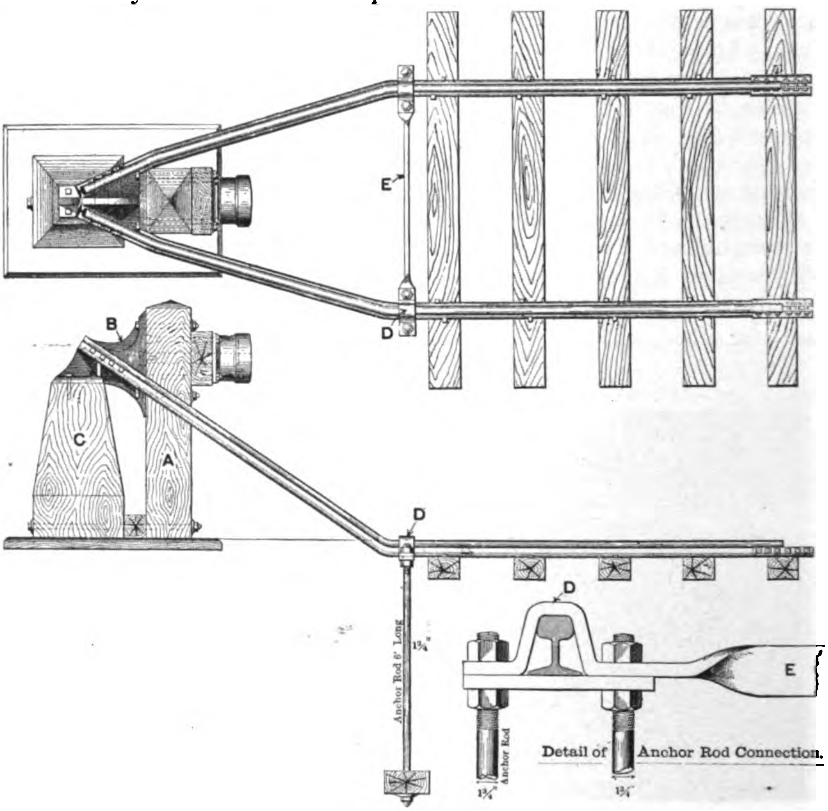

Fig. 462.—Ellis Bumping Post.

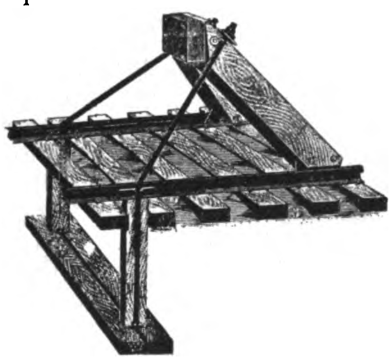
About the simplest form of bumping post is a heavy vertical post set in the track and braced at the back with a stick of timber. A contrivance of this kind is sometimes made by setting a bunch of ties, two wide and two deep, in the ground about 4 ft., and bracing them with two leaning ties footed against a tie placed crosswise to them in the ground. It goes without saying that such a piece of construction will not stand a very heavy jar, and in reality it is only an excuse for a bumping post. A very substantial bumping post is made by driving a group of piles into the ground at the end of the track, to serve as a backing for the buffer block. Tough oak piles are hard to break off, and, being somewhat springy, are hard to knock out in ordinary usage. In bumping posts of this style in service on the Pittsburg, Ft. Wayne & Chicago Ry., four piles are used. The piles are driven two abreast, in two rows about a foot apart, with a stick of 12x12-in. timber between the two rows at the hight of the buffer block, the whole being bolted through and through.

An improved bumper of the "framed" type is made by framing the post into the middle of a heavy longitudinal sill, buried about 2 ft. under the track. The vertical post is secured against being lifted off the sill by a heavy strap passing under the sill, and, in addition to a leaning timber at the back of the post, footing into the sill and serving as a brace, there is a heavy bolt or stay rod passed through the brace timber just in rear of the vertical post, thus holding the brace timber down to the sill. More commonly a pair of such frames is used, being placed parallel and about 2 ft. apart, center to center. A cross timber is placed in front of the two vertical posts for a buffer block or deadwood support, and the buffer block is sometimes backed by a set of car springs and faced with heavy steel plate. The sills abut against a cross timber buried in the ground to serve as a backing piece. The sills are usually made of 12x12-in. timber, the vertical post of 12x16-in. timber and the brace piece of 12x16-in. timber. Bumping posts of framed timbers are somewhat expensive and, of course, rot out quite rapidly. Although they were formerly in service on a large number of roads bumping posts made so largely of timber are gradually going out of use.

The type of bumping post which now seems to meet with most favor is some form of construction which is anchored to the track rails, so that a blow against the post is largely transmitted to the rails in a manner to put them in tensile stress. The different styles of posts designed on this principle are almost too numerous to mention. The original post of this type and one of the simplest, and perhaps best known, is the Ellis bumping post, shown as Fig. 462. A heavy oak post (*A*) is set in the ground, or stood upon a plank platform resting upon masonry or a bed of ties, and this post is secured in an upright position by bending both track rails upward at an angle of about 35 deg. and inward, so as to embrace the post at about the hight of the buffer block. A heavy casting *B*, resting upon the top of another post *C*, serves as a backing for the stop post *A*, directly behind the buffer block. Both rails are securely bolted to this casting by large bolts which pass through all three. A strut *E* with clamps *D* is placed between the rails at the point where they bend upward, so as to prevent them from being drawn together when under tensile stress. At the same point the rails are held down by anchor rods secured to a buried timber, which, in addition to the weight of the car, makes the rails quite secure against being lifted. In applying this bumping post to a trestle the anchor rods are secured to the track stringers. The bumping post shown has a spring buffer and is for passenger cars. The post for freight cars has simply the buffer block or deadwood faced with a heavy striking plate. The end rails of the track which bend up around an Ellis post should be full length, so as to put the splices as far back as possible. With short end rails these splices or the bolts in the same are liable to break and let the joint pull apart when a car strikes the post. As used at some points on the Chicago, Rock Island & Pacific Ry. the splice at the joint with each bent end rail and at the next joint back— that is, at the last two joints on each side of the track—is reinforced by pieces of rail 6 ft. long used as splice bars. They are placed outside the ordinary 6-bolt splice bars and bolted to the rail at each end by three ⅞-in. bolts through filler blocks. An interesting application of this bumping post is where a stub track runs against a wall, like the wall of a building, and it is desired to save every possible foot of space. In a case of this kind the stop post (*A*) is cut short and stood in an opening in the wall, and the block which supports the back casting (*C*) is placed on the other side of the wall. This arrangement brings the striking face of the post even with the face of the wall.

A bumping post in extensive use on the Baltimore & Ohio R. R., known as the "Triangular" post, is formed by bending both track rails straight up at an angle of about 45 deg., so as to form a backing for a heavy stick of timber placed crosswise the track at the hight of a drawbar. The backs of the rails so bent up are braced by short pieces of rail bent at about the same slant and footing into timbers running longitudinally under the track and extending in rear of the bumping post. At the point where each track rail turns upward it is anchored to the longitudinal timber underneath, and a timber is placed across the rails to serve as a wheel stop. In other forms of bumping posts of the general type now being considered the track rails are not disturbed. The simplest form of bumping post employing this feature is had by setting a heavy post in the ground and staying its top by heavy rods bolted to the webs of the rails some 7 or 8 ft. in advance of the post. At the upper end the rods engage with a heavy plate which backs up the post. In some cases the buffer consists of a block backed up by rubber or car springs and in other cases it consists of a swing post hinged to the main post at the ground and backed by springs at the top. A bumping post that is extensively used on the Grand Trunk Ry. has an oak post standing on each rail, with a cross beam between the two at proper hight for the buffer. The center of this beam is braced by three diverging oak struts footing against a timber laid across the rails in rear of the upright posts. The foot of each upright post supporting the bumper beam, and each end of the cross timber on the rails, is backed by a casting clamped to the rail.



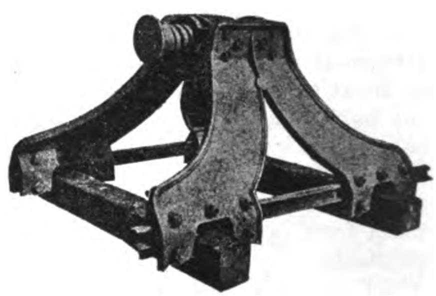


Fig. 463.—Economy Bumping Post. Fig. 464.—Haley Bumping Post.

The most numerous class of bumping posts are anchored to the rails by some form of tie rods, in front, and braced at the back by struts footing into the rails by some bolted or clamped connection. The Economy, the Fairbanks-Morse and Gibralter bumpers are of this description. The Economy bumper, in use on the Chicago, Milwaukee & St. Paul Ry., is shown as Fig. 463. Two heavy oak struts are bolted at their base to the track rails and brought together at their upper ends against the back of the buffer block. These strut timbers stand at an inclination of about 45 deg. and are secured in position by heavy tie rods anchored to ties or long timbers buried up beneath the track. Between the anchor timbers and the rails there are timber struts which serve to utilize the weight of the track and the load upon it to prevent the lifting of the anchored timbers. At the points where the tie rods straddle the rails there are cast bearing pieces bolted to the rail, with lugs in position to prevent the straightening out of the tie rods. The Fairbanks-Morse bumping post consists of a 12x12-in. post set deeply in the ground, in the middle of the track, and through bolted between two ties spaced 10 ins. apart and let into the post 1 in. on each side, this post being anchored to the rails in front and braced to them at the back. The anchor rods are 1¼x4-in. iron straps bolted to the web of the rail on the outside and passed back of the post. The back braces consist of two pieces of old rail bent up to bear against the back of the post at the top and bent at their feet to bolt against the track rails through filler blocks. At the feet of the back braces there is a stub switch rod to prevent the rails from being spread apart by outward pressure from the back braces, and there is another switch rod on the rails at the anchor rod connection, to act as a strut and hold the rails against being pulled together. The buffer consists of a set of ordinary car springs backed by the post and faced with a heavy striking plate. The Gibraltar bumping post consists of a bumping head backed by two brace rails running straight back and inclined at an angle of 45 deg. with the horizontal. These brace rails run down to a base plate, to which they are riveted, to make connection with the end rails of the track, which are bent inward and riveted to the same base plate, which lies on a tie in the center of the track. To prevent the bumping head from rising when it is struck there is a heavy U-bolt passing through the head and secured to a long piece of inverted rail laid under the ties. This inverted rail extends from underneath the base plate, in the rear, to a point in advance of the position of a car truck when the car is run up to the post. To hold the bumping head central there are two stay rods anchored to the rails in advance of the bumper head. The Cox bumping post, designed by Mr. J. B. Cox, chief engineer of the Chicago Junction Ry., is built slightly out of center with the track, to bring the center line

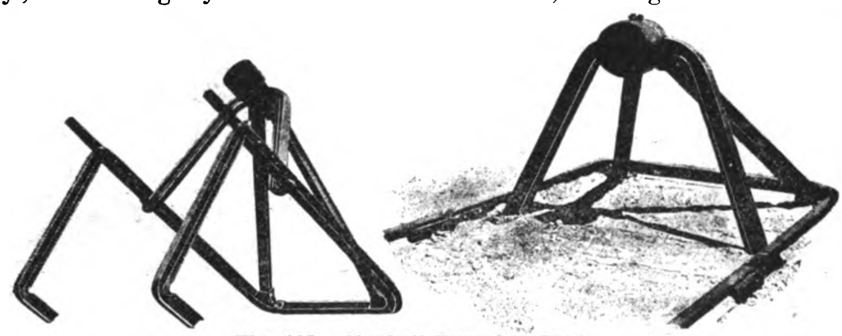

Fig. 465.—Haskell Bumping Post.

of the post to coincide with the striking part of the M. C. B. coupler head, which is not central with the track. The post is a 15-in. I-beam with web transverse to the track, standing upon a base plate which is placed upon a tie, and 1¾-in. anchor rods run down to a cross timber buried 6 ft. below the rail, as in Fig. 463. At the point where the anchor rods pass vertically downward they are attached to the webs of the rails, on the outside, as in Fig. 463, and at this point the rails are cross-tied by a 4x6-in. angle iron strut. The striking plate stands even with this strut and is backed against the post by a 12x12-in. oak timber 3 ft. long supported upon angle iron braces footing into the angle iron cross tie. The track cross ties rest upon a set of longitudinal timbers, and under these there is blocking running down upon the anchor timber to prevent it from being pulled up by stress on the anchor rods.

The Haley bumping post (Fig. 464) is made entirely of metal and consists essentially of two heavy, flanged A-frames with their feet bolted to the track rails and the tops inclined together and carrying a coiled spring buffer. The legs of the frame are of cast steel, the feet straddle the ties and are shaped to fit the contour of the rails. A similarly shaped clamping plate is placed on the inner side of the rail and secured to the main frame by means of three bolts above the rail and two beneath. Attached to the lower bolts in the forward legs there are anchor rods secured to a piece of rail buried beneath a bed of ties 4 or 5 ft. under the track. Between the tops of the side frames there are two transverse webs, through which the buffer rod or plunger passes. The buffer acts against two double coiled springs, one being placed back of the buffer head and the other between the transverse webs. The space between the side frames permits the pilot of an engine to pass between them, so that the pilot drawhead may engage with the buffer. The plunger is set off the center of the post, so as to receive a straight blow from coupler knuckles. The Haskell bumping post, devised by Mr. B. Haskell, superintendent of motive power of the Pere Marquette R. R., is made principally of old rails and is bolted to the end of the track rails, as shown in Fig. 465. A single rail is bent into a loop, for a base, the rear corners of which support the diverging braces of the buffer. The front ends of the base rail are turned downward into the earth and the extreme ends are bent up to engage an anchor timber. The buffer consists of a pocket and cap holding the buffing springs.

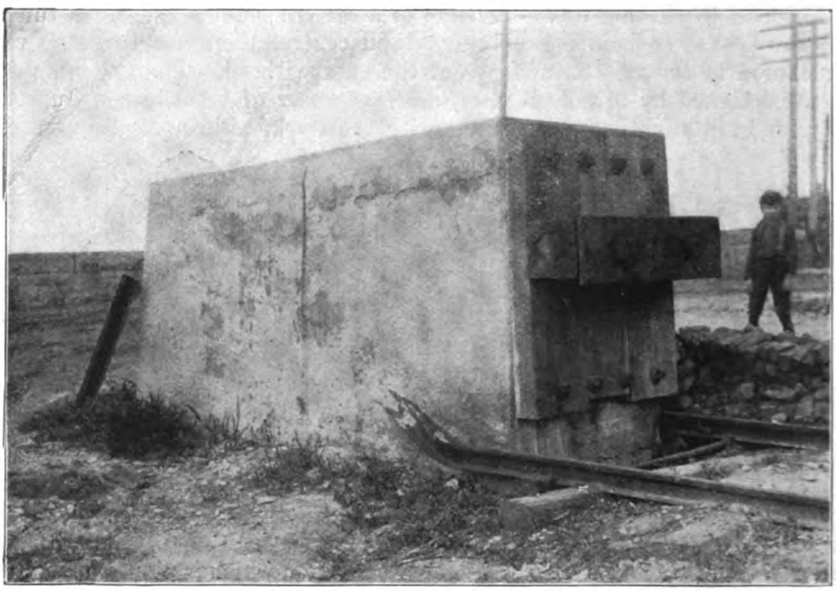

Fig. 466.—Concrete Bumping Post, C., R. I. & P. Ry.

At the ends of stub tracks in the freight yard of the Chicago, Rock Island & Pacific Ry., between Forty-second and Forty-third streets, Chicago, there are some bumping posts of monolithic concrete masonry. Essentially, each bumping post consists of a concrete pier 10 ft. long, 4½ ft. wide, at the deadwood, and 9 ft. deep, reaching 4 ft. below the surface of the ground. The sides of the pier have a slight batter. Just in front of the pier the rails are united by a switch rod. The pier is faced with 4-in. planks standing vertically and bolted to the masonry, so that the shock from cars is distributed over the whole surface. The deadwood consists of an oak timber faced with iron plate and bolted to the pier through the facing plank with two large bolts. Each rear corner of the pier is protected against damage from wagon wheels by a fender consisting of a piece of rail standing in the ground and leaning toward the pier. Respecting the rail connection with the pier there are three different plans. In one style the rails stop short and are in no way connected with the concrete mass. In another style the track rails extend into the pier, being bent inward on the level of the track to meet in the interior of the mass of concrete. In the third style of construction (Fig. 466) the track rails straddle the front end of the pier and are bent both inward and upward, like the rails of an Ellis bumping post, running into the concrete until they nearly meet, where they are held together by cross rods, so as to take firm hold of the pier. These "posts" cost $50 each, complete in place (which was $25 less than the purchase price and cost of erecting approvable posts of patented designs then on the market), and those to which the rails are attached have given satisfactory service. The one built independent of the rails rises at the front end when bumped hard, and the dirt jarred under it must be dug out occasionally to let it down. The one with the rails bent inward but not upward has stood well. One of those built with the rails bent both inward and upward withstood the shock of a 25-car train thrown against it so hard that a car-load of large dimension stones was unloaded over the top of the pier and the car broken in two and doubled up. The pier was cracked diagonally from bottom to top, following the line of the bent-up rails, but was not moved out of serviceable position.

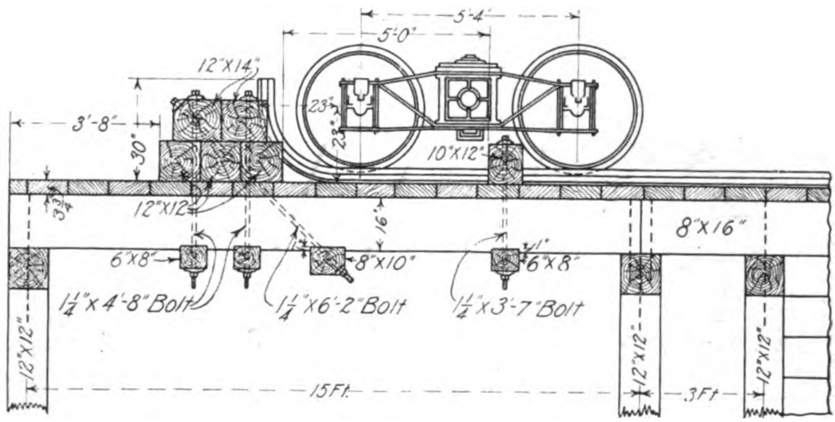

Fig. 467.—Standard Bumper for Ore Docks, Duluth & Iron Range R. R.

For absorbing the shock of striking cars, so that the full force will not act suddenly on the post, rubber springs and spiral springs are employed, as already explained. What is perhaps the most complete arrangement of this kind is the Webb hydraulic buffer, used on the London & Northwestern Ry., in England. This consists of a pair of braced posts backing up hydraulic cushion cylinders or dashpots which bring the striking car to rest without recoil. Each of the two buffer heads is backed by a piston working within a 9-in. cylinder 2 ft. long perforated with thirty ¼-in. holes and enclosed by an outer tight casing with a 1¼-in. annular space between them. Connecting with this annular space there is a vessel or well partially filled with a mixture of petroleum, soap and water, which is forced up into the annular space and inner cylinder by air pressure at 45 lbs., whenever the buffer is in normal position. As the piston is pushed in, the liquid escapes from the inner cylinder into the annular space and into the well against the air pressure, but with constantly increasing resistance, owing to the diminishing number of escape holes ahead of the piston. Under constant use the full pressure can be maintained about six months without attention. When the pressure decreases it is restored by means of a hand pump.

Not every type of bumping post in extensive use is applicable to track on trestles or other elevated structures, and hence there are a number of special designs for such service. Figure 467 shows the plans of a standard bumper in use on ore docks of the Duluth & Iron Range R. R. The bumper proper consists of five heavy timbers in two layers—three 12x12-in. pieces in the bottom and two 12x14-in. pieces in the top layer—placed crosswise the stringers and anchored to the same with long bolts and brace rods. Against these timbers the rails are curved upward to a radius of 23 ins., and just in advance of them a 10x12-in. timber chock, on edge, is notched over each rail and bolted fast to the stringers. This chock serves to stop the car or to retard its motion when jumped by the leading pair of wheels, and it is placed at such a distance from the bumper proper that the second pair of wheels meets the chock at about the same time that the leading pair meets the bumper. The bumper and chock timbers extend continuously across the double track running over the ore pockets.

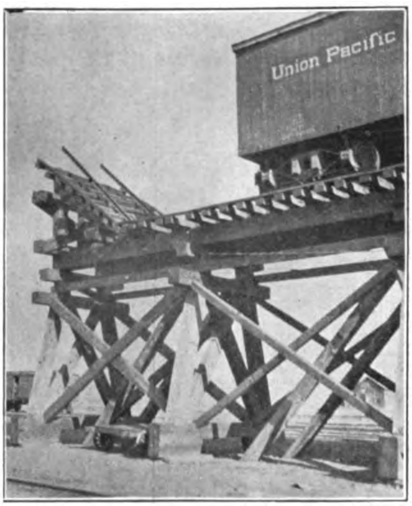

Fig. 468.—Car Stop on Trestle, Union Pacific R. R.

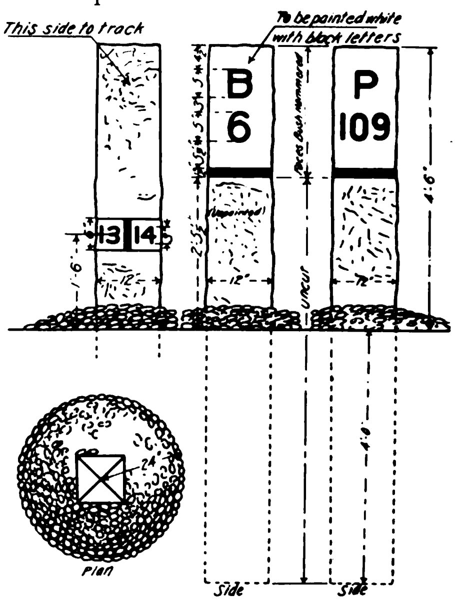

Fig. 469.—Granite Mile Post, Boston & Maine R. R.

Figure 468 shows a form of car stop used on trestles of coaling stations at several places on the Union Pacific R. R. The end of the track is upturned at an angle of about 45 deg. and supported by a timber framing at the back. This backing consists of a low bent, on which are laid leaning stringers to support the track, the bent being stayed by long bolts running forward to the cap of the second trestle bent from the end, and from this cap long bolts are run to the cap of the third trestle bent. The ground bents near the end of the trestle are then braced together and also by leaning timbers run to the ground. The leaning stringers are notched over a cross beam securely bolted to the horizontal track stringers. This short and steep incline is supposed to be sufficient to stop a car running against it at any speed to be expected in such a place. The bumping post for the end of coaling trestles on the Southern Ry. is braced up from the ground by long timbers, to relieve the trestle of longitudinal stress when the bumper is struck by cars.

158. Sign Boards.—Sign boards and sign posts should be arranged according to some system. Those used for different purposes should vary distinctly in shape, so that a glance at one, even after dark, will instantly reveal what it stands for. Thus, for example, the board or panel on a post used for one purpose might be round; that for another, square or rectangular; another, diamond-shaped, and so on. Everything should be plain and distinct, without attempt at ornamentation, and the signs should be worded as briefly as may be consistent with properly conveying the meaning. Running signs should be placed near the track, no part being nearer the rail than 7 ft., however. The minimum distance on some roads is 10 ft. from the rail. Where two or more would come at about the same place they should be moved a little way apart, keeping within limits prescribed by law for the locality. The posts should always be long enough to set firmly in the ground. In districts where the snowfall is deep the hight of the post above the ground must be governed somewhat accordingly. Brush should at all times be kept clear of sign boards and clear of the ground over which it is necessary to look in order to see the sign from the trains at the proper distance.

Mile posts are usually 10x10 ins.x8 or 9 ft., set 3 ft. in the ground. They are usually painted white, with the numbers put on plainly, in black, and sometimes also the initial of the city or terminal point from which the distance is reckoned. The distances from two terminals are sometimes placed on the same mile post, but usually on opposite sides, and each on that side which faces in the direction of the place; so that one looking ahead from a train will see the distance to the point from which he is traveling. In cases, however, the two distances are placed on adjacent sides of the post and the post is turned cornerwise to the direction of the track, so that both inscriptions may be seen simultaneously, as one approaches the post. The Grand Trunk Ry. has mile posts of triangular section, set with the back side parallel with the track. The distances to the terminals are painted on the two faces of the post which stand oblique to the track. This arrangement is convenient for passengers. The top of the post is sharpened, to shed rain. If more than one distance is given on the same mile post the initial of the place should appear with each distance. It is, however, a matter of some convenience to mark on each mile post the distance to the nearest station, in both directions, in which case, to avoid confusion with the terminals, the initial of the station should be omitted and the number indicating the distance should be in small figures placed low-down on the post, and on the side of the post facing from the station. The Michigan Central R. R. uses minor posts set at the half-mile and quarter-mile points.

In line with permanent or more durable construction, stone mile posts are used quite extensively, being in some cases a stone of square cross section, and in other cases a slab, roughly dressed, with smoothly dressed faces for lettering. The Lehigh Valley R. R. uses a flagstone 20 ins. wide, 3½ ins. thick, and 6½ ft. long, set 3 ft. in the ground. A 16-in. patch at the top is painted white, with black letters, and the remainder of the post is painted black. The stone mile post of the Boston & Maine R. R. is of granite, 12 ins. square in section, 8½ ft. long, set 4 ft. in the ground. The side faces, occupying 24½ ins. of the top part of the post, are bush-hammered, while the remaining surface of the post is uncut. Distances are painted on the post with black letters and figures 5 ins. high on a white field. On mile posts which divide sections there is a face 6 ins. high, 1½ ft. from the ground, on the side toward the track, with painted figures 3 ins. high. Thus, the post shown as Fig. 469 is 6 miles from Boston and 109 miles from Portland, and stands on the dividing line between Sections 13 and 14. The post at the ground line is kept free from grass and other vegetable growth by a heap of cobble stones 4 ft. in diameter.

The Chicago & Eastern Illinois R. R. is using mile posts made of concrete. These posts are 8x8 ins. x8 ft. long, set 3½ ft. in the ground. The concrete mixture consists of 1 part cement, 1 part sand and 2 parts of crushed stone. Near the top of the post there is a letter panel 14 ins. high, molded black, being colored with lampblack mixed in with the concrete, which is separated from the other concrete by strips of wood placed in the molding form. The letters and figures are molded in on this black panel, and after the concrete has set they are painted white. The weight of each post is 498 lbs., and the total cost, including labor and materials, is 82 cents.

Iron, in the shape of old boiler flues, is used a good deal for sign posts, including mile posts. On part of the Lehigh Valley R. R. system the mile posts are made by riveting a piece of old boiler plate 15 ins. square to the flattened end of an old boiler tube 8 ft. long set 3 ft. in the ground. The plate is fastened to the tube at one corner, so that its diagonals stand vertical and horizontal. The lower part of the tube is fastened with staples to a piece of tie 3 ft. long, standing vertically at the side of the tube and buried, to give the post stability in the ground. On some roads the mileage is marked on boards nailed to the telegraph poles. Such is the system on the Southern Pacific road, where the "mile boards" are nailed to the nearest telegraph pole, 10 ft. above ground and facing the track. On the Atchison, Topeka & Santa Fe Ry. the exact mile points are marked by posts 4 ins. square driven into the ground just outside the ends of the ties. The number of the mile is painted on the post and also in large figures upon a steel plate that is fastened to the nearest telegraph pole. As these wooden posts need renewing they are replaced by a piece of old boiler flue 3 ft. 10 ins. long set 2½ ft. in the ground. The top part of the flue for a length of 12 ins. is flattened together and figures ¾ in. high are stamped into the metal fully $^{1}/_{16}$ in. deep. Curve posts are made of the same material, the same size and marked in the same way. Above the ground line these posts are painted white.

Whistling posts for stations are usually marked "W" and "S," one above the other, and the post is placed ½ mile or one mile from the station; in other instances a station whistle board is used, having the name of the station painted thereon. Whistling posts for highway crossings, marked "W" and "X," are usually placed ¼ mile from the crossing, the distance being fixed by state law. Whistling posts are set on the engineer's side and ring posts (marked "R") usually on the fireman's side, at some distance from the crossing required by law—usually ¼ mile. The most ordinary style of whistle post is shown in Figure 276. On the Southern Ry. the standard whistle post for highway crossings is a cast iron post of +-shaped section, flattening into a plate at the top. The post is painted white, with two long cross bars and two short ones, in black, on the plate, to represent the whistle signal, thus: —— —— — —, reading down the post. Figure 551 shows a wooden post painted in this manner.

A convenient sign for the public at highway crossings consists of two crossed boards having the words "Railroad Crossing" on one board, and "Look Out for Cars" on the other. An open frame-work of diamond shape, with these words distributed around the four sides, is also a very common form of sign for highway crossings. On the Lake Shore & Michigan Southern Ry. the highway crossing sign board consists of a diamond frame of 1x10-in. boards sandwiched between two pieces of 2½x7-in. oak plank, which constitute the post part of the sign. This sign should be set facing the direction of the wagon road, at some conspicuous place near the track, but out of reach of vehicles loaded with bulky things like hay, etc. The usual distance from the track is 15 to 25 ft. Both sides of the board are lettered, so that, ordinarily, one sign board serves for both directions. Where there are a number of tracks at the crossing or wherever one board cannot be seen to good advantage from both directions, there should then be a sign on both sides of the track; in which case the lettering can be omitted from the track side of each board. Another warning that is placed on the crossing sign boards of some roads is: "Danger! Stop, Look and Listen."

Other sign boards in ordinary use along the track not already mentioned in connection with previous subjects, are "Stop," "Slow" (generally used in connection with every "Stop" sign), "Yard Limit," "Dump Ashes," "Water Tank. . . Mile Ahead," section limit posts, warning signs for private crossings; sign boards to mark the limits of towns and cities, county and state boundary lines, right-of-way boundaries; bridge number signs, flanger boards, rail record posts, rail monuments for marking the ownership of tracks, "No Thoroughfare" and "Do Not Trespass" signs; and station signs at points where there is no depot, such usually being lettered on both sides and placed at right angles to the track. A common form of board for a stop or slow sign is a cast iron plate of oval form $\frac{1}{4}$ or $\frac{3}{8}$ in. thick, bolted to a post. The letters are raised $\frac{1}{8}$ in. and cast integral with the plate, and there is a $\frac{1}{2}$-in. rib at the border. The slow and stop signs of the Pennsylvania R. R. are semaphore arms fixed to posts, the arm being let into the post and nailed fast. The slow board has the conventional fish-tail end and is painted green, with white letters; the stop board is painted red, with white letters. The stop sign at a drawbridge is usually placed 200 ft. from the end of the span, and at railroad crossings or junction points, 400 ft. from the crossing, the exact distance, however, being generally, regulated by law. In addition there is usually a slow board or cautionary sign placed one mile from the crossing, junction or drawbridge, lettered "R. R. Crossing One Mile," the word "Junction" or "Drawbridge" being substituted as the case may require. Slow and stop boards carry lanterns or lamps at night, the color corresponding, of course, to the signification of the sign.

Right-of-way boundary posts are frequently made by cutting up the sound portions of old telegraph poles, painting white and setting every 500 ft. along the line, or at more frequent intervals, in case there are jogs or corners in the line. As permanency is one of the principal requirements of such posts a piece of rail is undoubtedly more suitable for the purpose, and such is in use on some roads. The Cincinnati, New Orleans & Texas Pacific Ry. has a short post with a circular cast iron plate painted black, with letters and figures stenciled in white, to give the location, name of manufacturer and the age of rails. The Chicago, Burlington & Quincy Ry. uses a rail monument for marking the ownership of tracks. The piece of rail is 4 ft. long, set 3 ft. in the ground, with the name of the company owning the tracks stamped in the head and base of the rail. A "Close Sand Valve" post is sometimes placed 200 ft. from interlocking switches or detector bars, to protect such apparatus from sand.

On some roads it is the practice to number the curves, beginning at one end of each division. On the Buffalo, Rochester & Pittsburg Ry. a triangular sign board is placed on a telegraph pole at each curve, giving the number of the curve and its degree of curvature. It is usual to put the number and degree of curve on stakes or monuments opposite the beginning and ending of every curve; and if the curve is spiraled, the number of the curve is placed on stakes where the spiral joins the tangent, and stakes showing both the number of the curve and the degree of curvature are placed at the ends of the circular curve; on compound curves, curve posts are placed at each point where the curvature changes—i. e., at each P. C. C. Such posts or stakes are usually set at the edge of the ballast, on the shoulder. The amount of superelevation for the curve, when marked at the curve, is usually placed on the back side of the stakes showing the number of the curve and the degree. On double track, where the two tracks have different elevations, elevation stakes are set outside each track; otherwise, one set of stakes outside the outer track is usually sufficient. On some roads a stake marked "E 0" (Elevation zero) is placed at the point on tangent where the elevation runs out, and another stake marked with the full elevation, as "E 4," is placed where full elevation is to be given. The numbers on wooden curve stakes or posts are frequently burned in with metal dies. The Southern Pacific Co. uses creosoted stakes. Curve monuments are treated in Chapter V, § 48, but it may be well enough to repeat here that a post that is very commonly used for this purpose is a piece of rail about 5 ft. long split up the web at the bottom and having the two parts bent outward to resist pulling up.

The prevailing colors for sign boards are a white ground with black letters, with a black border, if a border is used. Occasionally, however, the ground is made black with white letters; and to obtain distinctness without changing the shape of the board it is sometimes the practice to use white letters on a red or green background. The shape of sign boards and the details of design, such as the hight of post, the size of board or panel, the method of attaching the board to the post, etc., vary somewhat on different roads, but it is hardly worth while to go into particulars. The Cincinnati, New Orleans & Texas Pacific Ry. is one of the roads on which the sign boards for the various purposes vary quite widely in design. On the other hand, the Chicago, Burlington & Quincy Ry. might be cited as one of the roads on which the designs of the various standard track signs vary but little. The highway crossing whistle, station whistle, flanger, sand valve, derail, section, rail record, and clearance signs of this road are peeled cedar posts without boards or panels, with black lettering on a white patch near the top of the post. All sign boards or panels are rectangular in form, with the exception of the highway crossing sign, which has crossed pine boards, 6 ft. 2¼ ins. long, 10 ins. wide and 1¾ ins. thick, gained into opposite sides of a 16-ft. peeled cedar post set 4 ft. in the ground, the tips of the crossed boards, which stand at an angle of about 30 deg. with the horizontal, coming even with the top of the post. The boards are painted white on both sides, with black letters 8 ins. high, one board reading "Railroad" and the other "Crossing," while the post is faced on two sides and painted white with black letters, "Look Out for the Cars," reading down the post. The state line post is oak, 8x8 ins. x9 ft., set 3 ft. in the ground and painted white with black letters. The mile post is oak, 6x8 ins. x12 ft. long, set 4½ ft. in the ground and placed on the "right-hand side of the track looking from Mile Post 1." In locations where there is not sufficient room for a horizontal sign the stop and slow signs are painted on peeled cedar posts without boards or panels. In nearly every case the post and back of sign are painted with mineral paint and the signs are painted white, with black letters. All running signs are placed on the right-hand side of the track, and all other signs except mile posts are placed on the north or west side. The nearest point on any sign must not be nearer the rail than 7 ft.

On the Nashville, Chattanooga & St. Louis and the Pittsburg, Ft. Wayne & Chicago roads every fifth telegraph pole is numbered, for convenience of locating the bridges and other structures more closely than can be done with mile posts. The system also serves as a convenient means for locating defective places in the track, the scenes of accidents, the starting and ending points of new rail laid, etc. The section foremen in making their reports use the pole numbers to locate the places where work is done. The numbering starts at the division points. The Lehigh Valley and some other roads also have in practice the system of numbering the telegraph poles. Mail cranes, bridge signs, telltales or bridge warnings and station signs are customarily looked after by the bridge and buildings department, and signal posts and sign boards used in connection with interlocking switches and signals by the signal department.

Sign boards and posts should be maintained in a plumb position. A post which has become leaned over naturally appears like something which has gone out of use. As soon as the use for a sign board or post has ceased it should be removed: along a railroad there should be no signs posted which have no significance. A coat of fresh paint occasionally adds to the impressiveness of a sign; and a pile of cobble stones or rock ballast placed around the post, where it enters the ground, will protect it from fire and from decay which starts from contact with vegetable growth. The matter of keeping sign boards brightly painted is of considerable importance, and the expense is no small item. To a small extent enameled steel signs are being used. The enameling is done in the colors desired, and on either sheet or plate metal or cast iron. It is said that such signs or signals will stand for many years without rusting or tarnishing, the only care required being to wipe the dust off them occasionally. The conspicuousness of sign boards invites target practice, and in localities where huntsmen are numerous wooden signs soon become shattered by gun shots. In such places it is expedient to use sign boards of boiler plate or cast iron, the letters being stenciled on, in the former case, and raised and cast in with the plate in the latter, if the reading of the sign is to be permanent. Wooden panels may be kept from splitting by nailing battens at the back with clinched nails.

As a means of prolonging decay in wooden posts or telegraph poles it is quite largely the practice to dip the portion of the post which is to set in the ground, into hot coal tar or pitch. It is well known that the part of the post which decays first and most rapidly is a narrow ring at the ground line. A recently devised means of protecting timber against decay at this point is to encircle the post with a length of sewer pipe 2 or 3 ins. larger in diameter than the post and have it project about 2 ins. above the ground line. The space between the pipe casing and the post is then filled with asphalt or clean gravel and tar or pitch poured in hot, so as to fill any checks or seasoning cracks in the post. The space thus filled forms a water-tight packing around the post. In setting new poles or posts a solid section of pipe can be used, by slipping it over the end of the pole, but for poles already set a section of pipe in two parts is provided, the edges of the two parts being tongued and grooved, so as to fit tightly together and make a good joint. The tops of sign posts should be pointed or slanted, so as to shed water. As a means of resisting fire and decay iron posts are coming into use to a considerable extent, as already stated in some particular. Old boiler tubes, painted with some kind of preservative coating, are used for posts, and the sign is painted on a cast plate or sheet metal target riveted to the post. The Mathews post, in use on the Pennsylvania, the Missouri Pacific, the Wabash and other roads, consists of a steel T-bar secured to a length of sewer pipe by braces and a collar on the pipe, and set in the ground. The piece of pipe is filled with concrete or tamped with earth, as in the case with fence posts of similar construction, shown in Fig. 427. The standard track signs of the New York Central & Hudson River R. R. have posts of old rails and panels of $^3/_{16}$-in. steel plate. For a hight of 4 ft. above ground the post is painted black, and above that white. The posts for various signs are 12 to 15 ft. long, of which $4\frac{1}{2}$ to 5 ft. is set in the ground Around each post there is a cobble stone paving 5 ins. high and 2 to 3 ft. in diameter.

159. Signals.—Section foremen should understand thoroughly the established system of flag, lantern, hand, torpedo and whistle signals on their road for the operation of trains. Red flags and torpedoes should be carried on the hand car at all times, and during short days in winter a red lantern also. The flags should be attached to short sticks and, to keep them dry and clean, they should be carried in a galvanized sheet iron tube or in a box arranged upon or under the hand car. Torpedoes must be kept dry, and may best be carried in a tin can having a tight cover; a baking-powder box is the thing. The schedule of the trains, both passenger and freight, should be thoroughly learned, particularly so far as pertains to the time when each train is due on the section or at the first station in the direction from which the train approaches. Foremen should carry reliable watches, which they should frequently compare with the standard time of the company, as kept in telegraph stations or as carried by trainmen. If the foreman starts out at or passes a telegraph station at any time during the day he should get from the operator information regarding any irregularity in the running of the scheduled trains or what irregular trains are running, if any, and about what time he may expect them. It is also well to know in advance the number of sections boarded for each train.

Trackmen should never take up a rail or engage in any work which would be equally as dangerous to the passage of trains, without first putting out flagmen or red flags in both directions, if on single track, or against trains running on the track affected, in case of double track. The question of sending flagmen both ways for one track of a double-track road is usually covered by the rules of the company. "Anything that interferes with the safe passage of trains at full speed is an obstruction, and must not be undertaken without proper protection," is a rule generally followed. Loaded push cars on main track are considered obstructions to be protected by danger signals, although on some roads the rules permit their use in day time where there is a tangent of at least ½ mile, without signals. As the engineers of special trains are supposed to be looking out for such things permission of this kind is not inconsistent with good practice, but loaded push cars should not be used at night, or run around curves or be allowed to stand upon them, where the view is obstructed, without signal protection. No blasting should be done near the track without first sending stop signals in both directions. In doing work which disturbs or obstructs the track it should always be taken for granted that a train will come before the work is completed, and unless the rules of the company state differently, the danger signal should be sent three-quarters of a mile, which distance would be measured by counting 24 telegraph poles or 132 rails of 30 ft. length. If the train must approach over a down grade the flagman should go farther; if over an up grade of one per cent. or more, a quarter of a mile is far enough. If any of these distances bring the signaling point on a curve, and a tangent can be reached by going a little farther, then the flagman should go on as far as the tangent. Except in cases of emergency no work that will obstruct the track should be undertaken during heavy fogs or snow storms.

It is always best, where the force is large enough, to have a man stay with a stop signal until the work is done; but it is very expedient that he should remain, in any case, if the signal cannot be seen from the point where the work is going on, or during stormy, windy or foggy weather, or at night, or where children might be expected to be playing near the signal. The rules of many roads require that a man must always remain with a danger signal. The man who stays out with a danger signal should be instructed to remain at his post and stop all trains; and under no circumstances to leave his post until he is called in; and also to be sure that he recognizes the right party calling him before leaving.

A misunderstanding might arise by mistaking the accidental gesture or yell of some one not purposely intending to call him. Some companies require that flagmen must be sent both ways to guard an obstruction on one track only of a double track, the same as though the road was single track. When it is found necessary to run trains in both directions over one track of a double-track road, and the change is made under such circumstances that it might not be anticipated by the trackmen, if the first few trains sent in the contrary direction are required to run at reduced speed and blow the whistle frequently (as they should do), then under all ordinary circumstances there would be no need of sending flagmen both ways. Trains running in the wrong direction on any track ought to carry red flags or red lanterns in front. Work trains should run on the contrary track as little as possible, and then only from the nearest crossover to the point to be reached. Of course, within yard limits foremen know what to expect; but in any event where the expediency of sending a flagman might be in doubt it would be well to use the torpedo signal.

A "stop" signal is a red flag displayed by day or a red light by night. The mere presence of the signal on or near the track is all that is required, but if there is a man with it, it is best to swing it gently across the track; but any kind of light swung across the track, or a hand, hat, or other object waved violently on the track, by any person, is a signal to stop. The explosion of one torpedo is a signal to stop immediately; the explosion of two torpedoes is a signal to reduce speed immediately and look out for something ahead. When used by itself the stop torpedo signal is placed at the same distance from the danger point as the stop flag or stop lantern signal would be. The torpedo signal of caution (two torpedoes) is sometimes used by trackmen and placed $\frac{1}{4}$ or $\frac{1}{8}$ mile beyond the stop signal, to call the attention of the trainmen before the stop signal is reached. When used by the flagman of a train the caution torpedo signal is not taken up when he is called in, but is allowed to remain, so as to protect the train during the interval elapsing from the time the flagman is called until the train gets started. When used by trackmen the torpedoes should be taken up when the flagman is called in. Torpedoes should be used in addition to flags or lights whenever, by reason of fog, storm or other unfavorable condition, there is a doubt whether the flag or light may be seen, or whenever a stop signal is left without an attendant. But some roads require the use of the torpedo signal in all cases as an extra precaution taken under the supposition that no one on the approaching train might be looking ahead at the critical time. It should be placed at such a distance beyond the flag or lantern, that when exploded, the flag or lantern may be seen from the engine or head end of the train, but not closer than 150 ft. When two torpedoes are used they should be placed 60 ft. apart. Torpedoes for signals should be placed on the engineer's side, as the train approaches, but on third-rail track they should be placed on that rail which is used by trains of either gage. A man left with a stop signal should, at the approach of the train, wave the flag or lantern across the track until answered by whistle. If for any reason a torpedo signal cannot be given, and the flagman cannot draw the attention of any one on the engine, a handful of gravel tossed so as to strike the front of the cab will seldom fail to make known "what's up." Or if there is not time to do this he should try to throw a rock, club, a boot, or anything he can get hold of, through a window of the rear coach or caboose. There are plenty of old railroaders who have been in position to appreciate the force of this monition. A red or stop flag left standing should be placed in the middle of the track, spread out between two sticks quite firmly stuck into the ground, so as to be well displayed; a red lantern, if left alone (which is not good practice), should be placed just outside the rail on the engineer's side. Flagmen sent to stop trains should be instructed not to permit the engineer to proceed until the exact location of the danger point is clearly understood by the latter, so that no misunderstanding may arise in case a second crew should be working between the flagman and the danger point.

In connection with danger signals it may be interesting to mention that some roads have rules forbidding trackmen to wear red shirts as outer garments, as there have been instances where such have been mistaken for stop signals. In the same connection, also, attention may be called to the contingency when trackmen are caught without lantern or torpedoes, after dark, and occasion arises for stopping a train. In such event a switch lamp, if to be had, may be taken down and put into service, or a piece of waste may be lighted and waved on a stick. A red flag pinned around a white lantern will show a red light; and if the lantern at hand is poor and it is feared that it may be put out by being waved, such an arrangement is sometimes resorted to.

A "slow" signal (green flag or lantern) should be set up in a clear space outside the track, on the engineer's side, just far enough away to clear passing trains. A half mile is the usual distance for placing out a slow signal. In connection with a slow signal protecting a point at which no one is working, it is usual to place a white flag or lantern—that is a "clear" signal—to designate the point from which the train may proceed at full speed. At night it is well to use both the flag and the lantern, as then the flag, which, being white, is conspicuous, readily explains what the lantern is for. If a crew starts in to work between a slow signal and the point which the signal is protecting, another slow signal should be placed some little distance away, between this crew and the danger point, to indicate to an approaching train that the danger point is farther along. If a slow signal is to remain at the same point for any considerable length of time it is a good plan to set a post and attach the flag stick to it horizontally, so that the flag may hang downward, free and clear. A track nut tied to each loose corner or a piece of telegraph wire sewed into the edges of the cloth will prevent the furling of the flag by the wind. A simple and convenient flag and lantern holder in portable form may consist of a piece of 1¼-in. gas pipe 5 or 6 ft. long, pointed at one end, for sticking into the ground, and fitted at the other end with an ordinary T-coupling screwed on to hold the flag stick in a horizontal position. A piece of telegraph wire is bent around the "T" and formed into a hook for holding a lantern.

The fusee is a time-interval signal used principally for the protection of trains, at night or during heavy fogs or heavy snow storms. It consists of a pasteboard tube weighted and spiked at the lower end and filled with a slow-burning composition which will maintain ignition in a heavy wind or in snow or in rain. It burns with a brilliant colored light, illuminating the whole region roundabout, and is made to burn out in a definite time—five, ten or fifteen minutes, according to the interval desired. It is stuck into a tie or into the ground and lighted (and sometimes lighted and thrown from a train), and no train is supposed to run by it until it has burned out. An improved form burns a series of colored lights. The first, being red, say, will burn five minutes; the second green or blue, burns five minutes longer; and the third, white, finishes out the remainder of the interval. An engineer following the train from which this fusee has been thrown is thus enabled to tell very nearly the time which has elapsed since the train ahead departed, and may govern his movements accordingly. The fusee may thus be substituted for the cautionary torpedo signal (two torpedoes) left by a flagman to protect his train while he is running in, after being called. Permission should be granted section foremen to carry and use fusees, upon occasion. On crooked roads section crews are sometimes held out on the track until well into the night, waiting for delayed trains and fearing to venture forth with the hand car, especially if there is a bridge to cross. If caught without a lantern it is impracticable to flag the car in, and such a method of running is slow and laborious (for the flagman) at any time. Torpedoes left upon the track in such a case would be in service until exploded and would then needlessly bother the engineer, unless the train came along soon after they were placed. A 10-minute fusee would enable the car to get over a good distance, under protection, and the chances would be that in many or most instances the train would not arrive before the signal had burned out.

Trackmen should never hesitate to stop or slow up a *train of any class,* whenever in their judgment there is danger ahead of it, or about to be; as in the case of a threatening slide, for instance. Some are too timid in this respect; and while flagging a train some trackmen have been known to lose their presence of mind as completely as does an ordinary man when called upon to speak before a public audience. Any engineer or trainman who will abuse a trackman for holding a train, for any reasonable cause, ought to be reported to, and be dealt with by, the superintendent. Except in case of emergency, however, trackmen should avoid undertaking any piece of work which they cannot expect to have completed for the safe passage of regular trains before such trains are due. On most roads section foremen are required to have the track clear 10 minutes before train time. As for irregular trains, it is to be expected that they must be held occasionally, if trackmen have not been notified of their coming; but here is where "tall swearing" is too frequently indulged in.

Before appointing any man as section foreman the roadmaster should examine him thoroughly and be satisfied that he understands clearly how to signal trains on that particular road. The foremen should thoroughly instruct their men regarding signals, and entrust them only to those who are careful and reliable. The men oldest in point of service are usually the ones to rely upon, because of their experience; and also because careless or irresponsible men are not, or, at least, ought not to be, retained long in the crew. Trackmen should not disturb torpedoes, fusees, or other signals found placed along the track, but they should always endeavor to ascertain the cause for their having been placed there. Torpedoes unexpectedly knocked off the rail or exploded by the hand car should be replaced. This rule makes it necessary for section men to carry torpedoes on the hand car.

On almost all roads there is a signal used between trainmen and section hands for the purpose of getting information regarding the time between trains supposed to be running close together in the same direction, as, for instance, the different sections of a train. Although such signal is not usually authorized by the company, it often serves a useful purpose, nevertheless; and as railway men will use it anyway, I shall say a few words regarding the same, by way of correcting some wrong ways of giving it; for misunderstanding sometimes results from making it improperly. A trainman desiring information of a trackman whom he is passing, after an inquiring look or gesture, holds out both hands in front of the body, one hand over the other, the palms together. If the section man answers by holding both hands out a *little way* apart, one over the other, it indicates to the trainman that the train ahead passed but a short time previously; if the hands are extended *far apart,* one above the other, it is supposed to indicate that the train ahead passed a long time previously *for that class of train.* The same signals, when given by a trainman, in answer to an inquiry from a trackman, indicate to the trackman that the train following is known to be near or far, as the case may be. If the difference in time is as much as 10 minutes, but less than 20, the person, after giving a signal that the trains are close, holds up both hands with all the fingers extended. A shaking of the head by the person answering indicates that he is either in doubt or else does not know. In giving the signal it is important that one hand should be held vertically above the other, instead of extended apart horizontally, on account of the latter being the customary sign of recognition or "hello," among many people, especially among railroaders.

Trackmen and trainmen should not be too free in motioning one another; for when such matters become habitual it might, in case of need, be difficult to tell whether or not only a jest was intended; and tomfoolery should have no place around the railroad. It is all right, and often very convenient, to interchange signals when each party understands the other; but trainmen should put little confidence in information gained from men whom they do not recognize as trackmen, or whom they do not know; and then, only when they act as though they understand what they are doing. Trackmen wishing to hail trainmen for information should not bother the engineer if, while the train is approaching, they see they can catch the eye of the fireman, a brakeman, or the conductor, perchance stationed somewhere out on the train. The foreman or trackman who gives the signals should stand aside from the rest of the crew, near the track, and he should not talk or yell while signaling with his hands. Men just coming from other roads should be careful how they use signals familiar to their experience on the road from which they came, lest in the new place these same signals have different meanings.

While a train of any class is passing, all trackmen should habitually quit work, straighten their backs and take special notice of the locomotive, with reference to signals carried, and look for a signal from any part of the train. Too often men get into the habit of jumping into some kind of perfunctory work "while the trains are passing," keeping one eye on the train and taking note of nothing on it except the presence or absence of the roadmaster or some other "big boss." After a train has passed, the foreman is not always sure that he made careful observation of the locomotive for signals carried, especially if he was looking for a note to be dropped; and if he then wishes to put his car on the track, it is important to have the corroboration of his men as to whether signals were carried for a second section. If the men are permitted a minute's breathing spell while trains are passing they will usually take interest in observing the signals carried by the locomotive or anything unusual about the train. If anything is wrong with the running gear they should signal the trainmen to stop. On the Baltimore & Ohio R. R. section foremen, track-walkers and other watchmen, pumpers and fuel keepers at pumping and fuel stations where there is no telegraph office, are instructed to assist in keeping trains the proper distance apart. When on duty they are expected to display a green signal when passenger trains are closer than ten minutes apart or freight trains closer than seven minutes apart. These signals, unless waved violently, are not intended to stop trains, but to notify the engineer that he is running too close.

The roadmaster's office, when sending out new train schedules, as changes in the same are made from time to time, should recall and destroy all the old ones, thus making sure that they will be no longer used by the employees through mistake or oversight. On some roads a blank form is supplied to each foreman or other employee to whom a train schedule is sent, on which he acknowledges receipt of the schedule, stating the time he understands it is to take effect.

160. Slides.—Slides are most liable to occur in the spring, just after or during the breaking up of winter, when the ground is loosened up by the departure of the frost. Whenever there is the least likelihood that a slide can reach the track at any place the train dispatcher should be notified and trains should be given orders to run slow by that point. Slow signals should be set at the proper distance, and in addition a watchman should patrol the track just ahead of every train, carrying a shovel, so as to be able to remove any slight obstruction. A "speeder" or railroad velocipede is a convenient aid for a watchman in case he has to look after slides separated some distance, as with such means of locomotion he can get over a good stretch of track in a short time. It is important, nevertheless, that trains should be run under control, because a slide is just as liable (and perhaps more liable) to come down while a train is passing as at any other time. This time of the year is when a foreman should be particularly on the alert, and the best service he can render is to keep his eyes open and take precaution. If there comes a sudden change in the weather and a thaw is about to start, he should drop what work he can, or get out of bed, if it be at night, and send reliable men over those parts of the track where there is any probability of trouble, going himself to the point where he has reason to think the greatest danger is.

Small slides of material so soft that it will not lie on the slope of the bank, but which will accumulate at the bottom sufficiently to fill the ditch and pile up against the rail, are bothersome, because every shovelful taken away only makes room for more to follow. When the ditch gets filled water is held, the effect of which is to soften the foot of the bank, which will then have a tendency to slide out and cover the track. If the ditch is at the foot of a high clay bank it is important to keep it open, because then the water from above may pass off without soaking through or into the foot of the bank, and if the foot can be kept from softening too much, the top, at the worst, can only slide over it and adjust itself to a suitable slope. The best way to keep a ditch open under such conditions is to take measures before it is filled. One method which may be followed is to drive stakes at the back side of the ditch, jabbing or picking the holes through the frost, as well as may be; and if the stakes cannot be set firmly enough to hold, the top of the stake may be braced with a leaning piece footing against the end of a tie. Behind these stakes plank or old ties may be piled, one on top of the other, to hold the loose material which slides down the slope of the bank. This piling up of the soft material gives to it an easier slope than that of the original bank, so that the tendency of the surface to slide is decreased and at the same time, while the sliding pressure is held by the stakes and braces at the bottom, the plastic material so held only serves to weight down the bottom of the slope the more firmly. In this way it is usually an easy matter to take care of what loose material comes over the top of the abutment and to keep the ditch open. Any clay bank may be expected to give trouble so long as its foot of slope is allowed to soak in standing water, and there is no use in clearing away slides with the expectation that the bank will finally take a slope and cease to give trouble; as long as the foot of slope remains unstable the onward movement of mud will be endless. If, however, the ditch can be kept open and the foot of the bank from sliding, there is some hope of bringing the trouble to an end. Another method of taking care of thin mud and keeping the ditch open is to clean out the ditch and cover it over with planks, allowing free passage for the water below. Old ties may be used as cross pieces and the planks may be laid close together, parallel with the track. The planks make a good bed to shovel upon, thus facilitating the removal of the mud, and the foot of slope is enabled to drain itself out. Sawed ties or old bridge timbers laid side by side across the ditch are also used in such places.

In springy cuts where the banks are of soft material some means of under drainage will serve to keep the slope surfaces dry and prevent small slides or "sloughing off." As elsewhere stated, tile drains laid diagonally down the slopes, at intervals, are sometimes used in places like this. Another plan is to lay blind drains of loose rock in the slopes at right angles to the track. These drains are sometimes made as large as 3 ft. wide and 4 ft. deep. They carry off the water and act as buttresses for the support of the slope.

Where heavier slides are threatening or have previously occurred, it may pay to drive a row of piles along the back side of the ditch or at the toe of the slope and back them up with planks or with a wall of old ties. This is a means of protection frequently employed. One of the most valuable lessons of track engineering is to see the need of adopting measures to avoid a repetition of trouble that occurred some year previous. In through clay cuts on some parts of the Canadian Pacific Ry., in the Selkirk mountains, it has been found necessary to drive rows of piles at 5 ft. centers at the back side of the ditch on both sides of the track. To prevent these piles from being crowded toward the track by the pressure of the sliding bank, the two rows are braced apart by log struts passing under the track. Eight feet outside each row at the ditch line there is another row of piles driven at 3 ft. centers and braced against the first row. These outside rows are backed by a wall of logs and the space behind is filled in with gravel, to facilitate drainage.

One way to quickly clear away a slide, if the surroundings are favorable, is to tie sticks of dynamite together and shoot them off. Large quantities of mud can be thrown out in this way, but the scheme works best where the explosives may be placed behind rocks or stumps that are mixed in with the soft material. A large rock may be broken up by placing a charge of dynamite on top of it, covering the charge with dirt or mud or with a smaller rock and then firing the charge. The material of slides has also been removed by hydraulic operations. At a point on the Southern Pacific road in northern California, in 1890, a slide 300 ft. high and containing 9000 cu. yds. of earth and slaty rock was removed from a cut in nine days in this manner. The water was conducted to the site of operations through a 12-in. lap-welded pipe laid in 30-ft. sections. Twelve pumps with a combined discharge capacity of 3300 gals. per min. were used, taking steam from the boilers of four locomotives on side-track The nozzle employed was 3 to 4 ins. in diam., according to the character of the material. The average discharge of water under a pressure of 45 to 50 lbs. per sq. in. was 2000 gals. per min., and the material was carried off in a sluiceway. The operating force consisted of 30 laborers besides eight firemen, machinists, pump repairers and experts to handle the hydraulic jets, at a total expense of $200 per day, including fuel, making the expense about 20 cents per yard of material removed.

About the quickest way to get trains past a big slide, where there is room, is to lay a new piece of track around it, close to the material which has slidden down, and then cut the old track, throw it over and connect it to the ends of the new piece. If the arrangement is to be only temporary and trains are to run at reduced speed past the slide, no great pains need be taken with the curves or with the surface of the stretch of new track. There is an advantage in this arrangement, in that the work train, by using the track between the regular trains, may be employed in getting the material out of the way. The track may be moved over as the slide is cleaned up, until the old track is uncovered. In some cases where a detour track is laid at a slide it pays to put the run-around in good surface and alignment and to wait awhile before attempting to clear away the slide. The material can be easier handled if allowed to dry out some, and as a rule not so much material will slide down if that which came first is allowed to lie until the ground settles a little. After the material has dried out it will usually pay to handle it with a steam shovel.

A cause of numerous accidents to train operation is falling rocks, which, like slides, are most liable to come down at the breaking up of winter. Thawing ground and hard rains will sometimes cause large rocks on steep mountain slopes to let loose and tumble onto the track with great force. The action of frost, the softening of rock by disintegration and the expansion of ice in crevices will also dislodge large masses from ledges or from the shattered sides of blasted rock cuts from which the loose pieces have not been carefully examined and removed at the time of construction. The sides of mountains and hills which rise at a steep incline from the track should be thoroughly hunted over for hanging rocks and loose boulders that are liable to roll down upon the track during some spell of bad weather. To protect the rails from damage when large rocks are blasted from or rolled down a mountain side, the track may be covered with old ties piled up to form an incline over the ditch on the hill side; or the rails in the path of the descending rock may be temporarily taken up during some favorable interval between trains, which would usually be found on Sunday. Near Crawford's Notch, on the Maine Central R. R., a large rock on a steep rocky slope has been chained fast to prevent it from rolling down upon the track.

161. Washouts.—Washouts, often less expected than slides, occur in times of high water, caused by sudden thawing, continued rains or cloud-bursts. A man on the ground can usually foretell a washout some time before it takes place, by the action of the rising water and the appearance of things in general. It is of utmost importance, then, that during the severest rain storms the foreman and his men should be out patrolling the track with the hand car, leaving a man supplied with signals to guard each place which seems to be threatened, and continuing the inspection until it covers the entire section. Should the track become impassable for trains the foreman will of course protect them with signals and then promptly notify the roadmaster and the trainmaster of the nature and the extent of the obstruction. Where proper vigilance is exercised by the track forces it is seldom that trains need be in danger of running into washouts, and great damage to the track can oftentimes be avoided. There have been instances almost without number when, if some man equipped with a shovel had happened along at any time during an interval of three or four hours, he could in a few minutes have turned the course of the water which later caused a bad washout. Trestles, bridge abutments and approaches; the roadbed at culverts, opposite old water courses down side-hill and along parallel streams (especially small streams) are the points most liable to damage by high water. At trestles or culverts over streams in which ice or flood trash is running men should be stationed with long poles to push obstructions clear of the bents or openings.

At the time of each flood foremen should take measurements from top of rail to the extreme high-water level and report the same to the roadmaster, with the number of the bridge or opening. Records of this kind should be kept in the roadmaster's office for future reference, being useful when the size of bridge or culvert openings must be decided upon. It is a good plan to make a permanent high-water mark at each opening, by driving a spike or chiseling a mark on the abutment masonry. At trestle bridges it is also useful to make float observations of the velocity of the stream, so as to obtain data for determining the volume of water passing, which may be needed at some future time when it is desired to fill in the trestle and contract the waterway. It is just as important to get such data at small streams as at large ones, and perhaps even more so.

In time of high water foremen should be vigilant to stop the progress of the water when it begins to cut the banks or the roadbed. Ditch water which starts to gully out or cut deeper should be particularly watched. A push car is a handy thing to have on hand at such times. A truck-load of material thrown into the right place at the right time may avert much damage. Tendency to cave or form gullies may be checked by the use of brush or old ties, or by throwing in riprap stone or bags of sand. When the water rises high and threatens to wash across the track and undermine it, the ballast may be protected by laying bags of sand on the upstream side, or planks may be placed along the edge of the ballast and secured to stakes to stop the wash of a side current. Where water of limited quantity is backed up against the track and threatens to rise over the top of rail it is well to spread the ties here and there and dig trenches to let it through, selecting places where the current is least likely to do damage. Backwater in which there is but little or no current may still do a great deal of damage if the wind begins to blow and dash waves against an embankment or the ballast. Means of protection above mentioned (sand bags or plank) may be employed in such places, and hay, straw or brush is sometimes thrown on the water to break the force of the waves.

When bridges or trestles have been carried away the rebuilding of the structures falls, of course, to the bridge department; and also when embankments are washed out for considerable distances or deep gullies are scooped out under the track, the bridge department is usually called upon to build temporary trestles, by driving piles or erecting framed bents, leaving the filling to be done afterwards. In such event the track department assists the bridge department by loading material, and on roads subject to washouts the roadmasters are provided with lists showing the number and size of the various pieces of timber required to build a span of trestle and lay the bridge floor thereon, so that when the roadmaster is called upon to load material it is only necessary to telegraph the number of bents or spans of trestle to be built. A pile driver having a 20-ft. extension, and capable of turning completely around on the car, so as to drive at any angle and straight in front without reference to the direction in which the car is headed, is recommended as the best machine for use in emergencies of this kind. The pile driver and the bridge outfit should be kept in good repair at all times and a supply of piles should be kept in stock whether there is work of this kind in sight or not. A pile-driver gang of 10 men, driving four piles to the bent, can complete 5 to 10 panels of bridge work in 10 hours of daylight and 3 to 5 panels at night, according to the conditions encountered. This estimate includes the bridge floor. Where the washout is a long one it is usual to put two pile drivers into service, working from both ends of the washout, or if only one machine is available and the work must be done in a hurry, a pile driver is worked at one end and the work of erecting framed bents is carried on from the other.

Another way of quickly throwing a bridge across a gap is by cribbing with logs, old timbers or new ties, spanning shallow streams, if necessary, with stringers laid upon cribbed piers. Where the current is swift the piers may be sunk and held in position by loading the crib with rocks, railroad iron or by sacks filled with sand or earth. The cribbing should be kept level as it is built up, selecting ties of equal thickness for the same course. Where it becomes necessary to make the crib or pier wider than the length of a tie a stronger structure may be had by building two piers together than by building the two separately. By laying two ties in each tier and forming the crib of several tiers each way, all built or bound together, a pier may be built up 30 ft., or even higher, quite substantially. If the bottom is soft the crib should be started on a floor of ties or timbers. Crib construction of considerable length or hight requires a good many ties, but with a train-load of ties on the spot a bridge can be put down in a hurry. On such occasions the work-train force is usually increased by all section men available, and if there is not opportunity for all of the men to work at the seat of trouble, part of them can be sent to load material. If there is not deep water to contend with and plenty of ties are on hand, a bridge can be built by cribbing more rapidly than by driving piles, since a larger number of men can be set to work. Sawed ties are best for this purpose. If the company's supply of ties is scattered along the road, the roadmaster should in such cases telegraph the track forces nearest them to begin loading without delay, using flat cars, box cars, or any other available empty cars, or cars that can be quickly unloaded, if necessary. It should be the understanding that if the foreman is pressed with damaged track about that time he may send a trusted man off the section to hire extra help and load the ties. The track department of a railroad ought to be so well organized that when things have to move all the roadmaster need do is to wire general instructions. If, however, the section foremen are customarily withheld from the exercise of authority in small matters somewhat aside from routine work, depending upon the roadmaster for instructions in full, the roadmaster in times of emergency will always have his hands full attending to details, and he will be greatly hampered in his attention to the work of chief importance.

Where an embankment has been side-washed, leaving some portion of the original embankment with the track overhanging, which is frequently the case where there are streams parallel with the track, there are several methods of putting the track into condition to carry the trains temporarily. One method is to level down the remaining portion of the bank, so as to fill the space washed out. The track is thus let down to a lower level, in a sag, and is later raised by degrees by unloading material at the side of the track, raising the track and placing the material thereunder, after the manner of ballasting. Another method is to throw the track over far enough to obtain a bearing the whole length of the ties and then to fill in the space washed out by dumping material from one side of the train, throwing the track back toward its original location as fast as the fill is made. This arrangement of throwing the track to one side is known as a "shoofly," and where there is a sufficient width of undisturbed bank, it is undoubtedly the best plan to follow. If the undisturbed portion of the bank is not wide enough at the top to support the ties their whole length it may work well to throw the track over and level down the bank deep enough to secure the proper width. Another method is to leave the track where it is and support the overhanging side by trestling. The stringers are placed upon caps which are supported on one side by the bank and on the other side by piles or posts driven or set in the space where the bank has been washed away. Where a post is used to support the outer end of the cap and the bank is not deep, it is usual to lay a longitudinal sill under the outside rail and set a plumb post, placing the cap on the post and digging out the bank so as to project the cap through for support on that side. Stringers are then placed under the outer rail, resting upon the cap, so that the embankment carries one side of the track and the stringers the other. If the embankment or space washed out is deep, a short sill is laid, running into the bank, and both a plumb post and batter post are set and sway-braced to the cap. By this method the track is carried at grade, on the old alignment, and the space washed out is later filled in with material brought by the work train. Where there is reason to fear that the portion of the bank which remains standing may not be able to support that side of the track it is well to reinforce the track ties

Fig. 470.—Surfacing Track over Shallow Washouts.

with switch ties 12 to 16 ft. long, placed 4 to 6 ft. apart between the track ties, one end of the switch tie resting upon the stringers and the other end upon a bed of track ties out on the embankment, thereby securing support for the track in case the bank underneath the track should cave or slide away. Where the top of an embankment has been washed off for a depth not exceeding 3 or 4 ft. the track surface may be evened up by cribbing and blocking with old ties, as illustrated in Fig. 470, utilizing pieces of plank and boards for shims.

For a very complete treatment of the subject of handling washouts with bridge forces, including the equipment of machinery, a list of the tools needed, the organization of the crew and the plan and procedure of the operations, the reader is referred to two reports on "Methods and Special Appliances Used for Building Temporary Trestles over Washouts and Burnouts," made to the Association of Railway Superintendents of Bridges and Buildings in the year 1895 by Mr. R. M. Peck, of the Missouri Pacific Ry., and Mr. Geo. J. Bishop, then superintendent of bridges and buildings for the Chicago, Rock Island & Pacific Ry. In order to show the practical application of methods of repairing track and bridges in time of washouts it may prove instructive to relate briefly the particulars of a general washout on the St Paul & Duluth R. R., in 1897, and the methods of work pursued in restoring the line to condition for temporary operation. A more complete account, with illustrations of interesting scenes at various points where damage was done, may be found in the Railway and Engineering Review of Sept. 11, 1897.

On the morning of July 3, about 3 o'clock, an unusually severe rain storm extended along the line of the road from Hinckley (76 miles north of St. Paul) to Duluth, centering in a cloud-burst at Mahtowa Station (43 miles north of Hinckley). The sudden and unprecedented downpour of water resulted in the Kettle river and its tributary stream, the Moose river, overflowing their banks and rising higher than any previous record had shown, and the culverts and other waterways through embankments, which had proven to be of ample capacity during 20 years of service, failed utterly to carry the large amount of surface water which flowed to them. At Rutledge (18 miles north of Hinckley) embankments, 15 ft. high, serving as approaches to a bridge of 125 ft. span crossing the Kettle river, were completely washed away, and at a point four miles farther north the earth approach to the bridge over Willow river was washed out for a distance of 200 ft. Eight miles farther north four bents of a trestle over Moose river were carried out. From this point north for 6 miles there was not a continuous mile of track that was passable. Stretch after stretch of gravel embankments 12 and 15 ft. high were washed out, leaving rails and ties suspended over gaps 200 to 300 ft. in length. At Barnum, 37 miles north of Hinckley, a 40-ft. through girder bridge over Moose river was carried away and the earth approaches for 300 ft. in length were washed out. From Barnum north to Duluth (39 miles) there were some 50 more washouts, varying in length from 10 to 300 ft. and from 2 to 40 ft. in depth.

As soon as the first reports were received, all the track and bridge forces available were mobilized in the vicinity of Mahtowa and work trains with material, men and pile driver were started north from St. Paul, getting 15 miles north of Rutledge by noon of July 3, the day of the storm. Two hours afterward the approaches at Rutledge went out, so that the trains were cut off from supplies, both north and south, and the work proceeded slowly and with great difficulty. The following methods were adopted for putting the track in temporary repair: In all washouts of 2 ft. or less depth ties, largely old ones picked up on the right of way, were laid under the track ties, two or three wide and a sufficient number in depth to make the necessary hight, plank being used to shim between the top layer and the track ties. Where the washouts were deeper than 2 ft., and up to 4 ft., two 12x12-in. timbers were placed at right angles to the track, 12 ins. apart; upon these were placed short blocks parallel with the track, and on these 12x12-in. caps, upon which stringers were placed, these bents being spaced about 12 ft. centers. In washouts of more than 4 ft. and up to 16 or 18 ft. depth, piers of heavy timbers and ties were built, 12 ft. apart, and stringers placed upon these carried the track. These piers were constructed with a base of not less than 12 ft. width, and wider than that where the hight required it. The first course of timber or ties was laid parallel to the rails and the next at right angles, and so on up, the several courses being drift-bolted together. No attempt was made to put the track on its original grade across the deep washouts: in such places the track on the embankments at each end was dropped down to make an easy run-off.

It was found that this class of work could be carried on rapidly. It required no dimension work or time to measure and frame timber, as would have been necessary in the construction of timber trestles. Many of these piers were built in running water 2 ft. deep. Piling was used only to cross swift running or deep water and in the washouts of 20 ft. depth or more. Gunny sacks filled with sand or earth were found to be effective in stopping and preventing the water from cutting into the embankments around culverts and abutments, and were used with success. On Thursday the 8th, at 6 a. m., the temporary repairs had been completed with the exception of the bridge over the Kettle river, where traffic had to be transferred pending the erection of a temporary pier of piles to support one end of the bridge, the masonry pier at that end having been undermined, when it settled, letting the span down 18 ins. and throwing it out of line. All of the temporary repairs were made with timber, no earth being handled except in leveling off for the timber foundations. As soon as the line was opened for traffic a steam shovel was started to work excavating material to fill around the many temporary structures, the caps and stringers being removed as the holes were filled up.

Bank Protection.—A railway which follows the course of a stream requires careful watching in time of high water, particularly where the roadbed slope extends to or into the stream. Where the stream bends toward the track in such places, or wherever the embankment slope is washed by the full force of the current, protective works are usually necessary to prevent the flood water from cutting away the earthwork and washing out the track. Protection is likewise required in many places on the slopes of embankment approaches to bridges at stream crossings, where the current at time of high water may strike behind the abutment with considerable force. The most substantial protection in all such places is a paved slope or slope wall starting on the hard bed of the stream or below the shifting material of the bottom. The Lehigh Valley R. R., where it follows the Susquehanna River, between Pittston and Sayre, Pa., is protected by a good many miles of very substantial construction of this class. This wall was built by the state to protect the Pennsylvania & New York canal, and the railroad was built on the tow path of the canal. Paved slope wall is, however, very expensive, and is seldom built these days. The means most largely used to protect embankments against the abrasion of stream currents, the wash of lakes, etc., is riprap, which is loose rock dumped or thrown over the slope to a depth varying from a mere covering to several feet, according to the force of the current. On bottom which is not subject to deep scouring little or no attention is paid to the foundation for riprap, except, perhaps, to gradually increase the thickness of the deposit toward the bottom of the slope, because if the water begins to cut under the toe or bottom the loose rock from above will tumble into the hole and stop the process. The effectiveness of riprap increases with length of slope or decrease in the inclination, and in recognition of this principle, specifications usually require that wherever the current may strike against the bank the latter shall be graded to a slope at least as easy as 2 to 1; or if the embankment has been finished to a steeper slope, the riprap shall be so placed that its upper slope shall be 2 to 1. In this same connection it is pertinent to remark that the resistance of an unprotected earth embankment to the action of flowing water improves with length of slope; this for the simple reason that where the material stands fully up to the natural angle of repose the slightest cutting action of the water will start the bank to caving, which loosens up the material so that the water makes short work with it; whereas, if the slope is easy the scouring action may go deep and far before the bank will begin to fall of its own weight. In turning a stream into a new channel the embankment across the old water course should be sloped off at least 2 to 1 on the stream side and well tramped down by team work.

Hand-laid riprap is work in which some of the stones are placed by hand, in order to make the covering of uniform thickness or to make the slope uniform. The necessity for hand work increases with the size of the stones. Some roads specify that riprap shall consist of stones generally as large as two men can handle, but much larger stones are frequently used as part of the material. Large pieces of rock should lie next the earth slope, and the foundation is usually started by digging a V-shaped trench to hold the stones at the foot of slope. If dumped over the bank too promiscuously many of the larger rocks will roll away from the slope or stand out where they will be easily dislodged by floating ice or drifting logs and trees. The best protection is obtained where the largest stones are in the bottom of the course, with the small stones chinked in between. It also effects a saving of material to pay some attention to the distribution of the stones over the slope. Where the slope is exposed to ice jams it is commonly the practice to throw in brush with the stones, to bind the riprap together. The butts are placed outward and downward in the stream. Where the current is too direct or too strong for heavy riprap to stand, as is frequently the case along rapid mountain streams, wing dams, rock-filled cribs or piles backed up by a wall of logs and trailing brush are commonly used to protect the banks from wash. Stone cribs are usually built up of logs or old bridge timbers notched into each other at the corners and drift-bolted. At intervals of 8 to 12 ft., according to the size of the logs and the force of the current, the outside walls are tied together by cross partitions of logs notched in between and drift-bolted to the longitudinal timbers. The empty crib is then filled with loose rock, and if it lies parallel with the bank the space behind is filled in with riprap. If it is not built up to the high-water mark it is made to serve as the foundation for a riprap slope. In the bend of a stream where the current strikes hard against the bank it is sometimes necessary to build wing dams or stone cribs extending diagonally into the stream, to turn the course of the water away from the shore. In such cases the bank behind the cribs is protected with riprap, and to prevent the water from cutting around the shore end of the crib the bank at that point is heavily riprapped or paved.

In order to withstand a heavy current, stone cribbing must have a good foundation, and such cannot be obtained on a sand or mud bottom. When built on such material the crib is liable to be undercut and roll into the stream. A good substitute on soft bottom is a bulkhead of piles driven 4 to 7 ft. apart and walled up behind with alternate layers of logs and brush, backed up with stone. The brush should be of large size, like the limbs of trees or small trees 3 or 4 ins. in diameter at the butt. These butt ends should be laid trailing to the current and project 4 or 5 ft. from the log wall, to guard the piles against driftwood and ice. The tops or branches lie in the space behind the log wall, which should be filled with stones as fast as the logs or large poles and the brush are laid up. To withstand the action of waves on a lake or ocean front, a type of pier construction consisting of two rows of piles with the space between filled in with stone, is commonly used. The piles are usually driven close together, but sometimes 2 to 3 ft. apart and walled up behind with timber. Along a stream, however, where there is a bank immediately behind the bulkhead, one row of piles with back filling is generally found to be sufficient.

On gravel or rock bottom the toe of riprapping will take care of itself, as already stated, but where there is some doubt about the stability of the foundation in the stream it is a good plan to cover the bottom with a layer of brush 12 or 18 ins. thick and 1 to 2 rods wide, and start the foot of the riprap slope on it. On the deep sandy bottoms of some of the rivers of the Mississippi valley, however, ordinary construction of this kind will not stand. These streams, and notably the Missouri river, among others, are continually changing their channels in many places, cutting away the banks on the outer side of the bends and forming sand bars next the bank on the inner side. During high water such changes take place very rapidly. The banks of the river, which are usually sand and silt, stand vertically 12 to 20 ft. in hight, and when a rise occurs in the river the scour at the foot of the bank undermines it and it caves into the river in slices of 5 to 10 ft. width. The saturation of the bank in nearness to the river is also another cause of failure, for if there be a stratum of quicksand it will run out when the water falls and cause the caving of an additional width of bank. Such caving of the banks is a constant menace to railway roadbed located in nearness thereto, and measures have to be taken

Fig. 471.—Weaving Mattress for Bank Protection, A., T. & S. F. Ry.

to protect the banks in order to save the roadbed from washout. The most successful protection as yet adopted is the use of woven brush mattresses, this being the standard form of protection used by the Missouri River Commission. Among other roads, the Atchison, Topeka & Santa Fe Ry. has done considerable work of this character. The protective structure consists of young willow and cottonwood saplings about 15 ft. long and 1½ or 2 ins. diameter at the butt, woven into a mattress about 12 ins. thick and usually 70 to 90 ft. wide. The willows are cut along the river shore, where they grow very thickly, in places, and hence long and straight, with but few branches. In preparation for the work a row of piles is driven along the river bank, a little below low water mark and 10 or 12 ft. apart. These piles serve as an anchorage for the mattress, which is woven on a flat boat (Fig. 471), on a triangular frame. The mattress is woven around the piles as the work proceeds and is slipped into the river by dropping the boat down stream. In weaving the mattress a wire cable of ⅜ in. diameter is woven in across the mat, opposite each pile, to which the cable is tied. Cables are also woven into the mat lengthwise, about

10 ft. apart, and at each intersection of the cross cables the two are fastened together, pulled up through the mat and made fast to a toggle consisting of a stick of cord-wood. After about 200 ft. of the mattress is woven, depending upon the depth of the water, the work of sinking it is begun, which is accomplished by wiring a row of large stones to the outer edge, and then following down stream with a boat-load of stones and dropping them upon the mattress. The stones used weigh from 20 to 60 lbs. each. After the mattress has been sunk the bank of the river is graded down to a slope of 2 horizontal to 1 vertical. This work is usually done by the use of a hydraulic jet operated from a pump on a flat-boat. After the grading is completed the bank is covered with riprap to a depth of about 18 ins. Figure 472 shows the completed revetment, and from the appearance of the trees in the background the reader will recognize the same stretch of river bank that is shown in Fig. 471, when the work was started.

Fig. 472.—Revetment Work by A. T. & S. F. Ry. (Progress View in Fig. 471).

The Chicago & Alton Ry. has done a considerable amount of revetment work of similar construction on the Missouri river, in the vicinity of Cambridge, Mo. At this place the first thing done was to grade down the bank hydraulically to a slope of 2 to 1 between the limits of 2 ft. above standard high water and 3 ft. below standard low water. At this place the mattress was woven of willow brush 1 to 2 ins. in diameter at the butt and 15 to 25 ft. in length. The mattress is 12 ins. thick and 86 ft. wide, and the inner edge extends to a contour line 3 ft. above standard low water and is tied at intervals of 16 ft. 8 ins. to dead men planted in the bank 8 ft. back from the top of slope. The mattress was woven with five lines of $\frac{3}{8}$-in. galvanized wire cable running longitudinally, each line consisting of two parts—one cable under the mattress and one on top; and at intervals of 16 ft. 8 ins. there are transverse cables running both under and over the mattress, these being the cables that are run to the dead men. While the mattress was being woven these crossed cables were held together at their intersections by wooden boxes 12 ins. square and 4 ft. long, open top and bottom and slotted at the corners, and after the brush had been woven around them the slack of the cables was pulled up with a set of blocks and falls and the crossed cables were fastened together with iron clips. The stones for sinking the mattress to the bed of the river weigh 100 to 200 lbs each, but as far as 3 ft. below standard low water the interstices of the mattress were filled with spawls. The slope of the bank from low-water mark to a contour 2 ft. above standard high water was then shingle-paved with one-man stone, which were generally delivered on wheelbarrows from a barge tied up alongside. The work of "paving," so-called, was started at the top of the slope and proceeded toward the water. In this way the stones lean against one another up hill, and thus slope away from the water, which is considered a more effective arrangement than where they slope toward the water, as is the case with paving that is started from the bottom of a slope. One paver with enough wheelers to keep him employed (usually seven) completed 1300 to 1400 sq. ft. of paving per day. After the paving was completed the crevices were filled and the top covered with a layer of spawls or crushed stone 2 ins. deep. In this work a mattress force of 33 men completed an average of 90 lineal ft. of mattress each day of ten hours. The force consisted of one foreman, 10 weavers, 10 brush passers, three laborers carrying the supply of brush from the barge, five laborers handling the cables, three laborers sinking dead men, and a water boy. The average cost of all work, including both labor and material for the mattress and the paving, was $746.62 per 100 ft. of bank protected.

Revetment work constructed as above described is found to be effective on the Missouri river, although failures have occurred where the current has flowed directly against the bank and proper care has not been taken to keep the slope patched up as damage has occurred. As the mattress never decays under water the protection of the bank against undermining is permanent. The problem of checking the cutting action of the stream is therefore that of keeping the upper part of the bank covered, which can be done by additions of stone from time to time.

162. Change of Line.—The engineering department of a road is sometimes called upon to improve stretches of the line by cutting down the grades, straightening out or eliminating curves here and there, or perhaps by moving the track out from the foot of a troublesome slide. Work of this nature arises most frequently on lines hastily built through hilly or mountainous country, where the development of traffic or a demand for increased speed of trains and heavier train loads in later years makes it incumbent or desirable to improve those portions of the road most difficult to operate or maintain. Methods of raising or lowering track in place are considered in connection with the subject of track elevation and depression, further along in this chapter, the object here being to take up methods of work involved in change of alignment.

Where the new roadbed is some distance from the old one it is customary to lay a piece of new track upon the new location and connect with the old track at the ends by cutting the old track and throwing it to the new alignment, when the time comes to make the change. If, however, the new location is near the old one and there is no serious obstruction between the two, the track may be moved over bodily to the new location, with less work than would be required to build it with new material or to take up and relay the old material. If the work is done in the right way, track handled in this manner need not be permanently impaired. In getting ready to move such a piece of track the ballast should be removed from between the ties as far as the shifted track is not thrown entirely off its bed, but not farther As such work offers a good opportunity for renewing the unsound ties, the spikes in all the worthless ties should be drawn before the shifting movement begins, thus leaving them lie in their beds and avoiding the handling of useless material. The sub-grade on the new location should be dressed off evenly, and if close by the old track it should be covered with ballast to such a depth that after the track is moved it will not require raising more than an inch or two to put it to final surface. Such preparation can be easily made if grade stakes are set to give the surface.

If the track is strongly embedded it should be lifted with a jack or lever before attempting to throw it; or it may be broken loose by having the men pry up the ends of the ties with their bars. A gang of at least 12 men is required to move a piece of track any considerable distance, and 15 or 20 men are none too many. There should be bars for all of the men. The practice of doubling up on the bars is hard on the bars and fatiguing on the men; the men discommode one another, they cannot exert their strength fully and easily, and much time is lost in getting ready for action, for one man must first plant the bar and then wait for his partner to get his feet adjusted between the ties and take hold. (The same objections apply to the practice of doubling the men on the bars when lining track in ordinary maintenance repairs). In order to make desirable progress on a big job it is necessary to have two or more gangs of men throwing on the track at the same time, one gang following up the other. In any case the track must be thrown by hitches, and it should be thrown each time as far as it will go without binding or springing back—usually not more than 2 ft., but depending to some extent on the number of men throwing on it and the manner in which they are distributed along it. If the track to be moved is straight and disconnected at both ends, the work of throwing may begin at either end; if connected at one end the throwing should first begin at that end. If the track is curved and is to be moved toward the outside of the curve, the throwing should begin at the disconnected end and progress toward the connected end; if the track is to be thrown toward the inside of the curve the throwing should begin at the connected end. In the last case it will help to keep the track from binding if the disconnected end is first thrown outward temporarily for some distance back from the end—that is, as though to straighten the track—in order that the middle portion may be more easily got even with the end. Where quite a long stretch of track is to be moved, it is best to let it remain connected at the ends and cut it loose in the middle, dropping a rail, or whatever length is necessary, in case the newly located line is shorter than the old one.

The length of rail necessary to make the connection after the track is thrown to the new alignment may be determined by calculation or by careful measurement with a steel tape. The best way to take this measurement is to set stakes on the line of the rails in the new position, using the surveyor's stakes on center line for a guide, and then take a measurement on the line of each rail separately. Unless the work is rushing, however, it is not worth while to bother about the connection until after the track is moved over, for it is a matter of but a few minutes to cut two pieces of rail to fit the opening; and the bolt holes at the joints may be drilled at any time after the connection is made. When cutting pieces of rail to make the connection, allowance should be made for closed joints, and joints pulled apart too widely, which will afterward need to be adjusted to proper opening. In case the excess of misadjustment is in joints pulled widely apart, it is only necessary to drive the rails together far enough back to make room for the connecting pieces, leaving the adjustment of the joints over the whole stretch to be made at any time after the connection is made. A good way to open the joints on a curve that is being lined in is to throw it a few inches past the center stakes in the rough lining, and then by moving it back to the stakes at the last, the track will stretch and pull the joints apart. It is just as well, also, to connect up temporarily with a pair of switch points and adjust the rails to their proper expansion openings before cutting pieces to fill the gaps. A great deal of work of the kind here considered must be done in gravel pits in order to move the track into the bank, after a cutting has been taken by a steam shovel or by a crew of men loading by hand, but in such places it is not necessary to go to much pains with the work, and the element of time is not so important as when moving main track.

In handling track in the manner described the ties must swing around askew to the rails, first one way and then the other, and by the

Fig. 472 A.—Throwing Track with a Lidgerwood Unloader; Before Pulling.

Fig. 472 B.—Throwing Track with a Lidgerwood Unloader; After Pulling.

time the track has been moved into its new position the ties will be out of square and need respacing; which can be easily done by two men working together, one on each side of the track, tapping the ties to proper position with hammers. In order to keep the ties properly spaced while track is being moved in short sections bodily (without bending), it is the practice with some to spike inch boards to the ties, parallel with, and outside of, the rails, but such an arrangement takes more time than is really gained, for it is an easy matter to tap the ties to their proper position with hammers after the track is thrown to its place. Where ballast is laid on the sub-grade before the track is thrown over, the track will usually be in condition to let trains pass slowly as soon as it is thrown approximately to line and connected, and the ties straightened, without doing any surfacing. Before the ties are ballasted they should all be placed squarely across the track, held up with bars and the spikes tightened down to the rail flange. On busy roads such pieces of work, if on main track, are usually done on Sunday. The train dispatcher should always be notified of the change, and trains should receive orders to slow up at the place until the track is safe for full speed. Slow flags or lanterns should be kept out until the track is in good running order.

In connection with the subject of transposing rails on curves mention was made of the practice of hauling strings of rails over the ties with a locomotive. The same method may be employed to haul a section of track endwise to a new position. The piece of track to be transported should be cut into sections as long as the locomotive can pull and then should be moved sidewise and thrown upon the track on which the locomotive is hauling. Attachment may be made by hooking a switch rope into a chain looped around both rails a little distance back from the end, with a strut placed between the rails to prevent them from being pulled together. The section of track is then hauled along on the rails, behind the locomotive, until it is opposite the point where it is to be used, when it may be moved sidewise off the track and thrown over to the new position. If only one section is to be hauled over the same track, the rails may be lubricated behind the locomotive. The occasion for work of this kind is sometimes met with in yards, and sometimes a switch lead or turnout is hauled in the same way. If the section of track or the turnout must be dragged over the ground, as for instance when hauling from a direction sidewise to the track, through a snatch block, a skidway of rails should be laid and lubricated with car oil. In order to prevent the ties from catching on the ends of the rails, the leaving end of each rail should be blocked an inch or two higher than the entering end of the next rail ahead. In some cases where track has been moved up or down a steep bank it was first cut into sections of four to six rail lengths each and one section was shifted at a time, over a skidway of rails, laying two skids for each rail length and hauling the section with switch ropes, through snatch blocks, or with block and tackle by the men. To stiffen the rails that are used for skids they are sometimes spiked to old trestle stringers.

For shifting track laterally to a lower level, in grade reduction work, the Grand Trunk Western Ry. has used a Lidgerwood unloader and cable, pulling down about 100 ft. of track at a time. In rear of the unloader car a flat car is coupled, and on the opposite side of this car from the track to be moved a snatch block is chained to a stake pocket to take the side pull of the cable attached to the track. To prevent kinking the rail where the cable is attached a piece of old rail about 10 ft. long is laid on the gage side of the near rail of the track to be pulled, and the cable is hooked around both. Figure 472A shows the cable attached and ready to pull, and Fig. 472B shows the same piece of track pulled down the bank. The track is usually moved in two hitches of 7 or 8 ft. laterally at a time. After pulling the track into the position shown, all the way through the cut, the unloader is then backed up and the track is pulled over to a level bearing and to its proper distance from the other track. The pulling can be regulated so closely that at this second movement the track is aligned sufficiently straight for the work trains, without the use of bars. This work of pulling track with an unloader is done very quickly, and at much less expense than by moving it with a gang of men throwing with bars. In fact, it is rather a difficult piece of work to throw track over the edge of a bank with bars, for after the ties begin to project over the slope the rail stands so high above the ground that the men cannot get a purchase with their bars. To throw a mile of track laterally and to a lower grade by hand labor requires the services of a large gang of men for a whole day, and the average expense on this road has been about $175 per mile. By using the unloader the track was shifted to place at an average cost of $43 per mile, the ordinary distance being 15 ft. laterally and an average of 10 ft. vertically. The time required to do the work in this manner averaged 7½ hours. The expense stated covers the use of the unloader, a locomotive and crew, four laborers and one foreman.

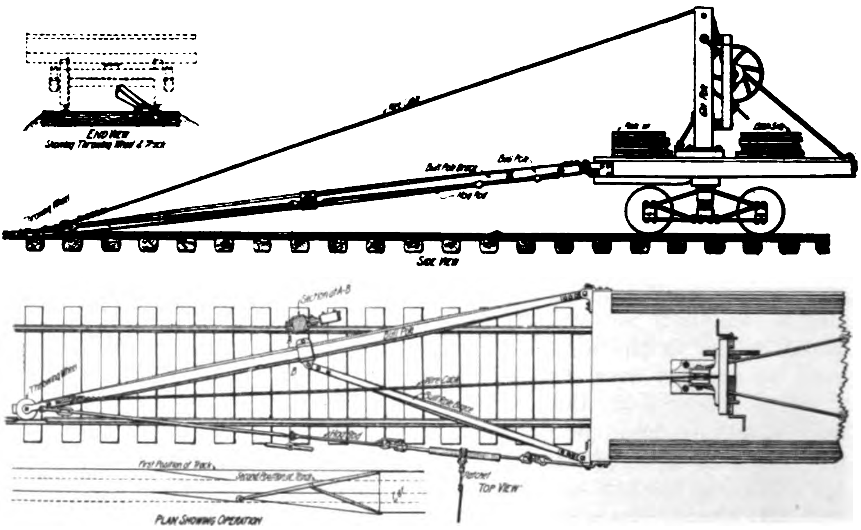

Fig. 473.—The Creese Track Thrower.

On the Pennsylvania and the Baltimore & Ohio Southwestern roads a machine has been used for throwing track in a general change of alignment, which employs the tractive force of a locomotive. The locomotive is coupled to a car provided with devices which exert a side thrust against the rail and shove the track out of alignment as the car is moved along, the operation resembling in some respects the trick of a snake when he crawls into a hole and closes the hole behind himself. The contrivance is known as the Creese track mover, being named after the inventor, Mr. D. C. Creese, formerly a carpenter foreman of the Pennsylvania R. R. The throwing arrangement consists in a stout pole 32 ft. long, known as the "bull pole," attached to a casting at the corner of a flat car and extending longitudinally in the track to exert pressure against the head of the rail through a 15-in. pulley at the end called the "throwing wheel." The general arrangement of the parts is shown in Fig. 473. This pole is braced about midway by a timber strut and stayed at the end by a 1½-in. "hog rod," adjustable by means of a ratchet pulling jack. Both the hog rod and bracing strut are attached to the opposite corner of the car from the bull pole connection, and the positions of the bull pole and its braces are reversible, making it possible to throw the track to either side, as desired. Before starting to throw track the ballast is removed from the ends of the ties, but not from between them, and a small section of the track is moved with bars in the usual manner. After this is done the pole is adjusted so as to crowd against the rail in its new position, and as the car is pulled forward or pushed backward by a locomotive the track is crowded over to its new position. At the rear end of the car there are two screw jacks, hinged to the decking, in position to be swung over between the end sill and the engine tender. Before starting to move track these jacks are screwed up, so as to stiffen the car against the tender. The car is also heavily loaded on either side with old rails, to give it stability. At the service end of the car a pulley is fixed at the top of a "gin pole" 9 ft. high, over which is passed a wire cable, worked by a crab on the gin pole, for raising the bull pole clear of the track when it is not in use.

On one occasion on the B. & O. S. W. R. R. a mile of track was thrown a lateral distance of 3 ft. with this car in three hours. The maximum movement was 20 ins., the car being hauled over the track two times at some points and three times at others. The cost of labor for the four men, and for the engine and crew operating it, was $17.50. On another occasion 2500 ft. of track was moved sidewise 11 ft. The minimum throw was 6 ins., the maximum throw 38 ins. at one time, and the track was moved over without taking out the ballast except at the ends of the ties. The time required to throw this length of track was four hours, and the cost, including the labor of four men, the engine and crew, was $16.00.

163. Policing.—Broken spikes, splice bars and bolts; castings, etc. dropped from trains; and other like material, should not be allowed to accumulate along the track, but should be picked up clean and carried to a scrap pile near the tool house. The best time to attend to such work is daily; for if a certain day is set for it each month it will either be forgotten or some other work will be on hand. In yards lumps of coal, pieces of car equipment, track material, etc., should be cleaned up each day, so that the yard may be kept clear and remove as far as possible from trainmen the danger of stumbling when getting on and off trains or when coupling or uncoupling cars. Whenever brake shoes, coupler parts or other pieces of car iron, or car doors, are seen lying in or near the track in going to work in the morning, the section crew should start early enough to have time to pick up such scrap material when homeward bound in the evening. Foremen should get the men into the habit of carrying to the hand car bits of iron and other scrap which may be found wherever work is being done. A good time to pick up scrap generally is during the winter, when the ground is bare, or in the spring, before the grass starts. At this time the right of way should be thoroughly cleared of all pieces of iron, old ties, large stones, lumps of coal and any other loose things which will hinder the mowing later in the season. A systematic way to do this is to divide the section crew each side of the track and walk over the right of way, clearing everything out of the way as the line advances, at the same time keeping the push car along to carry the scrap. Scrap which falls upon the track should be carried to small piles by the track-walkers. Freight dropped from cars should be taken to the nearest station and delivered to the agent, or shipped as marked, if there is no agent at a near station. At intervals of 60 or 90 days the scrap piles at the tool houses should be cleaned up and carried off by the work train or loaded onto a scrap car hauled by a local freight train. Work of the character here considered is commonly known as "policing." It includes a good deal of work not directly concerned in track surface or alignment or the safety of trains, but which nevertheless contributes toward general convenience and serves to preserve good order and a neat appearance in things generally along the line. Most of the duties coming under this description are elsewhere referred to, under one heading or another, so that it is not necessary to particularize to any great extent here.

Material lying along the track, such as lumber, ties, bridge timbers, etc., should be nicely piled, and proper clearance should be maintained, allowing no material to remain within 7 ft. of the rail on main track. The rules of some companies require a clearance of 8 ft., and some even 10 ft. from the rail, on main track, and as much as 6 or 7 ft. on side-tracks; on a few roads it is as small as 6 ft. for main track. The maximum out-to-out width of cars is about 10 ft. (the width of some furniture and Pullman cars will exceed this measurement by 2 or 3 ins.), so that the side of the car projects about 2½ ft. outside the track rail. To prevent injury to brakemen hanging from the sides of cars a clearance of 7 ft. is required. The rule requiring as much as 6 ft. clearance at loading tracks is continually transgressed and seldom strictly enforced. Such a rule puts shippers to great inconvenience, sometimes, and section foremen—who are supposed to see that the rule is complied with—must sometimes spend a great deal of time to little or no purpose trying to get shippers to observe the rule. If the required clearance on loading tracks was made 4 ft. there would still be 18 ins. of clear space outside of the widest car, and undoubtedly the rule would be more generally respected and heeded by shippers than a rule requiring clearance of 6 or 7 ft. Trainmen fully well understand that careless shippers will sometimes pile material dangerously near a loading track, despite the vigilance of the most alert section foreman, and therefore know what to expect in such places. In many cases the rules of the railway company are so unreasonable that shippers disregard them altogether and become very careless.

Section foremen are required to keep close watch for any encroachment on the company's right of way and to prevent adjoining landholders from erecting fences or buildings, altering ditches, obstructing culverts, piling material, building roads across the company's property or in any manner occupying the right of way without permission from the roadmaster or other official. Foremen should not permit fence wires or boards to be fastened to trestle posts or piles at waterways, as such will catch driftwood in time of flood, and might cause a washout. The piling of lumber, the erection of billboards, high board fences and like obstructions, and the planting of hedges, in the vicinity of grade highway crossings where they obstruct the view along the track, are a menace to highway travel and to train operation which should not only be forbidden on railway property but discouraged as much as possible on private land. In some locations it might pay railway companies to purchase lots and tear down buildings if by so doing a crossing watchman could be dispensed with. All trees, sound or unsound, liable to fall upon the track during storms should be cut down, whether on the right of way or private land. If permission to fell the trees cannot be obtained from the owners the foreman should consult the roadmaster. In some states railroad companies are permitted by law to condemn trees outside the right of way which endanger the track. It goes without saying that limbs of trees which obstruct trains or scratch paint from the cars should be trimmed or cut off. Foremen should promptly remove flood trash from bridge piers and abutments or trestle bents, and examine occasionally the sources of supply for water tanks or stations, clearing out accumulated leaves or drift of any kind tending to stop the intake. Culverts which have become partly filled should be cleaned out. Thick ice around bridge piling or small piers and abutments should be cut loose when thawing weather sets in.

Although the work of policing is important it is just as important that discrimination be exercised as to the amount of time devoted to it. Some men in authority are foolishly particular about the appearance of the track and seemingly ignorant about its real condition. On some of the most prosperous roads it may be well enough to spend time in cutting sod lines, scraping the ballast to a line on the shoulder and other fuss-work of like character, but on most roads the expenses of the track department are too closely scrutinized by the higher authorities to justify any such extravagance, and only such policing should be done as will serve some useful purpose, as already pointed out. Roadmasters should not fail to appreciate the foreman who keeps his track in smooth condition, even should his landscape gardening fall somewhat below standard, for there are trackmen who will spend time at cutting grass, picking stones and smoothing off the ballast when they should be surfacing the rails. As with useful men in all walks of life, the efficient trackman will not waste time on mere appearances.

The track forces should not be called upon to do puttering work around stations, such as making and attending to flower beds, mowing and watering lawns, scrubbing floors, cleaning outhouses, etc. Trackmen set at such work usually feel as though they ought to make the job last as long as possible, and agents or operators in charge at stations are not liable to discourage such inclination so long as the men will hang around (either at the stove or in the shade) and make themselves handy at doing chores. The readiness with which the foreman is generally expected to comply with requests to assist the agent might lead an outsider to think that track work proper is, after all, the matter of secondary consideration. It is clearly the duty of the track department to clean up the tracks around stations and loading platforms, but not the sweepings from the station. On any well regulated road the agent who would sweep dirt and rubbish upon the track would be expected to clean up his own muss. As for attending to the menial duties of the station agent no such practice should be permitted by the roadmaster. If clean floors and well-kept lawns at stations are advantageous to the transportation department, then that department should furnish its own labor to do such work, or authorize the agent to hire the necessary labor. On some roads the work required to maintain station buildings and grounds in neat appearance is performed by a floating gang of gardeners specially equipped for such service. Such a system is to be commended, for the practice of drawing men from the section for every odd piece of work performed on the company's property seriously handicaps the foreman in his appointed work. It may safely be stated that trackmen in general are required to do too much work which does not count on the track. Such work as the handling of heavy freight, assistance in car repairing, setting telegraph poles, stringing wires—and a good deal of it, too—often comes during that season of the year when track work of the greatest importance is pressing. If, then, under such circumstances the track gets down the roadmaster should not judge too harshly of the foreman. From all such work, as far as possible, the section forces should be excused; but if no other source can be called upon the foreman should be permitted to hire extra help afterward to make up for the time lost to the section; but even such an arrangement will not fully recompense the inconvenience of working the section short-handed at frequent intervals.

Aside from the plan of keeping the right of way in tidy condition as it is found, it will frequently work an advantage to improve the landscape. Much of the right of way that is turned over by the construction department is cut up with borrow pits and heaped with material wasted from cuts. A comparatively small amount of extra plowing and scraping, sometimes, will level down the most conspicuous of the high places, fill up unsightly hollows or round off abrupt changes in the surface, all to even better purpose than pleasing appearance. Elsewhere in this volume (under "Mowing," § 91) an instance is cited of the scheme of plowing, harrowing and seeding right of way, to put it into condition for machine mowing, at greatly reduced expense compared with hand labor. The substitution of a crop of grass for unsightly patches of weeds not only improves the looks of things but is an inducement for neighboring farmers to do the mowing without expense to the railway company. The sodding of slopes in cuts and on embankments is frequently a much needed protection to the earthwork.

The planting of trees along right of way for ornament has been occasionally proposed but seldom carried out. At least one case that is worthy of mention, however, is to be found along the "Old Road" (Michigan division) of the Lake Shore & Michigan Southern Ry., west of Adrian, Mich. In 1865 and 1866 European larches to the number of 16,000 and 20,000 chestnut trees were set out on this route, along both sides of the right of way, near the fences, about 50 ft. apart. The two kinds of trees were set generally alternating, a larch and then a chestnut. One object in this scheme was to stimulate the farmers to plant, but it appears that the example set by the railway company had but little influence. Most of these trees have thrived well. They have been trimmed to a stubby growth and have attained a good diameter, but many of the trees which have died out have not been replaced, which would seem to indicate that the practical results of the undertaking have perhaps not reached expectations.

164. Repairing Telegraph Wires.—Telegraph lines along railways are constructed and maintained either by the telegraph companies or by a special department of the railway company, and it is not intended here to enter into the subject of line construction and repair any further than to consider a few points with which the track department is most intimately concerned. Where the width of the right of way will permit, telegraph poles should be set so far from the track that they will not be liable to fall upon it in case they get broken off or pulled over during storms; this means a distance somewhat farther than the length of the pole out of the ground. The poles should be set to a good depth and the earth should be well tamped around them. A general rule for poles under 30 ft. long is to plant them one fifth of their length in the ground. The rules of the Western Union Telegraph Co. require that in earth excavation 25-ft. poles shall be set 5 ft. deep, 30 and 35-ft. poles 5½ ft. deep. the depth increasing 6 ins. for each additional 5 ft. up to a pole 60 ft.

long, which shall be set to a depth of 8 ft. In rock 25 and 30-ft. poles are set 4 and 4½ ft. deep, respectively. In soft material one-fourth part of coarse gravel or crushed rock is sometimes mixed with the dirt or sand to be filled in around the pole. Tools used in excavating holes for fence posts and telegraph poles are shown in Fig. 419. Engraving *C* shows a combined crow and digging bar, usually made in two sizes: octagon, 1 in. in diam., 7 ft. long, weighing 17 lbs.; and 1⅛-in. octagon 8 ft. long, weighing 28 lbs. Engraving *G* shows a combined digging and tamping bar made of either round or octagon steel, the size 1 in. in diam. and 7 ft. long weighing 19 lbs., and the size 1⅛ in. in diam. and 8 ft. long weighing 30 lbs. Spoons for excavating holes for telegraph poles have 6-ft., 7-ft. and 8-ft. handles, according to the general depth to which the poles are set. Engravings *B* and *D* show one style of blade and Engravings *F* and *H* another, the blade in the latter case being oval, 8½x10 ins. Tamping bars are made 8 ft. long, with either wooden or iron pipe handles, that shown as Engraving *A* having an ash handle shod with an iron tamping head.

The usual number of telegraph poles to the mile varies from 32 to 35, for an ordinary load of wires on straight line, to 40 poles on curves. The minimum length for telegraph poles has generally been 25 ft., but 20-ft. poles are being used to a considerable extent where not more than two cross arms are carried, as they are cheaper, are not subject to so much wind pressure and carry the stress from the wires better. In using poles of good length, however, there is the advantage that they may be cut off at the ground and reset when the buried part becomes decayed. It is desirable to keep the tops of the poles to an even grade, as nearly as may be practicable, and in order to do this some of the poles may be set a little deeper than others, using poles of extra length in the depressions. It is undesirable to have abrupt changes in the elevation of the line, for if an insulator pulls off or a tie wire breaks on the high pole the falling wire is likely to sag to the ground. Where there is a change in the hight of the poles or a sudden change in the topography it is well to make the difference in elevation gradually, by grading up or down, about 2 ft. to the pole. On curves the poles should be set up against the lateral stress of the wires sufficiently to prevent being pulled past the vertical position. Where there is a large number of wires in a curved line the lateral pull is usually counteracted either by bracing the poles with leaning posts or by setting the poles to rake or lean outward to the curve of the line. Poles that carry a good many wires around a sharp curve are sometimes raked 15 deg. or more, and on soft ground they are frequently guyed or braced besides. Where the line turns a corner or a considerable angle the pole should be braced or guyed. Wherever the line crosses the track the poles should be deeply set and well braced. On side hill the poles, if practicable, should be set on the down-hill side; otherwise they are liable to be carried toward the track by land slides or snow slides, by falling rocks, or by gravity, in case they become broken off or pulled over in time of storms. In districts where the heavy storms come always or nearly always from the same direction the poles should be set on the leeward side of the track, or the side "away from the wind;" otherwise, and no serious objections to the contrary, they are set on the side on which most of the stations stand, so that it will not be necessary to carry the line over the track.

Although linemen are employed to look after the telegraph lines of railways, yet it often happens that they cannot reach a break in the wires for some hours after it occurs; and as it is indispensable that the service of the wires be maintained as continuously as possible the section men should temporarily connect the wires whenever they find them parted. Lines running through woods are especially troublesome, owing to falling trees; but poles are struck by lightning occasionally and frozen sleet or high winds will break down the wires and break off or pull down poles carrying a heavy load of wires. In order to get the wire in working order it is only necessary to connect it and keep it off the ground. This can be done by pulling it so taut that it will hold itself up, or by stringing it along a fence or propping it on crotched sticks. An extra piece of wire is needed to tie a broken wire together, and, as a coil of wire is rather bulky and bothersome to carry every day on the hand car, coils of repair wire should be cached in places along the track, about a mile apart, known to all the hands; say near each mile post. When broken wires are found an endeavor should be made to connect each wire of the line and to keep the sagging wires apart. As soon as the wires are found down, a piece should be cut from one of the wires to tie up the rest, and while doing this two or three men may be sent with the hand car for wire to connect the line from which the piece was borrowed. In connecting wires temporarily on a curve they should be placed on the outside of the curve, so as to pull against the poles; otherwise, if they pull loose from their fastenings they might swing over to the track. The railway company's division wire—that is, the one used by the train dispatcher—should be known to the section men, and this wire, if down, should always receive first attention. No extra tools are needed for this work, as the wire has only to come in contact, and if twisted together with the hands it answers all purposes temporarily. For cutting the wire there will usually be a file on the hand car, or certainly a track chisel. Draw the wire across the edge of the chisel and strike the wire with a hammer, when it may be easily snapped in two. If no tools are at hand the wire should be twisted in two with the hands, so as to get at least one wire connected as soon as possible. After the wires are tied up the foreman should report the matter to headquarters as early as possible, stating the pole number, or just where the break exists, the number of poles broken or to be plumbed, and the number of insulators and cross arms broken, if any. If the wires are crossed, or in contact, and cannot be reached, the matter should be reported immediately to the nearest telegraph office.

Section foremen are usually instructed to trim trees which stand near telegraph lines, to prevent the branches from touching the wires when hard winds are blowing, and to inspect the line carefully after storms. Should section men or others sent to look for a break in the wires between two stations not find it on their section, they should either notify the men of the next section or else go on until the break is found, or until meeting repair men sent from the opposite direction. Wherever it is necessary to trim trees that stand on private property, such as shade trees or fruit trees, the aim should be to do the work in the spring, before the foliage starts, as permission can be most easily obtained at that time.

165. Disposition of Old Ties.—As an average for the whole country, about 400 old ties per mile are taken out of the track each year after the first five or six years from the time the track is built. About the best way to dispose of them on high fills is to let them slide endwise down the slope until they find a resting place. There they will be out of the way, will help hold the slope from sliding down, and, after rotting, will encourage the growth of brush, blackberry vines, and other vegetation, which is desirable on high fills or on steep side hill to hold the banks from being washed by rains. But in other places they are only in the way and must be disposed of at least cost, or to profit, when they can be put to some use. In summer, while busy renewing ties, section men have but little time to bother with old ties, except that they ought always to be trucked out of cuts within a day or so of the time they are removed from the track, and it is a good plan to take time at the end of each day's work to throw old ties into piles at convenient distances apart. Such clearing up adds much to the appearance of things, and where there is grass or weeds it facilitates mowing to have the old ties picked up. In this shape they are easiest disposed of.

In some localities old ties are eagerly sought for fuel, and people will often render some service in exchange for them. Of course the section men ought to have such things gratis. The foreman should require that all people who haul away old ties shall take them as they come, rotten ones with the rest, so that no further attention on his part need be paid to cleaning up. Old cedar ties or ties of other soft timber badly rail cut, but otherwise sound, are sometimes relaid in side-tracks, staggered, so that the cut portion does not come under the rail. Such old ties also make good fence posts. Redwood ties cut out in the tracks of the Southern Pacific Co., in California, have been sold for 15 cents each for this purpose. Old ties may be used for cribbing or walling up the foot of side-hill or embankment slopes. If the embankment is composed of gravel or other loose material a wall at the foot of the slope aids much in keeping the material from rolling down, or from being washed down by rains. Old ties can often be used to good advantage at washouts, as elsewhere explained, and wherever the condition of things is such that repair material is frequently in demand, a supply of them should be kept on hand at all times, at points convenient for loading. It is desirable to pile such material in places where it can be burned when it becomes too much decayed for service.

Old ties may also be used for building temporary loading platforms at side-tracks, for blocking freight on cars, at freight stations, for fuel at pumping stations and for locomotive kindling. Such fuel does not produce as much heat as cord wood, but it costs the company nothing except the cutting, and where wood is scarce and coal dear it undoubtedly pays to utilize old ties in this way. At Alliance, Ohio, the Pennsylvania Co. has a shearing machine for cutting and splitting old ties and other old timber into locomotive kindling. The machine shears the wood into blocks of any desired length, at the same time splitting the block into proper sizes for use. The capacity is about 10 cords of wood per hour. The Chicago, Burlington & Quincy Ry. also has, at its Western Avenue shops, in Chicago, a bulldozer machine for the same purpose. The machine has a vertical knife for cutting off and a horizontal one for splitting, and makes about eight strokes per minute. The power required to drive it is 15 h. p. Two men handle the ties at the machine, but when they are taken from a flat car an extra man is required to unload, and ordinarily two men remove the wood in wheelbarrows and pile it up. The total cost for unloading, cutting, splitting and piling is 37½ cents per cord, as against 78½ cents per cord when the ties were cut up with a circular saw and split with a pneumatic machine. At one time the engineering department in charge of the Toledo division of the Pennsylvania Lines West gathered statistics on the work of handling and cutting up old ties for locomotive kindling, to make a comparison with the cost of cord wood, which, in that locality, was quite "cheap." The report showed a slight difference in cost in favor of the old ties.

By winter time old ties which have been piled during the summer or fall will have become dry enough to burn, and all which cannot serve some useful purpose should be so disposed of. For kindling, a quantity of old waste may be picked up along the track and soaked with car oil or kerosene. Then during some forenoon when the wind is not blowing hard, preferably in damp weather or when the ground is covered with snow, the section men may go along and set fire to the heaps, placing a bunch of the oily waste in the bottom of each pile, at the windward end. An ax should be carried along to split off a little kindling where such is necessary to get the fire started. Then during the rest of the day the crew should be so divided that the men can come along about an hour apart to poke up the fire and throw together such piles as have fallen apart; thus done, there will usually be but little left of the old ties by the time the fire dies out. In this way the "picnic" of burning old ties need not last a week, as it often does where the whole crew is allowed to walk around together among a few piles, to visit and play with the fire. Of course due precaution and watchfulness must be exercised in setting fire to certain piles where the wind is liable to carry fire and damage fence or other property. Wherever convenient, in piling old ties, the pile should be made around a stump or old log on the right of way, so that both may be burned at the same time. After old ties have been burned the ash heaps should be poked over for spikes and stubs. When burning old ties it is a good plan to put all the old spikes on hand in the fire. In this way the grease and scaly rust are removed and cracks in defective spikes are shown up.

166. Taking Up Track.—The work of taking up abandoned track should be done according to some system, for, on general principles, every piece of material lost requires that the railway company must, in time, buy a piece to replace it. All the spikes should be pulled and put into boxes or kegs, and stubs of spikes, in ties sound enough to be used again, should be driven down. It is well to pull all the spikes before the rails are taken up, because if the spikes start hard the tie, without the weight of the rail to hold it down, may not lie firmly enough in its bed to admit of pulling the spike. The men should try to pull the spikes without bending them unnecessarily. Each pair of splices should be coupled together loosely with the same bolts that were used in them while in service, so that the bolts will not be lost. It is not worth the while to spend much time on nuts securely rusted fast to the bolts, because in many cases the bolt will twist in two before the nut will loosen. If the nut refuses to turn after exerting a reasonable amount of strength on it, time will be saved by knocking it off with a hammer. Where the track has not been much used the bolts are likely to be found somewhat rusted, and it is a good plan to squirt a little car oil on the thread of the bolt outside the nut; this will save time both in taking off the nut and in putting it on again. If the bolt sticks fast it should not be driven out, as such treatment may injure the thread, but the splices should be struck a side blow with a hammer, when usually both splices and all the bolts will come loose.

In taking up a piece of track of any considerable length, where the material must be loaded on cars from behind, there is more work than one might at first think. There must be a crew large enough to lift a rail and shove it onto the car—say at least 10 men—and then, since much time would be lost if the men were to stop work to shove the car ahead a rail or two at a time, it is cheaper to have a team to haul the car. An untrained team is sometimes not able to start a flat car after it is half loaded with rails, and must have the assistance of the crew, one or two of the men using pinch bars on the wheels. Under such circumstances it is best, when the car is once started, to haul it about 10 rail lengths before stopping, and then to use the team to drag the rails forward to the car for the men to load, beginning at the rear and hauling away as fast as the spikes are pulled and the splices taken off, so that as soon as the men are ready to load they will not have to wait on the team. If the ties are to be loaded two cars will be required, unless the disposition of the material will admit of piling the ties on top of the rails on each car. Three improvised stone sleds are a good means of conveyance. Part of the men may loosen the ties and load the sleds, and the other part load them onto the car, while the team hauls the empty and loaded sleds back and forth. The spikes, splices and bolts should be loaded on the same cars with the rails from which they were taken. A pair of splices coupled with bolts through two holes next one end, dropped straddle the side of a stake pocket, serves well for a car stake to hold the rails on the flat car. Pieces of rail too short to reach past three stakes should not be put on the outside of the car, lest the jarring of the car may cause them to shift endwise and fall off, between stakes. The foreman in charge should take note of the number of pieces of material put on each car. On a certain piece of work a gang of 10 men, with a team, took up and loaded 1200 ft. of track (2400 ft. of rails) without the ties per day of 10 hours. This figure is an average for the work of several weeks. The ties remained in place undisturbed and the rails and fastenings had to be loaded on cars hauled over the track which was being taken up, as the work progressed. The conditions were somewhat unfavorable, the claw bars being poor and the track slightly up grade, so that the men had to assist the team in moving the cars after they became half loaded.

Where the grade of the track is ascending appreciably a team and 10 men cannot move loaded cars to any advantage. In such case a work train is needed and, of course, it then pays to work a crew of good size. As it is both undesirable and costly to have to carry rails very far by hand, and as there would be insufficient room for a large crew to work when hauling the cars only a rail's length or two at a time, the most rapid method of taking up track with a work train and crew is about as follows: Pull the spikes from the rails, both sides, for 300 or 400 ft. at a stretch, without removing the bolts. Then throw each string of rails off the ties, cutting loose at the joint where the spike-pulling was dropped. By means of chain attach the two strings of rails to stake pockets at each side of the hind car, hooking the chain up short enough to hold the end of the rail off the ground. Then pull ahead with the train, dragging the rails along on the shoulders until the rear rail is opposite or past the end of the undisturbed track. Before pulling on the rails see that they are turned so that the nuts will not drag underneath. The whole string can be overturned easily by lifting simultaneously with several claw bars, catching the flange of the rail between the claws of the bar. While part of the men are taking off bolts the train can be backed up and the rest of the men can load the ties, which should be hauled ahead to the cars by team. Then, after the ties are loaded, the men should mass on the rails and pitch them on broadside as the flat car is hauled along opposite the spot where each rail is lying.

At one time the Flint & Pere Marquette R. R. (now Pere Marquette R. R.) had a piece of track to take up, and to avoid legal complications did it on Sunday. No spikes or bolts were loosened, nor was the dirt, which covered the ties badly in many cuts and at log railways, removed before the appointed day. In eight hours, between 8:20 a. m. and 5 p. m., one gang of 230 men took up and put over the end of the train the rails (56-lb.) on 6½ miles of track and two side-tracks. All frogs, switches, spikes, bolts and splices were picked up clean and loaded. No machinery was used, except some hastily constructed rollers on the cars and at the end to run the rails over.

In the work of improving the grades on the Wyoming division of the Union Pacific R. R., during the years 1899 and 1900, the company built 158 miles of new track on cut-off lines, saving 30.47 miles in distance and abandoning most of the old track. At the same time grades of 68 ft., 75 ft. and 98 ft. to the mile were reduced to a maximum of 43.3 ft. per mile, compensated (For a full account of this work, see the Railway and Engineering Review for Feb. 9, March 16, Aug. 10 and 17, 1901). In loading the material taken up on the abandoned tracks two methods were employed, one of them being novel and ingenious. On part of the track taken up the rails, ties, etc. were carried back from the rear of the train to the cars on which they were loaded by means of a Roberts track-laying machine operated in back motion (for description of this machine see § 30 and Fig. 35). The only modification necessary to adapt the machine to the work was to put live rollers on the tie extension of the "pioneer" car, which brought up the rear of the train. The train, in order from rear to front, consisted of pioneer car, two rail cars, locomotive, four tie cars, one box car and a caboose. Ahead of the train there was a gang of 12 to 20 men pulling spikes and removing splice bolts. All bolts except one were taken from each splice, and on tangent where the ties were in good condition the spikes were drawn from all ties except two under each rail. On the train and in the rear of it there was a gang of 42 to 44 men, distributed for the work as follows: Two men removing splices, 12 men pulling remaining spikes and lifting rails, 2 men gathering and carrying spikes, 12 men taking up ties, 4 to 6 men handling rails on the cars, 10 men handling ties on the cars. Working in this manner, the rails and ties had only to be lifted from the roadbed and placed on the rollways of the machine, which carried them forward to the cars whereon they were loaded. At the first side-track back of the point where the track was being taken up a gang was kept busy transferring rails and ties from the flat cars loaded by the machine, to stock, gondola and box cars, for shipment. Here all the ties were sorted into three grades: (1) good for main line; (2) good for side-track; (3) good for contractors' use in temporary lines on earthwork haul with light locomotives. The rails were sorted into three classes: (1) for relaying in main line and for use in important sidings; (2) for use in ordinary sidings; and (3) scrap. This transfer gang was also drawn upon for extra men needed at the front. When the work progressed continuously 6000 ft. of track could be taken up and loaded per day, but as cast iron pipe in culverts, telegraph poles, good timber from pile and framed trestles, and frequently fence posts and buildings, were loaded up and hauled away, the average daily progress was less than 4000 ft. of track taken up and loaded, including other material, as stated.

Although this method of handling the material was exceedingly convenient, and the only practicable one for rapid handling in localities where cuts and fills were numerous, yet on the plains, where teams could be used alongside the track, the latter was the more economical. As much of the track on the old location followed the surface closely there was a good deal of opportunity to use teams to advantage. The drawback with the machine loading was the necessity (for convenience of transportation) of transferring the rails and ties from the flat cars on which they were first loaded, to other cars; but for this the machine method would have been the more economical in all cases. As it was, the ties were hauled back by teams and loaded directly into box cars, sorting them as they were loaded. This gang had a flat car at the rear rigged with an extension over the center of the track, which carried a concave dolly about 2 ft. above top of rail, forming an incline on which the rails could be shoved up. Ahead of this car were the rail cars with dollies through the center, by which means the rails were sorted and shipped without transfer. Ahead of the rail cars were box cars for ties, then the engine and the caboose.

167. Purchasing and Handling Ties.—Ties bought at points along the road are usually delivered at side-tracks and piled up at the owner's risk until counted and accepted by the railway company. The piles should be made not nearer the track than 6 or 8 ft., according to the company's established rule for clearance in matters of this kind, and generally not farther from the track than 25 ft. The most convenient way of piling is to throw the ties together loosely, as cordwood is piled, about 4 ft. high, in piles not too long, leaving a space occasionally for walking through. This is about the way men will habitually pile them, because in such shape they are more conveniently handled over than when piled in square piles. For convenience in loading cars the ties should preferably be piled on ground not lower than the track. It is important to have the ties in the piles lie endwise to the direction of the prevailing winds, and off the ground, so as to get the best possible circulation of air for seasoning the timber quickly and for drying out the pile rapidly after rain storms. The best way to secure this arrangement is to lay in place for each pile two rows of old ties for a foundation. It is best to use old ties for these bottom rows, because they will not be taken up when the new ties are loaded, but will remain to invite later parties to pile their ties in the same place, thus securing an arrangement to suit the company without exacting any special requirements. Each kind of timber should be piled by itself. The foregoing covers about all the rules for piling ties that can be successfully exacted from the persons who have them to sell. After the ties have been handled over, inspected and counted, or while doing so, they should then be piled in the best manner for seasoning.

It is generally understood that ties season best when piled in square piles. One way of arranging them in such piles is in courses alternately parallel with and perpendicular to the line of the track. Ties sawed on four faces should be spaced an inch or two apart in each course, and the outside ties in each course may be turned on edge, so as to make an air space both over and under the intermediate ties of every course. This method applies to ties sawed on four faces but not to pole ties. The best way to pile pole ties, and in fact all ties, for that matter, is in layers of two one way, parallel with the prevailing winds, and eight the other way. Pole ties may be laid touching in each course or layer, but ties that are squared up on the sides should be separated by a little space, to allow for free circulation of air and evaporation. This method of piling is not so compact as the other and the winds have a better chance to blow through it. For convenience of handling, the piles should not be more than ten layers high, and the ties in the top layer should be laid close and sloping, so as to shed water. For convenience of inspection the piles should be separated by some little distance, and for fire protection and to make room for teams the rows of piles should be widely separated. Ties which have been floated down streams or which have lain in water for a considerable time should be stacked in a vertical position, to allow the water to drain out properly. Creosoted ties are more inflammable than the natural timber and should be piled well clear of buildings. In the dry regions of the West the top layer of tie piles along the right of way is covered with dirt, to protect them from catching fire from locomotive cinders.

Ties are generally bought according to specifications, and are counted by a tie inspector in the service of the railway company. He is supposed to see both faces of each tie its whole length, as the tie is rolled over before him and the party making the sale, and to pass upon the fitness of the tie as to size and quality. Ties smaller than the standard adopted by the company are thrown out as culls, and, if sound and not too small, are generally taken at a reduction—usually at half price. But it is not customary to accept a quantity of culls exceeding in number some certain fixed percentage of the whole number received. The railway company, drawing from its experience from year to year, determines upon what proportion of its ties in culls can be utilized in side-tracks. The acceptance of a reasonable number of culls is also in line with proper economy of timber, and should have some influence toward delaying a general advance in prices, as in this way much timber is utilized that might otherwise go to waste. After being sorted over the number in each pile should be counted carefully, marking the end of each tie with white chalk as it is counted. Both ends of each tie as it lies in the pile should then be spotted with white lead paint, to preclude any liability that the company will buy the same tie again, some time. First-class ties may be daubed with a single spot on the end and second-class ties with two spots. If two or more tie inspectors are employed on the same line they use paints of different color, white and red being preferred. After the ties have been counted the inspector gives the owner a receipt or voucher for the ties accepted, and at the same time makes out a report of the same which he forwards to headquarters that night. Really this report should be a duplicate, in facsimile, of the

Fig. 474.—Incline of Tie Hoist for Ohio River R. R., Ceredo, W. Va.

voucher given the owner of the ties, for which purpose a pocket duplicate or carbon copy book arranged with half the sheets perforated, so that they may be torn out, comes handy for the inspector's use. When large quantities of ties are bought at a distance they should by all means be made to pass inspection before being shipped. When purchasing sawed ties from saw mills, where the ties are loaded as they come from the saw, the inspector is usually required to be on the car, to see and pass upon each tie as it arrives. Unsound timber is much more generally found among sawed ties than among ordinary hewn ties, on account of the fact that they are usually made from larger trees.

Switch ties should, if anything, receive closer examination than cross ties of ordinary length, on account of the higher price paid for them and the desire that the timber should be of the soundest quality. It is not always possible to get from the same party ties of proper lengths to make complete sets of switch ties, and such as can be had are therefore paid for by the foot, stipulating that not more than a certain percentage of the whole will be accepted in any one length. It is not always customary with people selling switch ties to square up the ends until after the ties are inspected by the railway company, because the length which each piece will make may be affected by checks and other imperfections, which the inspector is supposed to look out for. It is usual for the owner to have men on hand with a crosscut saw ready to cut off each stick for all it will make, as allowed by the inspector.

Where the railway company's full supply of ties can generally be had along its own line it should be stated in advertising for ties that none will be accepted from any person who has not previously made known to the company the approximate number of ties he would like to furnish, and who has not received the company's assent thereto. With this understanding there need be no danger of having more ties hauled into the yards than the company cares to buy, as has been known to happen, sometimes, during occasional years of "hard times." Throughout the eastern or Atlantic states ties are usually hauled out to the track during the winter months and loaded onto cars and hauled away during the spring. But when ties are to remain in the yard for some time the piles, after being counted, should be rearranged in a manner to promote thorough seasoning and to diminish the risk from fire.

The tie inspector should be possessed of many good qualities. He should be a man of experience, having good knowledge and judgment of the kinds of timber suitable for ties. He must also have the personal qualities of quick decision, firmness and moral courage to a high degree. Upon his decisions hangs the expenditure of large sums of money for the better or worse of the company's interests. He should be strictly honest, and of good address; but above all he should be a total abstainer from intoxicating drinks, for, no matter how honest his purpose may be, if he will accept a "friendly" (?) drink now and then there will be lacking no effort on the part of some persons to get him into careless moods at convenient times. By checking reports of ties taken out of the yards with reports of purchases made by the inspector, it is possible to know pretty certainly whether the inspector's figures have been accurately made. If, therefore, he turns over to the company ties of a general good quality, and there stands against him nothing worse than such reports as might be expected from interested parties, the railway authorities should not be too ready to receive insinuations that he is unfit for the position. A man in such a position has sometimes a hard road to travel, and unless he is very agreeable and possessed of a good deal of tact he may not be able to maintain friendly relations with everybody.

In some quarters ties are brought to convenient loading points by rafting, or by "driving" them loosely in streams and catching them at the desired point with a boom. At some such places hoisting plants are installed to convey the ties from the stream to the cars. As an instance, the Ohio River R. R. receives a large portion of its tie supply at Ceredo, W. Va., on the Kanawha river. The ties are floated down the river and held in a boom under the railroad bridge, where they are taken off the hands of the tie men. To transport these ties to the company's cars with facility and economy there is a plant for hoisting the ties up the steep bank and to convey them along a platform extending between two side-tracks, from which the ties are put aboard the cars. The hoisting mechanism is a conveyor constructed with an endless roller chain carrying sharp spurs at intervals and running in a shallow trough. It consists of two sections, the first extending from the river to the top of the bank (Fig. 474), a distance of about 125 ft.; and the second, from the upper end of the first, a

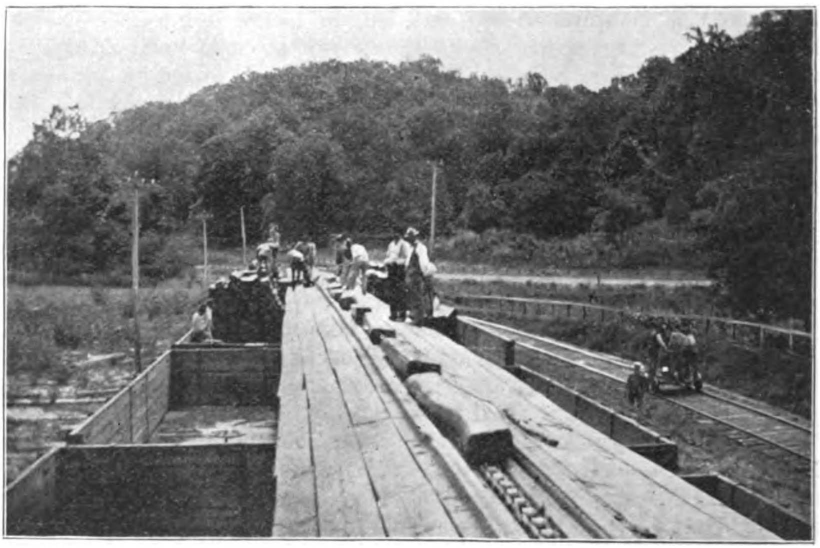

Fig. 475.—Loading Platform of Ceredo Tie Hoist, Ohio River R. R.

distance of 250 ft. on the level and between the tracks, as illustrated in Fig. 475. The foot of the incline hoist extends into the water a sufficient distance to admit of the floating ties being poled onto the moving chain. At either side of the chain runway there is a platform sloping toward, and projecting partly over, the cars, so that the ties are loaded onto the cars with but little effort. The chain runway is lined with strap iron to reduce the friction. The chain is usually run at a speed of about 100 ft. per minute, and is strong enough to carry a solid string of ties continually. It can, however, be speeded up to 150 ft. per minute, so that a capacity for carrying 800 or 900 ties per hour is possible. The power plant consists of a boiler and engine of 20 horse power. The Hocking Valley Ry., the Charleston, Clendennin & Sutton R. R. and the Kanawha & Michigan Ry. either have or have had similar plants.

168. Tie Preservation.—The increasing cost of timber, consequent upon the rapid destruction of the forests, has turned the attention of some railway companies toward timber preserving methods. It is estimated (1904) that upwards of 101 million ties are used annually for renewals by the steam railways of the United States, and 9 to 25 million more in new construction, and it is generally believed that consumption will soon overtake and exceed the supply of the diminishing forests. It has been proposed that to meet the situation railway companies should undertake tie cultivation by setting out forests of rapidly growing timber; or to relieve the annual demand, either by the use of metal ties or by preserving the timber by chemical treatment, or perhaps by both. The possibilities in tie cultivation have yet to be demonstrated, and although but relatively little has been done in timber preservation, in this country, yet the industry is considered as having progressed beyond the experimental stage. Such progress is not true of the metal tie, for, so far as American railways are concerned, it can hardly be considered that experimentation with metal ties has commenced with any degree of earnestness. Whatever tendency there is toward economy in the use of tie timber is therefore principally and almost entirely in the direction of chemical treatment.

Economy of Treated Ties.—Increase in the life of ties, obtainable within proper limits of expenditure, should operate to reduce the cost of track repairs in several ways. In the first place, the number of ties required for renewals within a considerable period is decreased in exact proportion to the increase in length of life; which carries with it, of course, a relative saving in labor for removing decayed ties. This saving is obviously greatest where the work of getting ties out of track, in renewals, is especially difficult and expensive, so that the logical procedure in beginning the use of treated ties is to first lay them under road crossings, in front of station platforms and in the middle or intermediate tracks of three and four-track lines, or wherever the main track is flanked on either side by a side-track. Since the renewing of ties always disturbs the surface of the track and impairs the bed more or less, it is readily seen that the cost of surfacing ought to decrease with increase in the life of the tie. More than this, many varieties of the cheaper woods are by preservative processes rendered available for tie timber where otherwise the life of the same would be too short for profitable use. This principle applies more especially to some of the soft woods requiring tie plates for the best results.

The money value of these advantages is readily calculable with close approximation except in the matter of diminished impairment of track surface. It is difficult to satisfactorily get at the ultimate cost of breaking up the embedment of ties in making renewals, but any trackman knows that it is an important item of maintenance expense. In renewing ties it is not practicable to at once get the new ties to take their proper share of the rail support. If the new tie is placed without dressing down the bed of the old tie the chances are that it will stand too high for some time, thus forming a "hump" in the track surface until the tie settles into the bed or until the rails cut into the tie to their proper level. If the bed of the old tie is dressed down it usually happens that the new tie will settle below the point where it can share in the rail support equally with the adjacent ties, thus throwing undue load upon the adjacent ties and eventually causing all to settle and impair the track surface. Again, in excavating the ballast to renew a tie the filling between the ties at that point is loosened up, thus impairing the surface drainage for the remainder of the season, so that during heavy showers or long-continued rain storms a disproportionate amount of water passes into the ballast and roadbed at such points. The ill effects resulting from such a condition are most readily perceptible in dirt-ballasted track, but in track well ballasted with better material, and well drained, it is not an unfamiliar sight in wet weather to find the ties "churning" at points where renewals have been made the same season. The fact that disturbance of filling and embedment in tie renewals is one of the principal causes of roughened track surface can be well established, but is perhaps not so forcibly apparent to all as it might be. That the degree of roughness in track surface produced by breaking up twice any assumed number of tie embedments per rail length is more than double that produced by disturbing only the given number, is too obvious to require detailed explanation.

So firmly am I convinced on these points that I would state my views of tie preservation economy in this way: Any preservative process which will double the natural life of the tie at a total cost for handling and treatment not exceeding the cost of the untreated tie—that is, doubling the life at an ultimate cost for the tie which is not more than double the first cost—is a paying proposition for any railway company. To double the life of the tie at an additional cost equal to first cost increases somewhat the direct money cost of the tie per annum, owing to interest on the extra investment, but against the interest charge there stands to the credit of the treated tie a reduction of half the expense of tie renewing, besides whatever saving accrues from the less frequent disturbance of tie embedment.

Let us take an example: Suppose that a pine tie costing 30 cents will last five years, and that by treating it at an additional cost (for handling, chemicals used, interest, depreciation of plant, etc.) of 30 cents the tie can be made to last 10 years. Looked at comparatively, the cost of the untreated tie will be 30 cents, plus 10 cents for putting it in the track, or 40 cents for five years' service, which is an average of 8 cents per year. The cost of 10 years' service for the treated tie will be 60 cents, plus 10 cents for putting it in the track, or 70 cents, which is an average of 7 cents per year—to which must be added a yearly interest charge on the additional investment of 30 cents. At 4 per cent this charge would be 1.2 cents, or a total average yearly cost for the treated tie of 8.2 cents, as against 8 cents for the untreated tie. Figured on this basis, 0.2 cent per tie per year, or a yearly cost of $5.60 to $6.00 per mile of track, is the price paid to avoid disturbing the embedment of all the ties once in 10 years. Expressed in another way, the advantage which accrues to stability of tie embedment and track surface by reducing the average tie renewals from one-fifth to one-tenth of the whole number each year, is secured at a yearly cost of five days' labor per mile of track.

That such is a favorable showing from the standpoint of economy, no one who understands how the conditions of rail support are affected by disturbing the embedment of the ties will be likely to dispute, but a simple calculation will remove any doubt. The average life of untreated ties of all kinds is about 6½ years, so that, on the average, something like 440 ties are removed from each mile of track each year. Assuming that chemical treatment will double the life of the ties—which, further along, is shown to be a fair estimate—the use of this agency will reduce the annual number of removals by 220. The cost of bar-tamping ties in gravel ballast, including digging out and filling in again, ranges from 2¼ to 6 cents each, according to the price of wages ($1.10 to $1.50 per day) and various conditions of the work, such as hight of lift or depth of open space under the ties, amount of material removed in opening out the ties for tamping, interference from trains, size and quality of the gravel etc.; but the average of a number of carefully kept records is 3.7 cents. In general practice new ties put into the track during renewals are either raised high and shovel tamped, or are bar tamped, at the time they are laid, and a few days later they receive another tamping with bars. On a large number of roads, however, perhaps the majority of heavy-traffic roads, it is considered necessary, in order to restore the original conditions of embedment, to give all new ties two extra tampings during the season of renewal. Where they do not receive this amount of extra work it is reasonable to suppose that the track surface will suffer in consequence. The advantage in reducing the number of tie renewals by 220 per mile per year is therefore an actual saving of from $8.14 to $16.28 of money that would otherwise be expended in tamping the new ties up to a proper bearing under the rails. This saving stands against the $5.60 or $6.00 representing, as above, the extra cost of treated over untreated ties, but the actual economy may be in much greater proportion, even if not calculable in dollars and cents, for there is no telling how much of the general work of track surfacing may be due to the settlement of old ties that are overburdened through lack of support from new ties lying adjacent. It is a matter of only ordinary experience to find new ties hanging by the spike heads, and particularly is this liable to be the case if there is a good deal of rain shortly after the ties have been placed. There are certain other indefinite advantages with the tie of long life, such as reduced wear and tear on rolling stock, due to the better average surface which results from the less frequent disturbance of the ballast.

Figured on the basis of a different financial system the showing is all the more favorable to the treated tie. The annual interest charge at 4 per cent on the amount necessary to purchase the untreated tie and place it in the track (40 cents) is 1.6 cents; and an outlay of 7.4 cents at the end of each year, if invested in a sinking fund, is sufficient to replace the tie in the track at the end of five years. The annual cost of the untreated tie is then $1.6+7.4=9$ cents. In the case of the treated tie the annual interest charge on the cost of placing it in the track (70 cents) is 2.8 cents, and the annual outlay toward a sinking fund sufficient to replace the tie in the track at the expiration of 10 years is 5.8 cents. The annual cost of the treated tie is thus seen to be $2.8+5.8$ cents$=8.6$ cents, or 0.4 cent in favor of the treated tie. Figured on either basis, higher first cost of tie, higher rate of interest or longer life for the untreated tie gives a less favorable showing for the treated tie. Thus, at a first cost of 40 cents, interest 5 per cent and a life of 6 and 12 years, respectively, for the untreated and the treated ties, the treated tie would cost 0.3 cent more yearly than the untreated tie; and at a first cost of 50 cents for the tie, interest 5 per cent and life of 6 and 12 years, the difference in favor of the untreated tie is 0.59 cent yearly—figured on the basis of borrowing the money to purchase the tie and to replace it by a sinking fund, in each case. From the standpoint of actual outlay, the economy is therefore greater the shorter the life of the untreated tie. Another way of looking at the question is to compare the ultimate costs of both kinds of ties for a term of years, adding compound interest. The total cost for an untreated tie costing 40 cents placed in the track and renewed at the end of 5 years, compound interest at 4 per cent, is $1.079 at the end of 10 years; and the total cost of the treated tie costing 70 cents placed in the track, interest compounded at the same rate, is $1.036 at the end of 10 years.

The foregoing discussion will serve to outline somewhat roughly the possibilities of tie preservation methods at an assumed increase of life of 100 per cent and a cost of treatment which is relatively high—an extreme case, so to speak. As a matter of fact, much better results than anything above calculated upon have been and are being obtained, so that in general cases there can be no doubt regarding the question of economy. This much further may be said regarding the general economy of tie preservation: Decrease in consumption of timber, due to increased life of preservative methods, ought to tend toward cheapening the first cost of ties, or at any rate to reduce the first cost to a figure far below what it would be were no efforts put forth to economize in the use of timber. A large percentage of the ties used are made from young timber, and by continually cutting out the younger trees for ties the growth of timber for other purposes is greatly hindered. If by preservative processes the life of the tie can be doubled, not only will the effect be to decrease in inverse ratio the rate of timber depletion, but also the saving of that much standing timber will enable the supply to more nearly keep pace with the demand. It must be apparent that the influence of such a saving on the timber supply of the country ought to be very great. The immediate result to the railway companies of such improved methods in the use of timber should be a two-fold economy, in that (besides the diminished consumption) by drawing less upon the timber supply the price of timber must inevitably be cheaper than it would be if the original rate of consumption was maintained.

Decay of Timber.—The natural decay of timber is caused by fungi, a vegetable growth consisting of innumerable microscopic plants, which consume the starchy matter in the wood and dissolve certain parts of the material which constitutes the cell walls or fiber. The fungi include a large group of a low order of leafless, colorless plants, the mycelia or thread-like sprouts of which penetrate the interior of the wood structure and excrete a ferment which dissolves certain constituents of the wood fiber to produce the food supply for the plant. The familiar punk and toadstools seen on trees and dead timber are the fruit of these fungi, and give off the minute germs or spores. The conditions essential to the germination and growth of these fungus threads are moisture, heat and the presence of air or oxygen. Regarding the condition last named it is generally known that timber which is continually submerged does not decay. Investigations of the Forestry Division of the U. S. Department of Agriculture show that wood containing less than ten per cent of moisture is not subject to decay. In respect to heat the fungoid growth requires moderate warmth, 40 to 120 deg. F. being the practical limits, and about 80 to 85 deg. the most favorable temperature. In a freezing temperature the fungi cease their activity and do not multiply, which accounts for the longer life of railway ties in cold climates. If, however, the temperature be raised to 150 deg. the fungi die, and in such temperature the wood, for the time being, is disinfected or sterilized. Thus it is that with many kinds of timber, if kept dry, the development of the fungi is extremely slow or absent entirely, for long periods, thereby insuring long life for the timber. But the condition most favorable to the growth and activity of the fungi is the fermentation of the sap. The sap of timber consists of water holding in solution quantities of sugar, albumen, starch, gums, oils, resins, acids, etc. When wood seasons the water in the sap evaporates, leaving the sugar, albumen etc., distributed through the pores of the wood in the solid condition. Of the substances named the most putrefiable is albumen, which is readily soluble in water. When moisture is taken into the wood the albumen goes into solution and sets up fermentation, induced by germs of fungi contained in the sap or in the knots of decayed limbs that have been closed over by the growth of the tree. If, however, the albumen is once coagulated it is afterward soluble only at high temperature and high pressure. The object aimed at in timber preserving processes is, therefore, to either coagulate the albumen or to remove the sap and replace it with some sterilizing agent.

The coagulation of the raw albumen may be effected by simply heating the timber, and such treatment is really all there is of one method of timber preservation, referred to further along. The simplest process for removing the sap is to soak the timber in water, preferably running water, for a considerable length of time. This process is known as "water seasoning," the theory being that the sap is diluted and gradually displaced—that is, removed by solution. This action is, of course, much accelerated by boiling or steeping the timber, but so far as actual practice is concerned neither method is employed to any considerable extent. A few experiments in "water seasoning" are said to have demonstrated the value of such treatment, and it is generally conceded, or at least generally supposed, that rafted lumber is more durable than lumber which has not been submerged in water. The method of removing the sap resorted to in general practice is to steam the timber in a closed retort, the consequent expansion of the cell walls driving out a portion of the liquid within the timber, and then to subject the timber to a vacuum, which causes it to expel the remaining portion. But while it is evident that the total or partial removal of the sap from the wood greatly retards decay, it is known that it only delays the progress of decay, for germs will enter the cells and propagate, in the presence of moisture, even if all the sap has been removed. To effectively preserve timber it therefore becomes necessary not only to remove the sap, but to sterilize the fiber against fungus growth by impregnating it with an antiseptic. The antiseptics most commonly used in this country are in the form of a vegetable oil or a metallic salt in solution, forced through the pores of the wood. The antiseptic would be proof against organic life, even if injected in the presence of the sap, providing thorough penetration could be had, but if the sap is not removed the entrance of any preserving solution through the cells of the wood is resisted by it, so that only shallow penetration into the wood can be had, thus leaving the interior still liable to decay.

Although many processes of preserving timber have been experimented with, in this and other countries, only four or five methods of treatment or combinations of the same have assumed commercial importance. The four principal methods are: (1) the vulcanizing process, (2) creosoting, (3) burnettizing, and (4) kyanizing. In Europe a fifth process, namely boucherizing, or impregnating with sulphate of copper, has been used to some extent, and a combination process known as the zinc-creosote treatment is also being used. Of these four processes only two have yet come to be recognized as practicable or profitable for extensive use, namely, creosoting and burnettizing. The former process, which consists in removing the sap from the wood and injecting into it creosote or dead oil of tar, is the more effective of the two, but the latter is the cheaper. It differs essentially from the former only in the liquid injected, which is the chloride of zinc ($Zn\ Cl_2$). Owing to the cheaper cost burnettizing has come to be much more extensively used in this country for tie preservation than creosoting, while for pile timber creosoting is used to the exclusion of the other, since under water zinc chloride is soon washed out. Creosote is also considered protection against sea worms, at least for a time, while burnettizing is not, although it is thought that if the chloride solution could be held in the timber it would be effective for this purpose; and a method intended to accomplish the retention is referred to further along.

Vulcanizing.—Vulcanizing, which is sometimes called the "roasting" process, consists in subjecting the timber to heat under pressure. It was invented by Mr. Samuel Haskin, and is sometimes also called "Haskin's process." The timber is run into a retort or long cylinder, which is then closed, and the first operation is to remove surplus moisture from the outside of the timber, due to casual exposure to rain or snow; but no attempt is made to expel the sap from the wood. The heat for this purpose is obtained by turning steam into a series of pipes. The air is first compressed to a pressure of 150 to 200 lbs. per sq. in. and then passed through a water separator, to remove the moisture, after which it is pumped through tubes heated by live steam and thence through a pipe system heated over a coke furnace, whereby its temperature is raised to 400 or 500 F. It is then delivered to the timber treating cylinders and kept in constant circulation by sending it in cycles through a circulating pump. The duration of this heating process is about eight hours. The cost of treating pine lumber is $8 to $10 per 1000 ft. B. M., and something more for hard wood. The cost of treating 6x8-in.x8 ft. pine ties is about 25 cents each. The process in this country has been worked by the New York Wood Vulcanizing Co., with a plant in New York City. In this plant there were four treating cylinders 6 ft. in diameter and 105 ft. long. In London, England, there is a plant worked by the Haskin Wood Vulcanizing Co.

The principal use of vulcanized wood in this country is for ties, guard timbers and planking in the floors of elevated railways. The Manhattan Elevated Ry., in New York; the Union Elevated Ry., in Brooklyn and the Northwestern Elevated R. R. in Chicago, are some of the roads using it. The timber that is generally used is southern yellow pine. Vulcanized ties and guard rails of this wood on the Manhattan Elevated Ry., in New York, have stood service longer than 17 years, but they showed signs of deterioration at that length of time. The life of untreated ties of the same kind of timber in the same service was six years.

The theory which is urged in support of the vulcanizing process is that the heat coagulates the albumen and the distillation of the sap transforms that liquid into various wood-preserving compounds, such as acids, wood creosote, etc., which are prevented from escaping from the wood by the pressure under which the treatment takes place. These substances finally solidify and seal up the pores of the wood. The pressure serves also to keep the wood from checking. The wood is therefore supposed to be impregnated with its own chemical products, or, as a German authority has said, "fried in its own fat." An analysis of a vulcanized oak tie, made at Columbia College some years ago, found that it contained 11.91 per cent of substances traceable to the action of high temperature on wood, including oils, turpentines, carbolic acid and resinous acids. Yellow pine timber treated by this process is said to have shown greater strength than before treatment. This view is supported by tests made at the Stevens Institute of Technology, Hoboken, N. J., in 1884 (See Railway Review, Feb. 21, 1891, page 123). This effect is due probably to the large amount of vegetable oil or pitch which, after distillation at the high temperature, solidifies and acts as a sort of filler between the fibers. On the other hand the claim that vulcanizing timber increases its strength is denied by some who profess to have made careful tests. One fault found with the process is that, however valuable may be the transformed liquid as an antiseptic, it is too thinly distributed throughout the timber to be highly effective; and another is that wood creosote, which is one of the important results of the process, is not an effective preservative of timber.

Creosoting.—Creosoting, as already stated, consists in impregnating the wood with a product obtained from the distillation of either wood or coal tar, called creosote. The coal-tar product is properly known as "dead oil of coal tar" and, strictly speaking, is not creosote, for creosote is a vegetable product and is not found in coal tar. Dead oil of coal tar contains a good deal of carbolic acid, and as creosote proper and carbolic acid resemble each other very much in smell, the two products are confounded by the commercial use of the same term for both. Among English-speaking engineers it is quite commonly the practice to refer to the two kinds of material as "coal-tar creosote" and "wood creosote." German experts usually observe the distinction and do not associate the term creosote with dead oil. Coal tar creosote distils at a temperature of 480 deg. F., contains naphthalene as its principal antiseptic element and is insoluble in water. Wood creosote is obtained from the destructive distillation of pine timber and contains paraffine as the principal antiseptic. Another important antiseptic property of both is due to the large percentage of carbolic acid contained. Dead oil is heavier than water, weighing about 8.8 lbs. per gallon, and before exposure it is colorless. The napthalene contained in dead oil melts at a temperature of 174 deg. F., and when once liquefied and entered within the wood cells it solidifies and becomes permanently fixed. Its specific gravity at the boiling point (212 to 220 F.) is 0.9778.

Creosoting is done in two different ways. In the Blythe process there are three stages: seasoning, extraction of sap and moisture, and the injection of oil. The ties, if not well seasoned, are sometimes kiln dried, so as to evaporate all moisture possible. They are then placed in large cylinders, to which live steam is admitted and held for several hours. The object of steaming is to liquefy the portions of the sap which have solidified during the process of seasoning. After the steam is let off the air is exhausted and a partial vacuum is maintained for a time, the result of which is that the moisture and the liquids formed by the steam in the interior of the timber are expelled and the delicate enclosures of the sap cells are broken down, clearing the way for ingress of the oil. While the vacuum is held heat is maintained by steam coils, to prevent the vapors from condensing and remaining in the timber. After the products of this treatment are drawn off the cylinder is then filled with the hot oil at about 175 deg. and held under pressure until the desired absorption has been obtained. In the Bethell process of treatment the oil is applied by pressure in the same manner but without previous steaming.

The details of the process as carried out at the works of the Southern Pacific Co., at Houston, Tex., are about as follows: The timber is run into a retort, which is then closed, and a vacuum of 22 to 24 ins. is set up and held about 10 minutes. Live steam is then turned in, destroying the vacuum and raising the temperature of the timber, and after 15 or 20 minutes another vacuum is pumped to open the pores of the wood. After holding the vacuum for 15 or 20 minutes live steam is again turned on and the pressure held for 6 to 8 hours, care being taken not to permit the temperature to exceed 250 deg. F. After blowing off the steam a vacuum of 24 to 26 ins. is again set up, the timber and retort meanwhile being held at a temperature of 225 deg. by a heating process. This (third) vacuum is maintained from four to six hours, after which the expelled liquids are drawn off and the cylinders are filled with creosote oil at a temperature of about 170 deg (to make it sufficiently fluid to enter the wood), when the pumps are again started and the pressure is raised to 80 or 100 lbs. per sq. in. and maintained from one to two hours, according to the quality of the timber. The average time of treatment is from 18 to 20 hours and the average absorption 1.2 gallons or about 10½ lbs. of creosote per cubic foot. The average cost of treatment has been as low as $10.23 per 1000 ft. B. M., for a year's work. Of this amount $8.26 represented the cost of the creosote oil, $1.23 the cost for labor, 59 cents the cost of the fuel and 15 cents the maintenance of the plant. At the works of the Norfolk Creosoting Co., Norfolk, Va., the timber is first subjected to the action of live steam for five to seven hours at a pressure of 35 to 55 lbs. per sq. in., the temperature not to exceed 275 deg. F. unless the timber is water soaked, in which case it may be permitted to reach 285 F. for the first half of the period. At the expiration of the steaming the chamber is emptied of sap and water and a vacuum of at least 20 ins. is set up and maintained at a temperature of 100 to 130 F. for a period of from five to eight hours, or until the discharge from the vacuum pump indicates, by absence of odor and taste, that the timber has ceased to expel sap. The chamber is again emptied of sap and water and the oil is admitted and pumped to such a pressure as will cause the absorption of the desired quantity per cubic foot or the desired depth of penetration into round timber, as computed from the readings of the measuring gages.

Creosoting is conceded to be the most effective of all timber treating processes. It is the process almost universally used in France, and in England it is more extensively used than any other. Creosoted beech ties on the Northern Ry. of France have an average life of 27 years in main track, and then the best of the ties removed in renewing out of face are used in side-tracks seven or eight years longer. On the Houston & Texas Central R. R. 70 per cent of a number of loblolly pine pole ties (natural life six years) laid in the Houston yard in 1874 were still in service after 26 years, the ties which had been taken out having been removed on account of rail cutting. Of 3000 creosoted ties of the same kind of timber placed in the track on the Houston prairie in 1880, 71.6 per cent were still in the track after 17 years, although many of them were more or less badly rail cut. By protecting these with tie plates nearly all were still in service after 22 years. In this track the gravel ballast was filled in to completely cover the ties. These ties were treated with imported material, and the results have been more satisfactory than those obtainable from the use of domestic creosote.

As to the relative merits of dead oil and wood creosote, the former is much the more efficient as an antiseptic and is always preferred in first-class work. Wood creosote is cheaper than dead oil and less dense. The weight of authority seems to establish that wood creosote is soluble in water and that paraffine, its principal constituent, is not an effective preservative of timber. It is usually specified that to exert the best antiseptic qualities, dead oil should contain no water or ammonia, or ingredients soluble in water; that it must be free from tar; that it should be completely liquid at 100 deg. F. According to German authorities, the oils found to be most desirable in oil of tar are those which boil at medium temperatures, as those which boil at low temperatures are too volatile for retention, and also too costly for the purpose, while those which boil at the higher temperatures are too heavy for effective penetration. The latter contain too much solid matter, or substances which harden upon the penetration of the solution into the cooler parts of the interior of the tie, thus obstructing the pores of the wood before its impregnation is complete. It therefore becomes important to remove from the creosote both the lightest and the heaviest oils, in order to retain the medium ones. The weight of the oil at 59 F. may not be less than 8.69 lbs. per gallon.

and not above 9.15 lbs. per gallon; that is, its specific gravity must lie between 1.045 and 1.10. Some of the German railway specifications require that it must not contain to exceed one per cent of lightly volatile oils which boil at a temperature lower than 257 F. Of the remaining constituents at least 75 per cent of the oils shall boil between 455 and 752 F. Twenty-four per cent at the most may boil at temperatures between 302 and 455 F.

Respecting the chief antiseptic property of creosote, experts are not entirely in agreement. The Germans seem to lay great stress upon the component carbolic acid in dead oil; in fact "oil of tar containing carbolic acid" is the term in common usage to denote the article of most approved quality. The specifications of the Prussian State Railways require that at least 10 per cent of the constituents of oil of tar must be oils of the carbolic acid type, dissolving in caustic soda lye of 1.15 specfic gravity. The constituent naphthalene of coal-tar creosote is seldom contained in quantities less than 5 per cent, and sometimes as large as 10 per cent and over, in the original tar, according to the graduation of the temperature in the production of the tar. According to the German view the antiseptic property of naphthalene resides in the fact that after the ties have become cooled it crystallizes and contributes toward the obstruction of the cells, thus preventing the escape of the volatile parts of the creosote and the entrance of moisture and fungi. If present in considerable quantity, however, it may prevent the entrance into the cells of the wood of the heavy oils of the creosote, and for this reason it is desired that the oil of tar shall be "as free as possible from naphthalene," and that, in any event, it be excluded to the point where none shall be precipitated at a temperature of 59 F. If such condition is not obtained the naphthalene will affect the fluidity of the creosote at this temperature. On the other hand some American authorities regard the naphthalene compounds, which occur in commercial dead oil of coal tar to the extent of from 30 to 60 per cent, by weight, as among the most effective constituents of the antiseptic, and consider that carbolic acid is unstable and too volatile at ordinary temperatures to be so classed. Naphthalene is insoluble in cold water, only slightly so in hot water, and at normal temperatures is only slightly volatile. The pyridine and the quinoline series and anthracene are other insoluble and non-volatile compounds that are classed among the most important antiseptic constituents. By way of contrast, the specification for creosoted timber of the Norfolk Creosoting Co. requires that the dead oil of coal tar must be fluid at 118 deg. F., the limits of the specific gravity are 1.015 and 1.05, the yield of naphthalene at a temperature of 410 to 470 deg. F. must be 40 to 60 per cent by volume, and the dead oil must not contain more than 5 per cent of carbolic acid. The specifications of the Southern Pacific Co. require that the material must be completely liquid at 100 deg. F. and contain 20 to 30 per cent of naphthalene.

The quantity of creosote injected is usually 10 to 12 lbs. per cubic foot for pine ties and 16 to 24 lbs. per cu. ft. for pine pile timber. Beech will readily take in 15 lbs. per cu. ft., but oak under similar conditions absorbs only about 4½ lbs. per cu ft. In England Baltic pine ties 5x10 ins.x8 ft. 11 ins. long are injected with 28 to 30 lbs. of creosote, at a cost of 25 to 30 cents each, and last about 16 years under heavy traffic. In France beech and other ties of the most perishable woods are injected with 60 lbs. of creosote, at a cost of about 65 cents per tie, and last 25 to 30 years. In the United States the creosoting process has, on account of its high cost, been applied to tie treatment but very little, although for piling and timbers used in wharves, piers and other structures subject to destruction by marine life it has been used extensively. On bridge timbers creosote is sometimes applied with a brush, three applications being made. The penetration is said to be sufficient to preserve the outer portion of the timber and equalize the life of all parts. For instance, where timber joins timber the fiber about the joint decays much sooner than parts of the timber not in contact. In some cases the caps and sills of trestle bents are preserved, while the posts are not, since the horizontal members are the most difficult of removal in making repairs.

Burnettizing.—The process most extensively employed for treating ties in this country has been the zinc chloride or burnettizing process, so named from Sir William Burnett, the inventor. The first roads to take it up were the Atchison, Topeka & Santa Fe (in 1885); the Union Pacific and the Chicago, Rock Island & Pacific (in 1886); and the Southern Pacific (in 1887). The process consists in subjecting the ties alternately to live steam and vacuum, to liquefy and extract the sap, and then to fill the treating cylinder with the zinc chloride solution and apply pressure to force it into the wood. The zinc-tannin or Wellhouse process is the same with the addition of glue and tannin, explained more in detail further along. The first plant built in this country for working the zinc chloride process was that of the Atchison, Topeka & Santa Fe Ry., at Las Vegas, N. M., in 1885. This plant was at first equipped with two retorts 6 ft. in diam. and 106 ft. long, and in 1896 the plant was enlarged by the addition of a third retort. This plant operates on mountain pine ties costing about 30 cents each. The cost of treatment by the zinc-tannin process has varied, during the years since the plant was built, from 15 to 11.8 cents per tie—for chemicals, fuel, labor and ordinary repairs to plant, interest and depreciation not included. The amount of dry chloride injected has varied, in the different years, from 0.28 to 0.47 lb. per cubic foot of timber. On the Union Pacific R. R. a plant was erected at Laramie, Wyo., in 1886, which was operated about two years, the product of the works being 242,000 ties treated by the zinc-tannin process. This plant had two retorts. It was closed during a period of financial stringency and later burned down and was not rebuilt. The plant of the Chicago Tie Preserving Co., in Chicago, was built in 1886, being equipped at first with two retorts. A third retort was added in 1891 and a fourth in 1894. This plant has been operated mainly on ties used by the Chicago, Rock Island & Pacific Ry. The process worked has been the zinc-tannin, at a contract price of about 16 cents per tie, and the ties treated have been principally hemlock, with some tamarack.

A plant for the Houston & Texas Central R. R. was constructed at Houston, Tex., in 1887, and for some years ties were burnettized at this plant for the Southern Pacific road. In 1891 the Southern Pacific Co. built a plant of its own near Houston, equipped with two cylinders, each 6 ft. in diam. and 112 ft. long, and another 5 ft. diam. and 109 ft. long, open at both ends, with narrow-gage tracks running entirely through the cylinders. At one end of the cylinders there is a yard containing untreated material and at the other end a yard in which the ties are piled after being put through the preserving process. In both yards there are steam traveling derricks. The kinds of wood treated are long-leaf and short-leaf yellow pine, from eastern Texas and western Louisiana, the natural life when used as ties being only three to four years. For preserving ties the chloride of zinc process is used and for bridge ties, timbers and piles the timber is creosoted. This company has also a portable plant, built in 1894, for the Pacific system of the road, which is operated alternately in California and

Oregon, being moved from point to point and set up on side-tracks specially prepared, it being cheaper to move the plant than to transport the ties several hundred miles to and from a stationary one. This outfit is equipped with two cylindrical retorts 6 ft. diam. and 114 ft. long, mounted on car trucks and provided with the necessary auxiliaries, such as boilers for steaming, air pumps, solution tanks, etc.; which are mounted on flat cars, the combined outfit forming a train of about eight cars. The arrangements for setting up the plant are so well planned that the expense of handling is reduced to a minimum. The two cylindrical retorts are run end foremost against a raised platform, so that ties can be run into and out of them on small trucks using a track inside the retort. About 2500 ties, in five charges, can be treated in 24 hours. California mountain pine and spruce, and Oregon fir are the timbers treated. The plant is also adaptive to creosoting either ties or long pile timbers, without any change in apparatus. The entire cost for materials, fuel, labor for operating and ordinary repairs to plant, for burnettizing with this plant has been as low as 8 cents each for soft-wood ties 7x8 ins.x8 ft. A reasonable estimate of the interest charge and an allowance for depreciation of equipment would probably have raised the cost to 10 cents per tie. The cost for burnettizing 6x8-in.x8-ft. yellow pine ties at the Houston plant has been as low as 6.44 cents per tie, for a year's work. The items of this cost were as follows: zinc chloride, 2.54 cents; fuel, 1.04 cents; labor, 2.63 cents; maintenance 0.23 cent.

After the treating of ties was started in this country, in 1885, progress in the development of the industry during the 12 succeeding years was slow, the A., T. & S. F., the C., R. I. & P. and the Southern Pacific being the only roads to take up the work on a considerable scale; but in the five-year period beginning with 1897 the number of plants was largely increased, being built either for, or to be used for, the following roads, at the places named: The Gulf, Colorado & Santa Fe Ry., at Somerville, Tex.; a second plant for the A., T. & S. F. Ry., at Bellemont, Ariz.; the Burlington & Missouri River R. R., at Edgemont, S. Dak., later removed to Sheridan, Wyo.; the Chicago & Eastern Illinois R. R., portable plant; the Great Northern Ry., at Kalispell, Mont.; the Missouri, Kansas & Texas Ry., at Greenville, Tex.; the Chicago, Rock Island & Texas Ry., at Alamogordo, N. Mex.; the Union Pacific R. R., portable plant; the Oregon Short Line R. R., portable plant; the Illinois Central R. R., at Carbondale, Ill.; the Mexican Central Ry., at Aguascalientes, Mex. At the works of the International Creosoting and Construction Co., in Beaumont, Tex., ties have been treated by the Wellhouse process for the Mexican Central and the Hutchinson & Southern (A., T. & S. F. system) roads. It is thus seen that west of Chicago the tie preserving business has become well established. The Southern Pacific, the Atchison, Topeka & Santa Fe, the Burlington & Missouri River and the Illinois Central roads use the straight burnettizing or zinc chloride process and the other roads named use the Wellhouse or zinc-tannin process. The engineers who have been most prominently connected with the development of the Burnett and Wellhouse processes in this country are the late Joseph P. Card, Mr. Octave Chanute and Samuel M. Rowe.

One of the largest tie treating plants in this country is that of the Texas Tie & Lumber Preserving Co., on the Gulf, Colorado & Santa Fe Ry., at Somerville, Tex. This plant was erected in 1897, with four retorts, and later the capacity was increased by two additional retorts and a chloride solution tank. The plant was built for treating ties, piling and other structural timber, and comprises all of the appliances essential for burnettizing and creosoting. On general principles the machinery and its arrangement are the same as in other plants constructed for the same purpose, the similarity in all respects being close except in some minor details, so that a description of this plant and its operation will answer

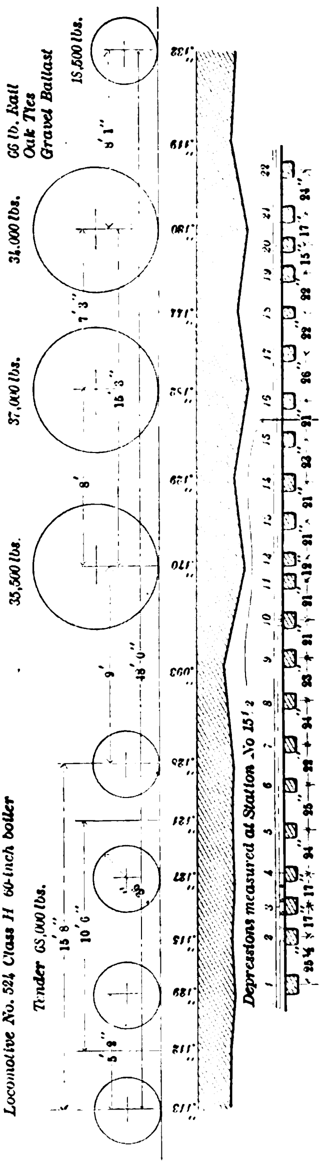

Fig. 476.—Experiments in Track Deflection.

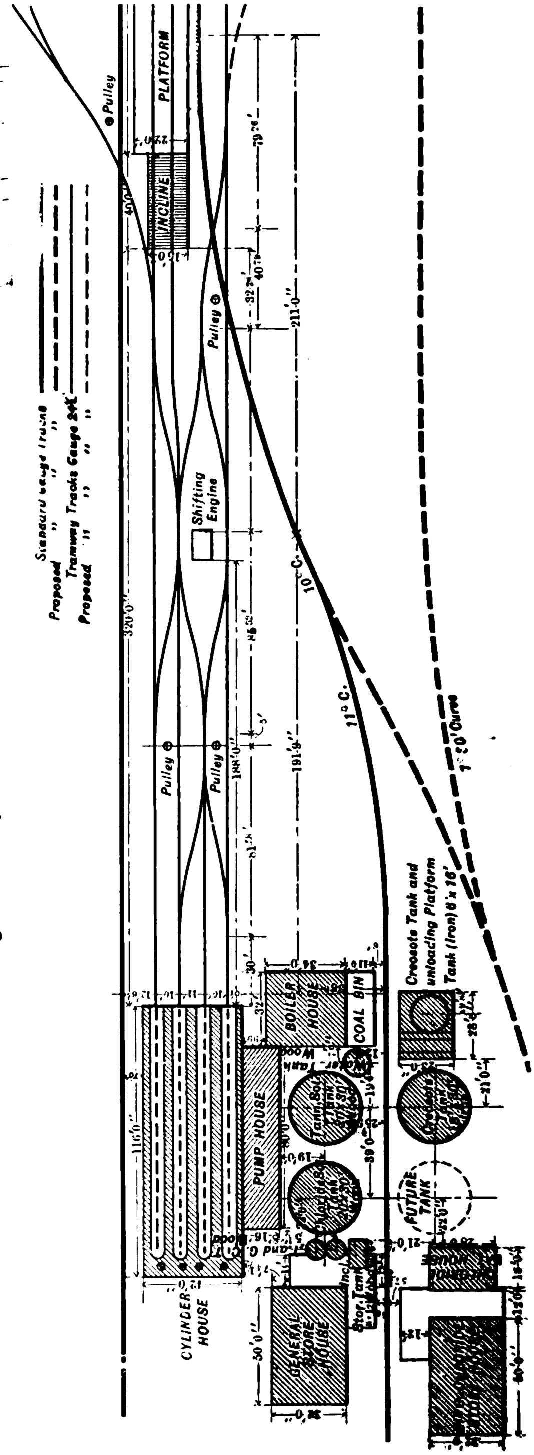

Fig. 477.—Layout of Tie Preserving Plant at Somerville, Tex.

for a typical case. Figure 477 shows the layout of the plant as first constructed, there being a cylinder house, 116x42 ft., containing four treating cylinders or retorts 109 ft. long and 6 ft. diam. Of the six cylinders which the plant now has two are fitted with apparatus necessary to creosote. The two extra cylinders lie adjacent to the four shown, in an addition to the cylinder house, the only rearrangement of the layout being to throw the main side-track farther out from the cylinder house. Adjoining the cylinder house is the pump house, containing the pumps, air compressors and valves admitting liquids to the retorts. For storing the zinc chloride and tannin solutions there are three wood tanks 30 ft. diam. and 20 ft. high, and for storing creosote there is an iron tank 30 ft. diam. and 18 ft. high. There is a general storehouse 50x32 ft., a zinc chloride storehouse 50x32 ft., and a building 18x28 ft. containing vats for mixing the chloride solution.

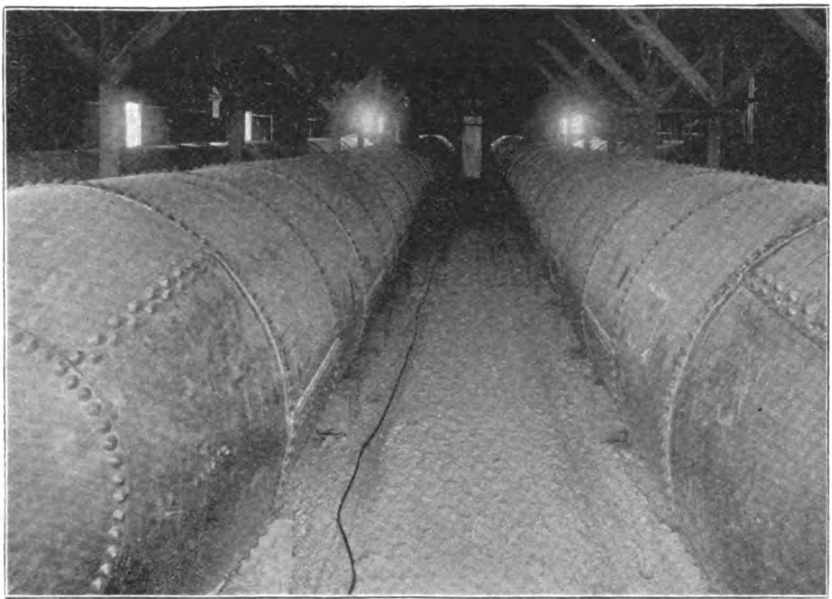

Fig. 478.—Interior of Cylinder House Showing Retorts.

The retorts or treating cylinders (Fig. 478) are made of $^7/_{16}$-in. steel plates in sections 4 ft. 3 ins. long overlapping one another $2\frac{1}{8}$ ins. Each retort has a top dome for admitting compressed air and a bottom dome for the admission of steam and liquids and for drawing off the liquids. Each retort is supported at intervals of 8 ft. $1\frac{5}{8}$ ins. (at the centers of alternate sheets) on oak saddles resting on rollers, so as to give with change in length of the retort due to variation of temperature. Between the ends of each pair of retorts there is a 12x12-in. gate post, and to these posts are hinged the heads for closing the retorts, weighing about 3000 lbs. each. The head is closed down and locked by 24 bars which radiate from the center and operate over fulcrums bearing on the outer rim of the head. The outer end of each of these clamp bars is held down by a staybolt attached to a cast iron flange riveted to the cylinder shell to serve as a seat for the head, and the inner end is attached to a plate backed by a large nut turning on a $3\frac{3}{8}$-in. screw, the head of which bears against the inside face of the retort head. This nut is turned by six spider arms, except for the last few turns in screwing down the head, when a large lever or wrench is employed to tighten it hard against its seat. In Fig. 479, which is a general view of the plant, one of these levers is shown in position on a cylinder head, and the head of the cylinder farthest to the right is shown swung open.

The ties are unloaded from cars run alongside the loading platform,

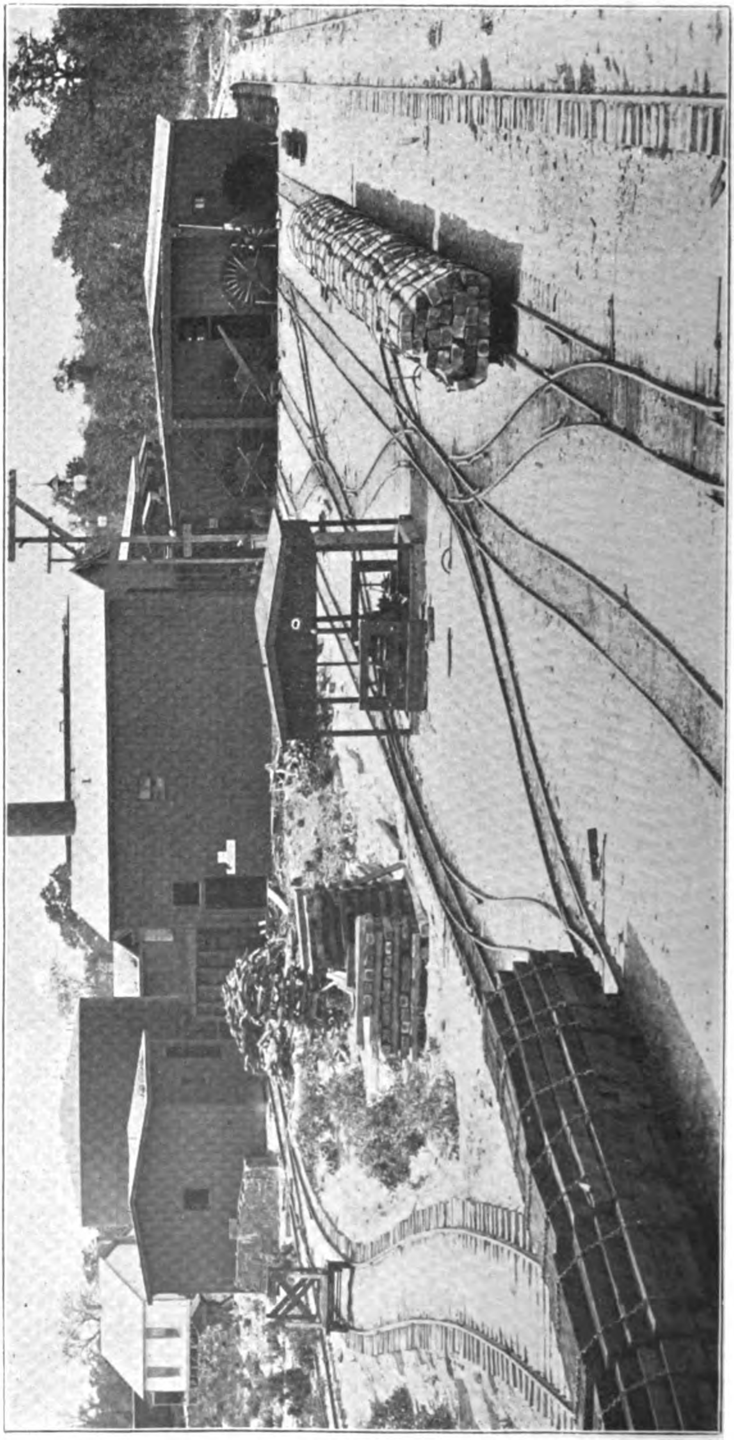

Fig. 479.—General View of Tie Preserving Plant at Somerville, Tex.

and transferred to the tram cars or trucks used in charging. From 25 to 35 ties are bound on each truck, in a cylindrical bunch, by chains, with sticks placed between the layers to give free circulation of the liquids. The trucks for each charge are run together in trains without coupling, so

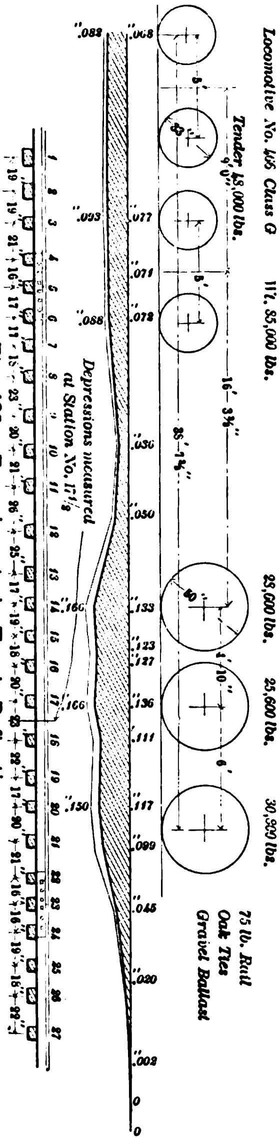

Fig. 480.—Experiments in Track Deflection.

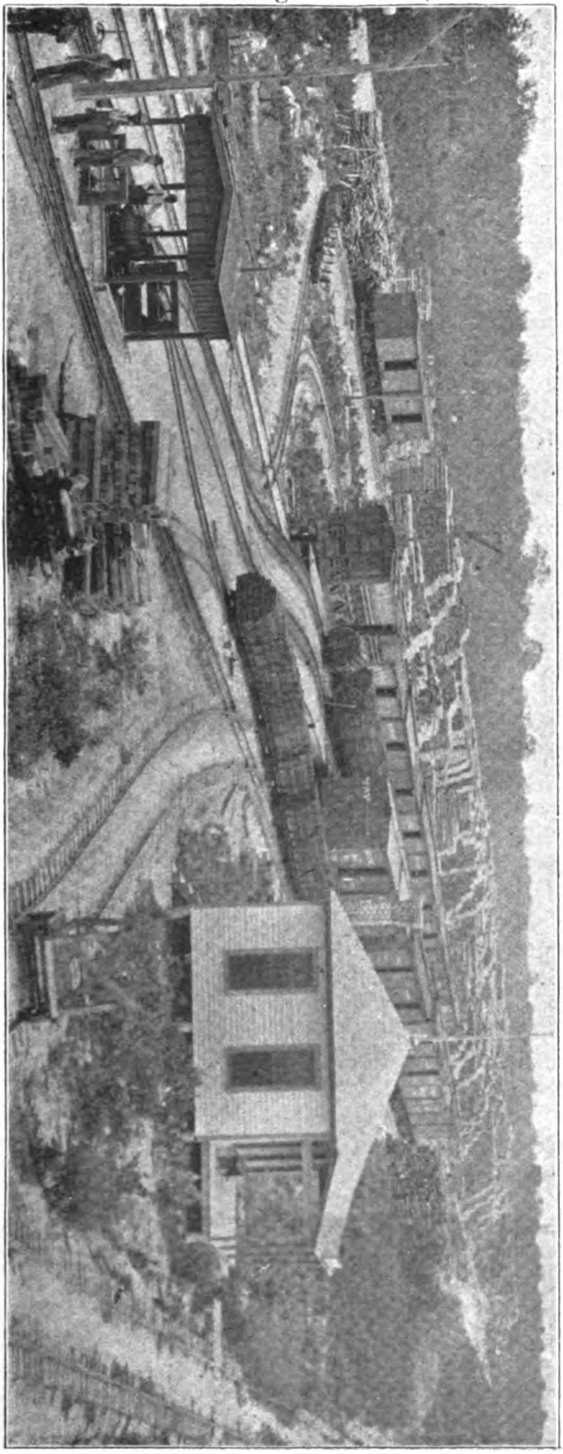

Fig. 481.—Tie Yard and Loading Platform of the Tie Preserving Plant at Somerville, Tex.

as to economize room. A train is run in and out of a retort by means of a cable attached to the hind car, which pushes those in front. The cable is hauled by a shifting engine with a winding drum. One of these engines is located near the cylinder house, as seen in Figs. 477 and 479, and the other (not shown) is at the side of the loading platform, 448 ft. in rear of the one shown. The engine near the cylinder house is used for shifting charges into and out of retorts 1 and 2 (numbered from the pump house), and that in the rear for shifting charges for retorts 3 and 4 and to handle all trains hauled onto the platform. In order to haul a train or charge into a retort the cable must be passed around a pulley at the rear end of the retort, shown in Fig. 477 by a conventional sign; in Fig. 478 the cable so used is seen lying stretched out on the floor. Figure 479 shows at the left a train of ties just taken out of retort No. 4, and at the right a train ready to be run into the same cylinder. The weight of a retort fully charged is 129 tons, of which 38 tons is the empty retort and 91 tons the charge. The latter is made up of 13 cars weighing in the aggregate 5.2 tons, the ties or timbers generally weighing about 35 tons, and the solution about 51 tons.

The gage of the tram tracks is 24½ ins., and where standard gage tracks coincide with the tram lines a third rail is laid. The ties shipped from the plant are run upon a loading platform between two standard-gage side-tracks. This platform is 450 ft. long from the top of the incline, but only one end of it appears in Fig. 477. Figure 481 shows this platform in relation to the tie yard and the various side-tracks and tram tracks.

In some tie preserving plants the first thing in order in the process is to set up a vacuum of 22 to 24 ins. and maintain it for about 10 minutes, to remove the air from the timber and open up the pores. The live steam is then turned in without breaking the vacuum. At the beginning of the treating process at the Somerville plant live steam is admitted as soon as the retort is closed, a 3-in. drain pipe being left open until all of the cold air is expelled; and after that is closed a 1-in. drain is left open while the steaming continues, to carry off the condensation and the sap which flows from the ties. The steam is held at a pressure of 30 to 45 lbs. per sq. in. from two to six hours, depending upon the size of the timber and its condition with respect to seasoning. Large timbers and piling require a longer time to heat through than small sizes. The more dense the timber the longer the time necessary to heat the fiber at the center. The heat of the steam serves to vaporize the liquid sap in the timber, liquefy some constituents of the sap which may have become solidified, and possibly to solidify some of the albumen, which coagulates at 167 deg. F. The steam is finally blown off, either into the atmosphere or into a coil in the creosote tank, in case creosote is being used. Without permitting the retort to cool, a vacuum of about 24 ins., or as near to that as can be, is pumped. This vacuum is obtained by the aid of surface condensers, such assistance to the pumps obviating the difficulty of obtaining a vacuum in the presence of vapor. The vacuum enables the timber to expel the sap and other liquefied matters, which collect at the bottom of the retort and are drained off through the bottom dome in process of pumping the vacuum. The vacuum pump is started as soon as the steam has been blown off sufficiently "to permit the pump to show any gage," in order that the vapor and air in the sap cells may begin their movement out of the timber. "If the retort is allowed to cool," says the manager of the plant, "the timber has a tendency to contract and the cells fill with air, making the work of 'emptying' the timber more difficult.

We find that in doing this we do not have to drain our cylinders after the vacuum, as they are perfectly dry at that time." Without breaking the vacuum the zinc chloride and glue solution is admitted, and as soon as the cylinder is full the pressure pumps are started. The pressure is worked hydraulically, by the solution pumps, and held at 105 lbs. per sq. in. for $1\frac{1}{2}$ hours. It is found, however, that almost all of the solution enters the timber while the pressure is being attained. In the experience at this plant the best results are obtained when the solution is brought to a temperature of about 120 deg., as a cold bath on hot timber does not aid absorption. The timber is allowed to take up all the solution it will. If the amount of pure chloride absorbed is found to be too great the strength of the solution for subsequent charges is weakened. The timber treated is principally southern sap pine, or what is known as loblolly, a small part being long-leaf pine; and it is allowed to absorb .35 to .45 lb. of the pure zinc chloride per cubic foot. After the surplus chloride solution has been forced back into the storage tank a solution of one half of 1 per cent tannin in water is introduced and kept up one hour under a pressure of 80 to 100 lbs. per sq. in. After the tannin solution has been forced out the retort is opened and the ties are run out. The liquids enter the retort by gravity and are forced out by compressed air. As soon as a charge is taken out another stands loaded ready to be taken in. The length of the run varies, of course, with the condition of the timber, but is usually eight to ten hours, and the capacity of the plant is 6000 to 9000 ties treated per day. The number of men employed is 130. The aim is to have all the timber thoroughly seasoned before treatment. The process of injecting creosote into piling or other timber is similar to that of burnettizing, 12 to 15 lbs. of creosote being used per cubic foot.

Zinc chloride is a product resulting from the treatment of metallic zinc with hydrochloric acid (H Cl). It is not manufactured at the plant, however, but is bought in the "fused" or crystal state in sheet iron drums, each containing 1000 lbs. of the salt. At the plant it is dissolved in water in the vats to a solution of about 1.6 to 2 per cent strength and with it is mixed dissolved glue in the proportion of about one half of 1 per cent by weight. In some other plants the glue is kept separate from the zinc chloride solution and is not introduced into the retort until after the chloride solution has been injected and the surplus drawn off. In this plant it has been found more satisfactory to mix the glue with the chloride solution, but arrangements have been made to keep the two separate in case it should be so desired. The creosote is unloaded from barrels (if imported from England) and tank cars and run into an underground tank 16 ft. diam. by 6 ft. high. Here it is heated by coils and pumped into the large tank, where it is again heated by coils to 150 to 175 deg. F. before it is run into the retorts. As creosote partially solidifies at ordinary temperatures, it must be heated in order to be handled, and for this reason it must be steamed by hose to about the consistency of molasses before it can be drawn from the barrels or tank cars.

A modern feature in this plant is the arrangement of the valves controlling the flow of liquids into and out of the retorts and tanks and the admission of compressed air to the retorts. In plants constructed previously to this one these valves were placed at the tanks and retorts, thus necessitating considerable running back and forth to open and shut valves. In this case all valves necessary for the operation of the plant are located in the pump room within easy reach of the engineer. Figure 482 is an interior view of this room. At the left of the room stand the pressure pumps, four in number, and just beyond are the valves which govern the admission of steam into the retorts. Near the center of the room, appearing something like brake shafts on freight cars, are the stems of valves beneath the floor which govern the admission of solutions into the retorts. Just back of these there is an engine and dynamo for lighting purposes. To the left of the engine stands the air compressor, while behind it is the hot well carrying the condensers, to the right of which stands the vacuum pump, not shown in the view. One engineer attends to all the movements. As the plant is operated continuously, both day and night (except 12 hours on Sunday), there are three engineers working eight hours each. The steam enters the bottom dome and is carried to the ends of the retort along the bottom, through coils which pass back and forth three times before the steam is finally exhausted into the open space. The bottom of the retort is in this way heated in advance of the top, and no trouble from strained sheets is experienced when, as is sometimes the case after a retort has been left open for a time, the bottom becomes covered with ice.

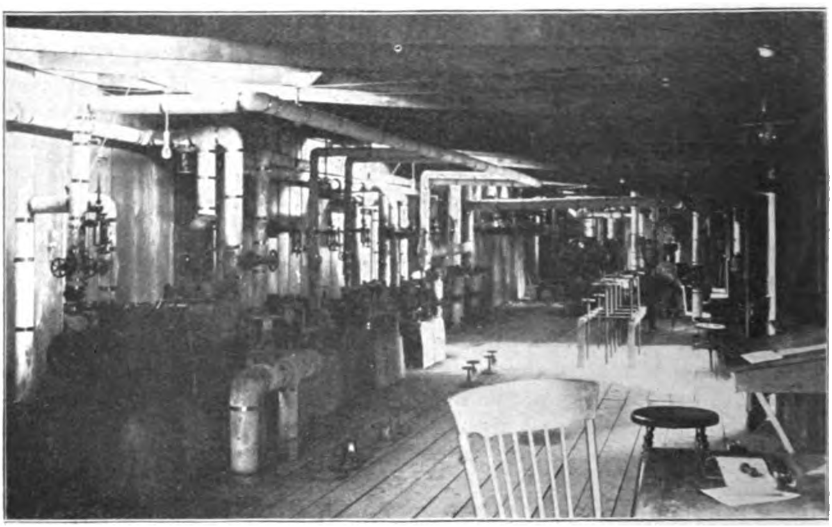

Fig. 482.—Compressor and Valve Room in Pump House.

The portable tie treating plant in service on the Chicago & Eastern Illinois R. R. was built by and is owned by the Chicago Tie Preserving Co. The plant has one retort 6 ft. diam. and 117 ft. long, in two sections, united at the middle by a bolted flange joint. Each 58½-ft. section is mounted on a pair of freight-car trucks, for transportation. As auxiliaries the plant has eight vertical cylindrical steel tanks 9½ ft. diam. and 9½ ft. high, for storage purposes; a steel measuring tank 8 ft. long, 5 ft. wide and 8 ft. high; the necessary air and water pumps, condenser and boilers, of which there are two of 50 h. p. each. There are five wooden storage tanks each 9½ ft. diam. and 9½ ft. high, two lead-lined vats for making the zinc chloride, two tubs for mixing gelatine (glue) and for tannin. There is a platform 320 ft. long and 22 ft. wide, provided with a six-ton scale, and 45 retort cars. The capacity of the plant is about 1000 ties per day. The ties treated at this plant are of water oak, red oak, yellow oak and black oak, having an average natural life of only four years when used for tie timber. The portable plants of the Union Pacific and Oregon Short Line roads are similarly constructed.

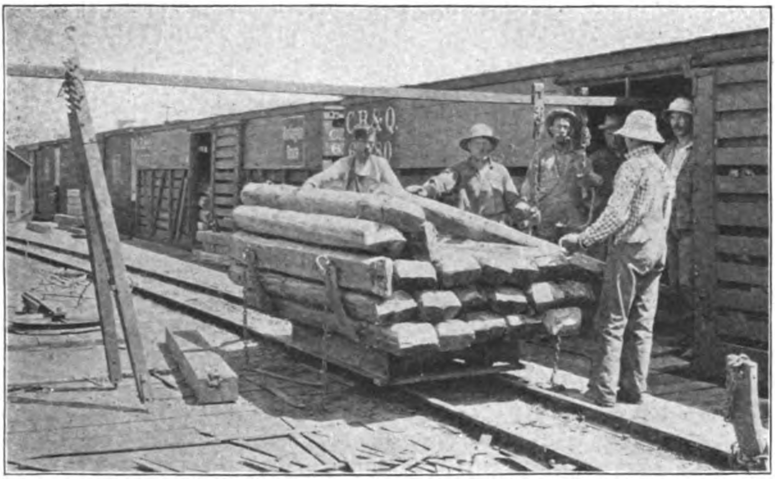

Fig. 482 A.—Angier Tie Loader; View on the Platform.

Fig. 482 B.—Angier Tie Loader; View in the Car.

The weight added to ties by preservative treatment increases materially the labor of handling them, and to reduce as far as possible the fatigue on the men and to expedite the loading of treated ties into box cars, Mr. F. J. Angier, superintendent of the Burlington & Missouri River plant at Sheridan, Wyo., designed a portable trolley arrangement that is set up on the loading platform to extend over and across the loaded tie-treating trucks. The device is used also at the Kalispell works of the Great Northern Ry. It consists of a light trestle leg or A-prop 7 or 8 ft. high, set up on the platform, and a double-rail trolley track running into the car door and branching toward each end of the car. Inside the car this track is supported on hangers clamped to the carlines and hung from the door rail. For carrying the ties there are two L-shaped stirrups, each swung from a trolley wheel by a piece of chain. Each tie handled is placed on the stirrup, at a balance, and steadied by the workman as it is run to place in the car. As the outer end of the trolley track is several inches higher than it is in the car the loaded trolley is moved with but little or no pushing. As the pile of ties gets lower on the truck the chain is let out on the trolley hook to adjust the hight of the stirrup and save lifting the ties. The loader is operated by six men, working at both ends of the car at the same time. The truck from the treating cylinders, holding 30 to 40 ties, is run upon the loading platform opposite the door of the car to be loaded and under the trolley track temporarily set up, as seen in Fig. 482A. Two men lift the ties from the tram car to the carriers. Two men—one for each carrier—push the ties into the cars, and two other men assist the carriers to unload and pile the ties up in place. The sequence of operation is readily understood by reference to Figs. 482A and 482B. A tram truck carrying 30 to 40 ties is unloaded and the ties are stacked up in the car in an average time of five minutes. When rushed, a car of 30 ties has been unloaded and piled up in the car in 1 minute and 50 seconds. The treated ties weigh 200 lbs. and more each, and when the ties were loaded entirely by hand the work required two men to a tie. With the loader six men easily handle 3000 ties in 10 hours. The same work required 10 men before the loader was put into service. The machine is quickly transferred from one car to another, taking but two or three minutes' time.

Regarding the strength of solution most suitable for the treatment there is some difference of opinion. The most general practice seems to favor a solution having a strength of 1.4 to 2 per cent, securing an absorption of one third to four tenths of the volume of the timber, or approximately $\frac{1}{2}$ to $\frac{3}{4}$ of one per cent, by weight, or, more exactly, $\frac{1}{4}$ to $\frac{1}{3}$ lb. per cubic foot, of the pure chloride, for the softer varieties of timber, such as pine. At the Houston plant of the Southern Pacific Co. the strength of the solution is 1.6 per cent, and 6x8-in.x8-ft. yellow pine ties absorb $4\frac{1}{2}$ gals. of the solution or 0.50 to 0.55 per cent, by weight, of the dry chloride salt. While there are many who believe that a stronger solution than stated will injure the fiber of the wood, or that the hygroscopic effect of the excess of salt will keep the timber continually moist, the Chicago Tie Preserving Co. uses a solution as strong as 3.7 to 3.9 per cent, securing an absorption of solution in sufficient quantity to inject $\frac{1}{2}$ lb. of the dry chloride per cubic foot, and no detrimental effects are reported. In Germany a solution of 1.9 to 2.6 per cent strength is considered standard practice. It is the opinion of some authorities who have had long experience with burnettizing that the matter of greatest importance is the thorough absorption of the solution by the timber, and that if such is obtained, a solution as strong as $1\frac{1}{2}$ per cent will give results practically as good as will a stronger solution. The zinc chloride, of itself, should be entirely free from acid, and before applying it to the timber it should be thoroughly stirred or "agitated" in the solution tanks, so that the salts will be evenly dissolved in the water. This is usually done by admitting compressed air through a system of small pipes called the "puddler." Failure to properly mix the solution might result in treating some of the ties with water, or very weak solution, and others with a solution that is too strong. To take up any free acid that may exist in the solution zinc blocks are placed in the mixing vats and solution tanks. In steaming the timber it is generally considered bad practice to use a pressure exceeding 20 lbs. per sq. in., such pressure corresponding to a temperature of 260 deg. F. Some think the temperature should be restricted to 240 deg., corresponding to a pressure of 10 lbs. per sq. in., or to 250 deg. at the outside. The effect of overheating is to make the fibers brittle, and the ties will fail by "shivering" under rail pressure. In practice this manner of failure and the cause thereof are quite well understood.

The amount of absorption in any charge of ties or timber may be obtained from the gage readings of the solution tank before and after treatment. The gage readings of the solution tank before and after filling the empty retort, and again with the empty trucks and wire cable inside (both obtained once for all), and the readings before and after forcing back the surplus solution, give all the data necessary to obtain the displacement or volume of any charge of timber; or, if the pieces are of regular size and shape, it may be obtained roughly by computation. At some plants it is the practice to take the solution from a special, accurately gaged measuring tank, instead of from the main tanks, as soon as the pressure pump is started, and then continue the pumping until a predetermined amount of the solution has been absorbed by the timber. The portable plant in service on the Chicago & Eastern Illinois R. R. is so arranged that each truck-load of ties may be weighed separately, before and after treatment, as the truck is being switched to and from the retort. If any load is found to have taken less solution than the amount determined upon, that truck is switched out of the train and treated again. Of course, the quantity of solution absorbed by a single truck-load can only be estimated, and that in a general way, by comparing the weight with that of other truck-loads, for it is impossible to find how much sap and water has been withdrawn by the steaming and vacuum processes.

In climate of ordinary rainfall or heavier it is found that metallic salts of any kind, being soluble in water, are washed or leached from the ties, thus removing the preservative agent. The Wellhouse process, used in connection with burnettizing, as already noted, consists in injecting into the tie with, or after, the zinc solution, a sufficient quantity of dissolved glue to close the pores, and afterward to inject an extract of hemlock bark known as tannin. The tannin is supposed to change the glue to a tough, insoluble, leathery substance which will occupy the interior of the tie to the exclusion of moisture, and thus prevent the leaching out of the antiseptic materials. The cost of adding the glue and tannin to the zinc chloride process is about two cents per tie. Regarding the practical economy of the Wellhouse or "zinc-tannin" process, conclusive data seem to be wanting. The Southern Pacific Co. and the Burlington & Missouri River R. R. obtain satisfactory results with the zinc chloride process without the addition of the glue and tannin. The life of the ties used on both these roads, however, is favored by a very dry climate, so that, on the real merits of the question, the practice in these cases is not decisive. The constant exposure of the ties to a damp atmosphere and wet ballast is thought to have a worse effect on the stability of the antiseptics than hard rain storms at occasional intervals. The method of applying the glue is also taken into consideration by students of the process. At some plants, as already noted, the chloride solution and glue are mixed together and forced into the timber together, after which the tannin solution is injected to set the glue. In other plants the zinc chloride, glue, and tannin are injected separately, it being believed that the fluidity of the chloride is impaired by the presence of the glue, and that a much better penetration is had by applying the solutions separately. It is also thought that by mixing the chloride and the glue the latter may not become so thoroughly fixed by the tannin, and that organic decomposition of the glue may result. On the other hand, by attempting to force the glue into a tie already fully impregnated with the chloride solution, it is doubtful if deep penetration can be had for the glue. Ties treated by the Wellhouse process require more time for seasoning than when treated by the zinc chloride process proper, which would seem to prove that the treatment has some influence on the passage of moisture through the wood.

Regarding the life of ties treated by the zinc chloride process, in this country, it does not appear that such carefully kept records as will determine the length of service, in all cases, and under all conditions in which the treated ties have been used on various roads, are available. In a general way, however, there is sufficient data of a positive nature to satisfactorily determine the life of special lots of ties treated by this process. The ties used on the Atchison, Topeka & Santa Fe Ry., in Colorado, New Mexico and Arizona are mountain pine, of coarse-grained, knotty, inferior timber, the only kind of timber available except at excessive cost. The life of these ties untreated is four to five years. All of the ties used in renewals since 1885 have been the native pine treated ties. On the Rio Grande division, where the rainfall is light, the average life of the treated ties is 12 years, and the average for seven divisions of the road, for a series of years, has been 11 years and a fraction, or 2½ to 3 times the natural life of the tie. Of the ties treated in 1885, 22.6 per cent were in service after 15 years, and a considerable number were still in the track after 17 years of service, with the prospect that a few would last as long as 20 years. From 1885 to 1889 this road used the Wellhouse process; from 1889 to 1893 the burnettizing process; from 1893 to 1900 the Wellhouse process again, changing back to the burnettizing or plain zinc chloride process in 1900. During the first 15 years of operation the plant at Las Vegas had treated upward of 3¾ million ties.

On the Pacific system of the Southern Pacific road the distribution of the timber supply is such that about three quarters of the mileage can be tied with redwood and other timber but little subject to decay. The remaining 25 per cent of the ties are of mountain pine and other quickly perishable woods which it is the policy of the company to burnettize; and the proportion of treated ties is being gradually increased with that end in view, having reached 21.7 per cent in 1901. In 1902 there were in the tracks of both the Atlantic and Pacific systems of this road 7,569,479 treated ties, of which 82,574 were creosoted and the remainder burnettized. This number constituted about 28 per cent of all ties in service. The average life of the treated ties laid on this road in 1887 was 7.89 years and of those laid in 1888, 9.73 years, but experience has shown that these ties were overheated during treatment, and indications seem favorable to a better showing for the ties treated subsequently. The average life of burnettized ties (principally hemlock, with a few tamarack) on the Chicago, Rock Island & Pacific Ry. has been 11½ years for the lines west of the Missouri river and 10½ years for the lines east of the river. Of 21,850 treated ties laid west of the river 2610 were in service after 15 years, but 1664 were taken out during the following year. On certain sections of the road 28.9 per cent of the treated hemlocks were still in service after 12 years and on other sections 58.8 per cent were in service after 12 years.

From the foregoing records it thus appears that inferior or short-lived timber can, by the application of the zinc chloride or zinc-tannin processes be made to last two to three times the natural life. In order to account for the decay of treated timber the authorities explain that in course of time the salts or other substances injected either undergo a change or disappear by leaching out. It is supposed that decay will take place even in the presence of antiseptics, after the quantity of the same in the timber has fallen below some definite limit. The early decay of a few ties among a lot which generally endure long service may be accounted for in several ways. It is only ordinary experience to find in a quantity of ties of the same kind of timber some which are less thoroughly seasoned than is supposed, and in consequence of different conditions of growth some sticks of timber are closer grained than others of the same species. For one cause or another it is frequently the case that a few ties in a lot otherwise good are so refractory to the standard treatment that an insufficient quantity of the antiseptic is absorbed to thoroughly sterilize the timber. And then, it will frequently occur that a tie in the incipient stage of decay will pass inspection with the defect undiscovered. One point on which experience is conclusive is that the best results are obtained in the arid regions. There is a general belief that both the zinc chloride and zinc-tannin processes harden timber. Neither of these processes corrodes the spikes to an appreciable extent.

The Zinc-Creosote Process.—As creosote is the best timber preservative and zinc chloride only less effective but much cheaper, the plan of combining the two with a view to obtain a result superior to the possibilities of a zinc solution alone, at medium cost, finds a good deal of encouragement, and on some of the German railways it has been practiced to a considerable extent. On the Prussian State Railways the ties are impregnated with an emulsion of zinc chloride and creosote, the latter being in sufficient quantity to effect a distribution of 1¼ lbs. per cubic foot of timber, while the chloride of zinc is present in the usual amount. The results of this treatment are said to be superior to those obtained with zinc chloride alone, and the use of the process in Germany is growing. It is said that by this treatment pine and beech ties are made to last 15 to 18 years, or generally about 25 per cent longer than when treated with zinc chloride alone. The additional cost, over ordinary burnettizing, is about 4 cents per tie. The process as worked in Europe was invented by and has been promoted by Mr. Julius Rutgers, of Berlin. The creosote or dead oil of coal tar required in this work must be light in specific gravity (1.020 to 1.055 at 59 deg. F.), in order to mix readily with the zinc solution, and the proportion of acids of the carbolic acid type is exceedingly high, being 20 to 25 per cent. The carbolic acid contained in the creosote is the only component of the latter which is soluble in chloride of zinc. As, however, the two materials have nearly equal specific gravities they readily form a thorough mechanical mixture.

As such creosote is high-priced there has been some experimenting with zinc chloride and ordinary coal tar creosote applied in separate injections. This is known as the Allardyce process, and as worked at the plant of the International Creosoting & Construction Co., at Beaumont, Tex., it consists of an injection of a 2-per cent solution of chloride of zinc, in quantity equivalent to about 12 lbs. per cu. ft. of timber, followed by a second injection of 3 lbs. of dead oil of coal tar to the cubic foot. The purpose of the comparatively light application of creosote is to form a water-proof coating or shell to close the pores of the wood and prevent the escape of the zinc salts. The first railroad in this country to experiment with the zinc-creosote process was the Chicago & Eastern Illinois, in 1902, the work being done with the portable plant of the Chicago Tie Preserving Co. In that instance 15,000 ties, mainly red oak, black oak and water oak, with, however, some sycamore and other inferior woods, were treated. The solution was mixed and injected to get ½ lb. of zinc chloride (dry salt) and 1.1 lbs. of creosote into the timber, per cubic foot. Tests showed that both the zinc chloride and the creosote oil penetrated the heart of the timber. White and yellow oak ties did not take the treatment as well as the other varieties named. The cost of the process was 6 cents per tie more than that of treating with zinc chloride alone. Further details of this double process, as worked in Europe, and of experience with the same, are given in § 6, Supplementary Notes.

Kyanizing.—In the kyanizing process the timber is boiled or "steeped" in a solution of bichloride of mercury ($Hg\ Cl_2$), commonly known as corrosive sublimate. This is the strongest antiseptic among metallic salts. To properly impregnate timber as large as railway ties requires a treatment lasting eight or ten days. The solution is an active poison and the material must be handled carefully. Where this process is used in Germany the surface of the timber is washed with hot water after treatment, to prevent poisoning cattle or other animals which might lick the efflorescence from the ties. The process was invented by John Howard Kyan, and was applied in England as early as 1832. In this country it was used by the Northern Central and the Boston & Maine roads for treating ties at an early day. The latter road used kyanized hemlock ties for about ten years, beginning in 1882. The strength of the solution was one part of the bichloride to 100 parts of water, by weight. The cost of treatment was 5½ cents per tie and the results are said to have been satisfactory. The eventual increase in the price of hemlock ties and the introduction of cedar ties at low cost led to the abandonment of the process.

In Lowell, Mass., the Locks and Canals Co. has maintained a kyanizing plant since 1848. Except for an interruption of 12 years, 1850 to 1862, the work of treating timber has been carried on pretty steadily. At this plant the steeping is performed in wooden tanks 50x7½ft.x4 ft. deep. Formerly this company (the corporation controlling the water power of the Merrimac river) treated large quantities of timber for its numerous bridges, and a good deal of lumber for buildings, fences and the basement floors of mills in the city. It is said that in and about the old mills and public works of the city there have been found many examples of kyanized pine and spruce lumber practically sound after standing in the ground or being otherwise exposed to the elements for more than 50 years. In Portsmouth, N. H., there are kyanizing works built by the Eastern R. R. (now part of the Boston & Maine R. R.) which have granite masonry treating tanks 60x9½ ft.x6 ft. deep, laid up in cement and coated with coal tar. The capacity of these tanks is 150,000 ft., B. M., of lumber. At these works, during the years 1882 to 1892, the Eastern R. R. kyanized about 800,000 hemlock and tamarack ties, which were put into the tracks all the way from Boston to Portland and also on the branch lines. Some of the kyanized hemlock ties put into the tracks of the Portsmouth & Dover R. R. (now B. & M. R. R.) in 1882 were still in service after 20 years, the timber being in sound condition but badly rail cut and practically worn out. At this plant and the one in Lowell (both operated by Otis Allen & Son) 750,000 to 1,000,000 ft. of lumber, mostly spruce, is kyanized each year. The price for treatment has in some years been $8 per 1000 ft. B. M. A good many ties for street railways have also been treated during late years. The process consists in filling the tank with the ties or lumber and barring it down, and then pumping in the solution (with wooden pumps, on account of the corrosive effect of the solution on iron). The wood is allowed to soak in the solution one day for every inch in thickness of the same. Sawed ties or lumber are separated by laths between the courses, to give room for circulation, but such are not used with hewn ties. In Europe the kyanizing process is worked by four companies.

Boucherizing.—In the Boucherie process the timber is impregnated with a solution of one pound of sulphate of copper ($Cu\ SO_4$) to 100 lbs. of water. The process is used to some extent in Europe, and while the results are satisfactory, as far as increase in the life of the tie is concerned, it is found that the rails and spikes are attacked and seriously corroded by sulphuric acid set free. The process as originally invented by Boucherie, in 1841, consists in injecting the solution into the timber by hydrostatic pressure. After the tree has been felled and cut into logs or into lengths for ties, each piece, with the bark still on, is tilted up and a solution of copper sulphate is applied by fitting a capsule tightly over the end of the log, to which is communicated a pipe containing the solution, which is long enough when standing upright to give the required pressure. The pressure is applied for a variable time, depending upon the absorptive properties of the wood, being about 48 hours for beech and 100 hours for oak. The impregnating solution expels the vegetable sap, which flows off at the lower end of the log, the process being completed when the exuding sap contains a ⅔ part of the solution. Impregnation with copper sulphate is used on the Southern Ry. of France, on the Bavarian State railways, and on the Austrian Southern Ry. As applied on the last-named road the impregnation is effected in ordinary pressure cylinders instead of by the original Boucherie method. Beech ties, which rot in two to three years when untreated, last about 12 years when impregnated with copper sulphate.

Various Processes.—The Thilmany process consists in an injection of either sulphate of copper or sulphate of zinc, with a second injection of chloride of barium. According to the theory of the process a chemical change takes place, the chloride of barium being changed to an insoluble salt which prevents the soluble copper or zinc salt from washing out. Ties treated by this process were at one time used on the Chicago & Alton, the Lake Shore & Michigan Southern, the Erie and the Wabash roads, but the results, so far as reported, are said to have been unsatisfactory.

The Hasselmann process is a chemical treatment intended to produce both a preservative and a hardening effect on the timber. The object aimed at is to effect a combination of the salts injected, to form insoluble products, and also to produce to some extent a chemical combination with the cellulose of the wood fiber. The process (or rather two processes under the same name) is applied in two different ways, one being a double boiling treatment and the other a single boiling. The former consists in boiling the wood in a solution of the sulphates of copper, iron and alumina (the copper and iron sulphates being crystallized together in the proportion of 20 parts of copper to 80 parts of iron), after which the wood is boiled a second time in a solution of chloride of lime and milk of lime (whitewash). The timber is run into a large cylinder or retort, which is then sealed, and immediately a partial vacuum is pumped, when a solution of cuprous sulphate of iron (7 per cent) and sulphate of aluminum (3 per cent) is run into the cylinder and afterwards heated by steam to a temperature of 212 to 284 deg. F., the pressure at the same time being gradually raised to about 40 or 45 lbs. per sq. in. The boiling of the timber in this solution is kept up for two or three hours, when the timber is taken out of the cylinder and permitted to stand for some time, to effect the completion of the chemical action. Meantime, the first solution is used (over and over) on seven or eight different charges of timber—that is, before the first charge of timber is boiled in the second solution. The second boiling of the timber takes place under the same conditions as before, the solution consisting of chloride of lime (1 in 50) and milk of lime (1 in 40). The theory is that the first boiling destroys the germs of fermentation and induces to some extent the chemical union of the preservative with the fiber of the wood, in addition to the formation of insoluble products, as above stated. The second boiling is supposed to harden the wood and render it a non-absorbent of moisture. The whole process, in two intervals, requires about six hours. The single-boiling treatment consists in boiling the wood in a solution of the sulphates of copper, iron and alumina and "kainit," a salt mined at Stassfurt, Germany, consisting chiefly of sulphate of potassa and magnesia and chloride of magnesia. It is claimed that this treatment compares favorably with other methods of timber preservation commonly in use, and so far as the hardening effect is concerned it is represented to be far superior. It is said that fir and beech ties become almost as hard as oak. An important advantage claimed for the process is that green timber can be treated, the unseasoned condition of the wood conducing to a more thorough impregnation of the salts. The process has been used to a considerable extent by the Bavarian State Railways for treating ties. In this country the process is worked by the Barschall Impregnating Co., New York, with a plant at Perth Amboy, N. J.

The creo-resinate process, which is worked by the United States Wood Preserving Co., New York, consists in first vulcanizing the timber and then impregnating it with a solution of 38 parts, by weight, of coal-tar creosote, 60 parts of melted resin and 2 parts of formaldehyde, followed by an application of milk of lime to solidify the resin and creosote oil. One writer has styled the results of the process as "vulcanized wood with an antiseptic shell." The process is intended as an improvement of creosoting, with the following claims for advantages: The vulcanizing of the wood sterilizes it throughout, which cannot be done by straight creosoting except at high cost, and even then it is difficult to penetrate the heart of the timber; the solution is cheaper than creosote; the resin renders the mixture water-proof and protects the sterilized interior against the entrance of fungi spores; the formaldehyde strengthens the antiseptic properties of the compound and restores what is lost in this respect by the adulteration of the creosote. In applying the treatment the timber is run into a retort, when the door is closed and the temperature is raised to 215 deg. F. without pressure, requiring about one hour, and this temperature is held for another hour without pressure, the purpose being to evaporate the moisture. The temperature is then gradually raised under an increasing pressure, to avoid injury to the fiber, until, in the course of two hours, the heat reaches 285 or 290 deg. F. and the pressure 90 lbs. per sq. in., and both are held at this for one hour. For another hour the cylinder is allowed to cool down gradually to 250 deg. and the pressure to reduce to 40 lbs. The pressure and heat are then reduced and a vacuum of 26 ins. is applied, under which the mixture, at a temperature of 175 to 200 deg., is run in and put under a pressure of 200 lbs. per sq. in. by hydraulic means, and held at this until the desired quantity of solution is absorbed. The liquid is then drawn off and the timber is run into another cylinder, where the milk of lime is applied at a temperature of about 150 deg. and at a pressure of 200 lbs. per sq. in. for a half hour. The treating solution weighs 8.9 lbs. per gal., and at 300 deg. the specific gravity is 1.068.

There are a number of patented preservative solutions on the market, represented as having stood the test of years of service, and for which various claims are made. Among the best known of such solutions are woodiline and carbolineum avenarius, the basic principle of each being creosote. The latter material is a mixture of creosote and chlorine gas. The chief claim for these solutions is that their application requires only the soaking of the ties or timber in the heated solution for a short time, it not being necessary that a deep penetration should be had. This simplifies very much the method of application, over those heretofore named. The amount of material absorbed is comparatively small, and the first cost of apparatus very much reduced, as compared with methods requiring the extraction of the sap. An ordinary vat open to the air, with steam coils for heating the solution and a crane for lifting bunches of ties in and out, constitute about all the necessary outfit for applying the solution to the timber. Either solution is also applied, sometimes, with a brush and used as a paint. The Pennsylvania R. R. has used considerable quantities of woodiline for tie treatment, and on the Alabama Midland branch of the Plant System carbolineum avenarius has been applied to ties to some extent. As patented solutions have not yet come into extensive use, and as in some cases their constituent parts are kept secret, an impartial discussion of their merits is not easily undertaken. It is at least fair to say that general experience has not yet proven such simple processes as efficacious as the more thorough methods of treatment involving the extraction of the sap.

There are a few other tie preserving processes and materials that have been experimented with in a small way. In 1902 the Gulf, Colorado & Santa Fe Ry. began experimenting with crude petroleum. The process employed consisted in merely soaking the ties 24 hours in an open vat containing the oil, which came from Beaumont wells. Untreated long-leaf pine ties, average weight 134½ lbs., absorbed an average of 5.67 lbs. of oil per tie. Ties of the same kind of timber previously treated with a 2-per cent solution of zinc chloride, average weight 186 lbs., absorbed an average of 3.49 lbs. of oil per tie. Untreated loblolly pine ties, average weight 124 lbs., absorbed an average of 4.24 lbs. of oil each, and the same kind of timber previously treated with a 2-per cent solution of zinc chloride, average weight 170½ lbs., took up an average of 3.15 lbs. of oil per tie. All the ties were hewn, and, with the exception of the untreated loblolly, had been thoroughly seasoned before soaking in the petroleum; the loblolly had not been as well seasoned as the others. The treated ties were allowed to dry out before soaking in the oil. These ties were laid in an experimental section of track on the Montgomery branch, with a miscellaneous lot of other ties treated with various processes, and are again referred to further along. On bridge ties paint, applied in the ordinary way, has been used by a few roads with results reported to be quite satisfactory. It is perhaps unnecessary to say that ties that are to be painted should first be thoroughly seasoned. Long-leaf yellow pine ties painted with two coats of red oxide of iron and linseed oil, all daps being painted before the ties were placed, were in sound condition after 12 years of service, but had then to be renewed because of rail cutting under heavy traffic.

Mention should be made of various kinds of timber, not hitherto pointed out, that are being treated and used for ties in different parts of the country. The timbers available to the plant of the Great Northern Ry., at Kalispell, Mont., are fir, "bull pine" and large quantities of tamarack, some portion of which is locally known as "mountain tamarack." The timbers treated at the Missouri, Kansas & Texas Ry. plant, at Greenville, Tex., are Texas pine, some post oak and large quantities of sweet gum. The last-named timber is in quality something of the nature of poplar, and in the untreated condition is entirely worthless for any purposes of construction. When treated, however, it renders good service for ties and bridge timber. Some bridge guard rails of this timber treated by the Wellhouse process have stood service longer than 17 years. The timber treated by the Ayer & Lord Tie Co., at Carbondale, Ill. (zinc chloride process), is red oak and black oak. The Atchison, Topeka & Santa Fe Ry. has experimented with treated cottonwood in a small way. These ties began to fail after nine years of service. At the end of 11 years 56 per cent have been removed and at the end of 15 years 86 per cent had been removed. Treated Colorado pine ties began to fail slowly after six years, but after 10 years 66 per cent were still in service and after 15 years 62 per cent were still in the track. In 1901 the Pennsylvania Co. had 16,716 beech ties treated by the Wellhouse process, and during the years 1898 to 1901 the Pittsburg, Cincinnati, Chicago & St. Louis Ry. had 86,956 beech ties treated by the same process. In an experiment with 86 treated Norway pine ties on the Duluth & Iron Range R. R., 92 per cent were still in service after 11 years.

In order to determine the relative merits of various kinds of timber preservatives and processes, as well as the relative durabilities of different kinds of timber treated by the same process, the tie committee of the American Railway Engineering and Maintenance of Way Association, in co-operation with a number of railroads and timber-treating establishments and the United States Department of Agriculture, began, in November, 1901, a practical experiment. With a view to hasten the results of the test as much as possible a region was selected in southern Texas where the climate is favorable to very rapid decay, the annual rainfall and average temperature being high. The place is on the Montgomery branch of the Gulf, Colorado & Santa Fe Ry., near Waukegan, Tex., where untreated pine ties have generally decayed in 12 to 14 months and burnettized ties in two to four years. This experiment was started with 5850 ties of the following kinds of wood: long-leaf, short-leaf and loblolly pine; white, black, red, Spanish and turkey oak; willow oak, hemlock, beech and tamarack. Each kind of wood, generally in lots of 50 or 100 ties each, was treated with five or more of the following processes: zinc chloride (burnettizing), zinc-tannin (Wellhouse), zinc-creosote (Allardyce), with both American and English oils; Hasselmann, crude petroleum, zinc chloride and crude petroleum combined, and spiritine. In addition to this, one lot of ties of each kind of timber was laid untreated, and one lot of 100 red-heart pine ties was treated with the Hasselmann process. The ties were allowed to season several months before laying, and each was marked with three zinc-coated wire record nails stamped to show the date, the kind of timber and the kind of treatment. In the middle of the track the ballast was dressed to cover the tops of the ties.

Experience has taught that only sound timber should be treated, and that most kinds of timber should be thoroughly seasoned before treatment and again after treatment or before the ties are put into service. Unsound wood will absorb a larger quantity of solution than that in sound condition, and if decay has commenced before treatment it cannot be stopped. In Europe the tie-treating contractors exact a discount of 5 per cent from the guarantee to cover "sick" ties, the hidden defects in which cannot be discovered by the usual inspection. Ties treated with the bark on absorb an excessive amount of solution, greatly increasing the cost and giving poor service. A few varieties of timber seem to take treatment best when in the green condition, while most kinds will absorb the solution more satisfactorily after thorough seasoning. At the works of the Chicago Tie Preserving Co. it has been found that hemlock ties improve in receptivity by seasoning, absorbing more of the solution after seasoning than when first received. It has also been found that more sap can be extracted from a partially seasoned hemlock tie than from one freshly cut. To account for this fact it is supposed that when the tie is full of sap it is impossible to heat the interior sufficiently to convert the watery portion of the sap into steam. Hemlock ties cut in summer absorb less than ties of the same timber cut in winter. On the other hand, Oregon fir is said to receive treatment better when green than dry, the phenomenon being explained on the theory that the resin in the wood solidifies upon seasoning, forming obstructions to the penetration of the solution. Timber treated without seasoning usually requires extra work, such as prolongation of the steaming and vacuum and increase of pressure and of the time of applying the same, in order to inject the desired quantity of solution. Nevertheless, at some of the American plants but little heed is paid to the matter of seasoning before treatment. At the Houston plant of the Southern Pacific Co. it has been the practice to treat yellow pine ties felled at all seasons of the year and without regard to seasoning. Ties that have been floated down streams lose more or less of their sap and absorb the treating solution more readily than ties that have not been in the water.

Wood thoroughly seasoned in the air still contains from 16 to 20 per cent of water, and when air-dried wood is exposed for a considerable time to a temperature as high as 277 deg. F. the quantity of water is reduced 75 or 80 per cent. A cubic foot of air-dried white oak weighs about 53.3 lbs. and contains 8.5 lbs. (16 per cent) of water and 44.8 lbs. of fiber. The fiber occupies about 50 per cent of the space, the sap about 10 per cent, and the air which fills the cells not occupied by the sap, about 40 per cent. The specific gravity of wood fiber in all kinds of timber is about 1.5, the variation in weight and density of different kinds of timber being accounted for by the relative amount of space occupied by the cells. Oak and the harder woods, being closer grained, absorb less solution in any process of treatment and are more difficult of penetration, requiring usually a much longer period for the injection of the liquid. In this country chemical treatment of white oak ties has not been practiced to any considerable extent, and as cedar is very durable, so far as rot is concerned, it is not classed among the timbers admitting of economical results from chemical treatment. The timbers selected for treatment are in general the open-grained, porous and sappy varieties of wood, or those which absorb liquids most readily. The amount of solution actually absorbed, however, is sometimes quite variable in the same kind of timber. Thus, at the works of the Chicago Tie Preserving Co. hemlock ties cut in the same place, seasoned in the same way and treated in the same charge, have been known to absorb as low as 13 per cent and as high as 80 per cent, in weight, of the solution.

It is generally conceded that after treatment, ties of any kind of timber, treated with any of the processes, should be loosely piled and thoroughly seasoned before they are put into the track. In the case with burnettized ties the zinc salt is soluble and the water injected with the chloride should evaporate before the tie is inserted in the track, leaving only the salt in the wood; or, if treated by the zinc-tannin process, the leathery pellicles formed by the glue and tannin should have time to dry and harden before the tie is exposed to moisture. Otherwise the moisture in the soil or ballast will begin at once to leach out the zinc salt. In order that the penetration may be thorough where decay is most liable to start some think it advisable to bore the spike holes in the tie before treating and also to do whatever adzing or spotting is necessary at the rail seats. At the old Laramie plant of the Union Pacific R. R. the ties, previous to treating, were run through a special machine which cut them to a uniform length, spotted them for the rail seats and bored the spike holes. Another advantage in boring for spikes is that they can be driven without crushing the fibers of the wood.

In order to secure satisfactory records of the life of treated ties they should be marked in some ineffaceable manner. A means employed in Germany and to a considerable extent in this country is to drive into each tie a galvanized nail with the year of preparation stamped on the head. The date of treatment may also be stamped into the tie, but of course is liable to become effaced by the decay of the timber. In France two dating nails are used—one at the works, when the tie is treated, and another when it is laid in the track.

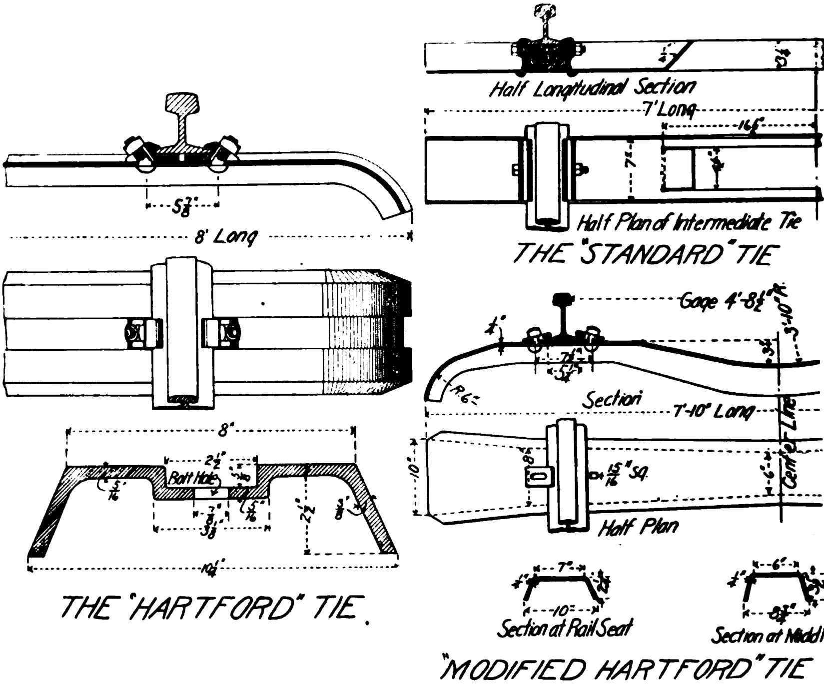

Fig. 483.—American Types of Steel Ties.

In view of the fact that experience with chemically treated ties in Europe has been larger and longer than it has in this country, the particulars and general results of the practice there are both interesting and instructive for comparison with our own practice. An account of this work in Europe is given in Supplementary Notes, § 201. The subject of tree planting by railway companies, as a source of supply for tie timber, is treated as § 202 of Supplementary Notes.

169. Metal Ties.—On the whole, American railroad managers have been slow to seek economy in the use of ties. The chief explanation for this apparent indifference is that our forest areas have been widely distributed, and in most parts of the country an abundant supply of timber has been available at low price. Notwithstanding that this supply has been rapidly vanishing, yet in many quarters where the local forests have become nearly or quite exhausted of tie timber, cheap freight rates, frequently owing to convenience of water transportation, have made it possible to supply the demand from distant sources previously not drawn upon, and at a cost which has been satisfactory. On this account it is easy to see why experiments with substitutes for wooden ties have not been a pressing necessity. As to the use of metal ties in this country there is scarcely no report, for all that has been done has been strictly experimental in character, and that on a scale that is quite insignificant. On this point it will suffice to explain that all the experimental work undertaken with metal ties in this country up to the year 1904 comprised a combined length of less than five miles of track laid with such ties. From the present outlook it would seem that the same tendency will prevail for some time to come, whatever the ultimate result may be, since the attention which is being devoted to frugality in the use of tie timber seems to be leading largely in the direction of tie preservation.

Although the patents issued on metal ties in this country may be numbered by hundreds, only a very few types have succeeded to a trial of any consequence, and an account of the trials on two or three roads will bring out practically all that has been learned about the use of metal ties in this country. In 1889 the New York Central & Hudson River R. R. laid 721 steel ties under 80-lb. rails on a stretch of 1576 ft. of stone-ballasted main track, at Garrison's, N. Y. These ties were of the Hartford type, shown in Fig. 483. This tie, as will be seen, was an inverted trough 8 ft. long, the ends being closed by curving the tie downward about 6 ins. With the exception of the curved ends the tie was straight. The width of the tie face was 8 ins. and the depth 2½ ins., the side flanges spreading to a width of 10½ ins. at the lower edges. The thickness of metal in the face or "top table," as it is called, was $^5/_{16}$ in. and in the flanges, ⅜ in. The tie was of rolled Bessemer steel and there was a channel or groove 2½ ins. wide and ⅝ in. deep along the middle of the top table for the entire length of the tie. The weight of the tie, including fastenings, was 150 lbs. Before laying the ties they were treated with a coating of asphaltum composition applied at a temperature of 300 deg. F. The fastenings for the rail consisted of wedge-shaped clips placed in the channel, and bent bolts ⅞ in. in diameter, passed up through the tie from below. In order to facilitate adjustment of the gage the clip was slotted for the bolt and the bolt was screwed down upon the inclined face of the clip, holding the rail firmly so long as the bolt remained tight. The bolts had the Harvey "grip" thread and no washer or special nut lock was used. At joints the angle bars (6-bolt, 40 ins. long) were notched to allow the clips to engage the rail flange. The ties, including the fastenings, cost $3.11 each. The ballast on which these ties were laid was 24 ins. deep, consisting of a 6-in. bottom course of stones 4 to 6 ins. in diameter and an 18-in. course of rock broken to pass a 2-in. ring. In the filling of the track the ballast was brought level with the tops of the ties and the ballast line was 6½ ft. from the rail. The results with this tie were not entirely satisfactory. Although it made a good showing so far as durability was concerned, it was found difficult to throw the track in line and the expense of keeping the track in surface was about twice the cost of the same maintenance item in an equal length of track laid on wooden ties. The tendency of the ballast was to work away from the tie at the ends, loosening the tie and causing it and the fastenings to rattle while trains were passing, These ties were removed in 1899, after 10 years of service under about 50 trains per day.

In 1896 this company laid 3375 ft. of track with 1350 steel ties at 110th St., New York City. The design of these ties was a modification of the Hartford pattern, as shown at the right in Fig. 483. The tie was pressed from a Bessemer steel (0.10 per cent carbon) plate ¼ in. thick, and resembled an ox yoke in shape. The length was 7 ft. 10 ins. The ends were turned down and the middle portion curved downward 3 ins. to a radius of 3 ft. 10 ins. The width of the tie face at the middle was 6 ins.

and at the rail seat 7 ins. The bottom width at the middle was $8\frac{3}{4}$ ins. and at the rail seat 10 ins. The depth of the tie at the middle was $3\frac{1}{2}$ ins., and at the rail seat $2\frac{1}{4}$ ins. The rail was fastened with wedge-shaped clips and $\frac{7}{8}$-in. bolts, as in the original design. The weight of the tie, including fastenings, was 100 lbs. and the cost was $2.50. In filling the track the curved portion at the middle of the tie was covered with ballast. These ties gave less satisfaction than those of the older design in use at Garrison's, being hard to throw in line and less able to stand the crushing weight of trains, in consequence of which they failed by crushing under the rail and by breaking in the middle. They were removed in 1899, after being in service three years under a traffic of 250 trains per day.

The "Standard" tie, shown at the upper right hand in Fig. 483, was of plain channel section, stamped from a steel plate $\frac{1}{4}$ in. thick, and was laid open side up. The side flanges of the channel were vertical and $3\frac{1}{4}$ ins. deep, and the ends of the tie were open. The tie was 7 ft. long and 7 ins. wide, except in the case of joint ties, which were 10 ins. wide. As will be seen in the illustration, a portion of the bottom of the channel at the middle of the tie was cut out, leaving an open space. The part cut out was $4\frac{1}{2}$ ins. wide and 24 ins. long, but the bottom was actually cut loose for a length of 33 ins., so that a flap-like piece $4\frac{1}{2}$ ins. long remained at each end of the opening and was bent upward at an angle of 45 deg., so as to offer resistance to lateral motion, the tie being filled with ballast. The rail was supported upon a block of creosoted oak wood fitted into the channel. This block was $2\frac{5}{8}$ ins. deep and sustained its load endwise the grain. The rail was supported entirely by the block, the sides of the tie being cut away to a depth of $\frac{1}{2}$ in. (thus weakening the tie at the point of greatest bending moment) to make room for the rail flange. The fastening for each rail consisted of two Z-shaped clamps, the upper clasp of each clamp engaging with the rail flange and the two claws forming the lower projection of the clamp engaging the bottom of the tie through holes. On intermediate ties the clamps were held to their engagement with the rail by one $\frac{3}{4}$-in. bolt passing horizontally through the clamps and the wooden block, while at joint ties two bolts were used. The intermediate ties weighed 82 lbs. and cost $2.50 each; the joint ties weighed 105 lbs. each and cost $3.50.

In October, 1889, a stretch of 1000 ft. of main track on the Chicago & Western Indiana R. R., at 69th street, Chicago, was laid with "Standard" ties spaced $23\frac{1}{3}$ ins. centers. The ties were ballasted with gravel; the joints were spliced with plain fish plates (angle bars could not be used owing to the interference between the horizontal leg of the bar and the tie clamp); the rails were laid with square joints, supported. The traffic over these ties was heavy, amounting to about 80 trains per day, all in one direction. After some five or six years of service it was found necessary to replace the ties at the joints with wooden ones, but the intermediate ties remained in the track until the spring of 1899, when all were removed. The condition of the ties at the time of removal would lead one to think that they had reached the full limit of their usefulness. They were badly corroded, the flanges in some cases being reduced to the thickness of a knife blade, and many of the ties were cracked or broken at the rail seat. The oak blocking at the rail seat was in much better condition than the metal portion of the tie, being practically as sound as new timber.

The Standard tie was tried on several other roads but in no case did it remain as long in service as on the Chicago & Western Indiana R. R. In 1890 about $\frac{3}{4}$ mile of track on the Delaware & Hudson R. R., near Saratoga Springs, N. Y., was laid with these ties, but they were found to be unsatisfactory and were taken out after a year's service. The ballast in which the ties were laid was fine gravel, and the difficulty seems to have been in keeping the track to surface. The Long Island R. R. laid 500 Standard steel ties, 16 ties to a rail length of 30 ft., and these ties remained in service three years under a traffic of 130 trains per day, except the joint ties, which were removed at the end of 18 months and replaced with wooden ties. It was found difficult to keep the track in line on curves and the use of fish plates at the joints, instead of angle bars, made it difficult to hold the joints to surface. During the three years in which these ties were in service the cost of maintenance exceeded the usual cost of maintenance for track laid on wooden ties by about 30 per cent. Another experiment with the Standard tie was tried on the Philadelphia & Reading Ry., ¾ mile of main track in Philadelphia being laid with these ties in the summer of 1891. The track was laid with 80-lb. rails, in slag ballast, and the traffic averaged about 260 trains per day. It was found that the ties worked up and down in the ballast and it became difficult to keep the track in line and surface.

In the designing of all or nearly all the metal ties which have been experimented with to any extent, economy of material has been the principal aim rather than the production of a tie properly shaped for the conditions which it must meet in service. This statement is made with the full understanding that thousands of miles of track laid with metal ties are now in service in foreign countries, with evident satisfaction. The type of tie which appears to meet with most favor abroad is a tie of trough section, laid open side downward, and not departing widely in principle from the Hartford tie, which was tried on the New York Central R. R. Notwithstanding this fact it is doubtful if any tie of this pattern can satisfactorily fulfill the maintenance requirements of the railroads of this country, considering the weight of our rolling stock and the climatic conditions prevailing. In attempting to distribute a minimum quantity of metal to obtain the required stiffness, the tie of trough section seems to respond most readily to this one requirement, but it is the worst possible form of tie for the operations of track surfacing. Granting that the tie will eventually settle itself into the ballast until a compact bed is formed, the difficulty is found in tamping such a tie with any degree of facility and effectiveness when low portions of the track must be raised and surfaced. Suppose that a tie is raised an inch or such matter and the ballast is to be tamped up to hold the tie. As it would be impossible to force the ballast into the crescent-shaped cavity next the tie surface, with either a tamping bar, tamping pick, or any other tool known to the occupation of a trackman, it becomes necessary to break up the core of material filling the entire cavity on the under side of the tie, thereby destroying its compactness, which is the essential quality required to hold the tie in its raised position. While it is true that in the use of the tamping pick in stone ballast, in a small lift, it becomes necessary to break up the old bed to some extent in order to tamp the tie, nevertheless such disturbance does not extend to any considerable depth into the ballast, and the force of the pick is exerted against a layer of material in immediate contact with the bottom face of the tie—which cannot be the case in tamping a tie of trough section. During the early months of 1901 the Bess. & Lake Erie R. R. laid 2135 ft. of main track with steel ties, near Osgood, Pa. These are of inverted trough section, with flaring sides, top face 5 ins. wide and the sides 3½ ins. deep. The ties weigh 208 lbs. each. Fully realizing the difficulty of properly tamping them with the customary tools, use has been made of air-blast apparatus, consisting of a No. 3 Root blower clamped to the rail and turned by two hand cranks. The ballast is slag and tamping is done by raising the ties and blowing pulverized or finely broken slag under them. Figure 483A shows a stretch of this steel-tied track, with the air-blast machine in position for service. Some details of the design and operation of air tamping machinery are given in § 85. The use of the same with wooden ties, where the conditions are most favorable to its operation, has been only experimental.

The tie of ideal shape, and, in fact, the only one which can properly perform the functions of a tie, is one having a flat bottom easily accessible for tamping, and the under face of the tie should be straight. If the tie dips in the middle a cavity is formed in the ballast to collect and hold water, to be churned by the trains; and whether the middle of the tie be curved downward or upward, the uneven bed must form a serious obstruction to the work of throwing the track to its proper alignment from time to time. To do good service a tie should also have depth, for if there be not a considerable depth of filling between the ties the layer of ballast immediately adjoining the bottom face of the tie, especially after the tie

Fig. 483A—Air Blast Apparatus for Tamping Track, B. & L. E. R. R.

has been newly tamped, is easily shaken out of place by the action of moving trains. Depth of tie is also required in order to obtain the necessary stiffness, but the scheme of deepening the tie and forming it of thicker metal calls, of course, for more material, and the additional metal required may encroach upon the margin of cost which decides the economy of the metal tie. It is perhaps but a truism to propose that a metal tie with a flat, straight bottom face and with depth and stiffness equivalent to these features of the wooden tie, would serve as well as the wooden tie for a track support; and such requirements will probably have to be met before the metal tie can successfully cope with the conditions which obtain on American railroads. That the tie should contain but few parts and be so designed that it can be produced with but little hand labor goes almost without saying.

Of the commercial shapes the T-bar and the I-beam seem best adapted to the requirements of a metal tie, as the desired stiffness can be obtained with a moderate weight of metal and the bottom face of the tie is of the right shape to properly support the track and admit of tamping by practicable means. The Bidwell steel tie is designed as an inverted T-section, to be rolled from soft steel, with a base 8 ins. wide and $\frac{3}{8}$ in. thick and a vertical leg of the same thickness and 4 ins. high. The support for the rail consists of a plate bent into the shape of a "U" and inverted over the vertical leg and riveted to the bottom leg. The vertical leg of the tie is notched for the rail seat, and the fastening consists of a lip in the top edge of this leg, for one side of the rail flange, and a clasp attached to the vertical leg, on the other side. A section of track in the Kansas City yards of the Chicago & Alton Ry. was laid with these ties in 1897, the T-shape being formed by riveting together two angle bars. The Chester steel tie, laid experimentally on the Huntingdon & Broad Top Mountain R. R., at Huntingdon, Pa., in 1899, consists of three separable parts, being composed of an inverted steel T-bar 6 ft. long, reinforced by a section of inverted trough placed transversely at either end to afford extra bearing and support for the rail. The horizontal leg or bottom of the T-bar is 4 ins. wide and the vertical leg 3 ins. high, the latter being mortised for rail seats at the proper gage, while the trough-shaped base pieces are slotted to hold firmly to the T-bar and in a manner to form the rail seat; or, in other words, the T-bar extends through a slot in each leg of the inverted-trough base pieces. Each base piece has two lugs struck up to engage and clamp the inner flange of the rail, and the mortise or notch in the vertical leg of the T-bar is cut under so as to form a hook or projecting clip to clamp the outer flange of the rail. This notching of the T-bar prevents the rail from being crowded out of gage, either outward or inward. The rails are thus attached to the ties without a bolt, wedge, clip, pin or other loose fastening. The thickness of metal in the T-bar is $\frac{3}{8}$-in. and each base piece is 10 ins. long and 10 ins. wide, with depending flanges 5 ins. deep, the thickness of the metal being $\frac{3}{8}$ in. The weight of the T-bar is 53 lbs. and the total weight of the tie is 90 lbs. The Bidwell steel tie was illustrated and described in the Railway and Engineering Review of March 25, 1899, and the Chester steel tie in the issue of Dec. 30, 1899, where further details are to be found.

The I-beam principle of steel tie design has been applied by Roadmaster C. Buhrer, of the Lake Shore & Michigan Southern Ry. The original idea with Mr. Buhrer was to utilize scrap material exclusively by rerolling old rails, the head of the rail to be spread out into a flange 8 ins. wide, to form the bottom face of a tie somewhat shallower than the original rail section. Facilities for rerolling rails in this manner were not, however, in commercial use, and some question was raised as to whether such a shape could be cheaply rolled. When it came to the question of providing ties for an experiment, the quantity not being large enough to induce the mill people to roll them to shape out of old rails, the bottom face of the tie was formed by riveting a steel plate to the head of the old rail. The tie was then inverted, the base of the old rail serving as the top face of the tie. The fastening devised was simple and secure, consisting of ordinary clips held by bolts passed through the upper flange from below. To assist in holding the tie in alignment, or from shifting longitudinally on its bed, depressions were made in the lower flange, under each rail seat. In the spring of 1901 a stretch of 300 ft. of track was laid with ties $8\frac{1}{2}$ ft. long made in this manner. The location is on a curve about $2\frac{1}{2}$ miles east of Sandusky, O., where all the trains run at a high rate of speed. The ties were made of 65-lb. scrap steel rails and were laid at 2 ft. centers to replace wooden ties 7 ins. thick. The steel ties being only $4\frac{1}{2}$ ins. deep, the work of tamping the new bed was carefully done, but after that no particular attention was given to them. These ties have held the rails in good gage, alignment and surface, and, so far as service is concerned, they have given excellent satisfaction. Being shallower, they are tamped with less labor in digging out the ballast than is required for wooden ties, and as the bottom face is wide and flat the work of tamping has been just as efficient in holding the surface as it is with wooden ties. These ties admit of nearly, if not quite, as much flexibility of use as wooden ties. They can be put into the track as cheaply as wooden ties, and they can be used promiscuously to replace decayed wooden ones, tie for tie, in the same manner that wooden ties are placed in renewals. It is not necessary to lay them out of face. On these ties a rail can be exchanged or the rails can be shimmed in winter, as readily as on wooden ties.

If the cost of ties made by utilizing the material of worn-out rails could be kept within an economical limit the proposition would certainly be enticing. The weight of this tie is one of the chief points of criticism. If made 8 ft. long, from an old 65-lb. rail, the weight would be about 160 lbs. Of course it is to be considered that the scrap value of the tie when worn out and removed from the track would be an important item. The quantity of metal then available would be the original weight less only that lost by corrosion. Taking one year with another, the value of scrap rails to a railway company is quite variable. In past years there have been times when 160 lbs. of scrap rail metal would not net the railway company more than 80 cents. At 4 per cent the annual interest charge on the material in each tie, at this value, would be only 3.2 cents, which would be quite reasonable, but the average price of scrap rail steel is higher than the figure stated, and in making cost comparisons with ties of different design or of lighter weight the expense of transporting the material to and from the mills, the cost of rerolling, and the final loss by corrosion in the track (which might be little or much, according to the character of the soil or of the ballast) should be taken into consideration. Without actually attempting to reroll the old rails into ties, estimates on that item would, of course, be only speculative. The excellent service which the experimental steel ties have given on the L. S. & M. S. Ry. suggests that the design is worthy of careful investigation. It might be that old rails of considerably lighter weight than 65 lbs. per yd. could be worked over into ties of sufficient strength, or it might be found that the ties could be rolled direct from new metal at an economical figure.

Composite Steel and Concrete Ties.—The cheap cost of concrete and its durability have been taken into account in the study of substitutes for wooden ties, and experiments with this material have been undertaken on several roads. The general idea is that the concrete should be reinforced with a steel member or framework of some kind, more especially to prevent breakage from center binding or heaving, and to hold the material together in case of fracture or breakage, thus securing the gage. So far as direct compressive stress is concerned the concrete is regarded to be reliable. About the first experiment in this direction was made in Chicago, with some ties designed by Mr. J. J Harrell and put into the main track of the Pittsburg, Ft. Wayne & Chicago Ry., near the Union station, in the summer of 1899. The design consisted of concrete molded around a truss of 1-in. rods, put together on the style of a trussed pipe brake beam. The ties were 7 ft. 4 ins. long, 8½ ins. deep under the rails, 10 ins. wide on bottom under the rail seats and 6 ins. wide on bottom under the middle portion of the tie. The ties were 30 in number laid under 85-lb. rails in broken stone ballast, on a curve of 6½ deg. The traffic over the ties was very heavy, consisting of the east-bound passenger trains of the road named and all the west-bound passenger trains of the Chicago, Burlington & Quincy and the Chicago & Alton roads. Although it became apparent quite early that the life of these ties would be short, they nevertheless outdid the expectations of some by lasting 17 months before they were removed from the track, and the experiment was instructive. Two or three of the ties cracked transversely at the middle, the appearances indicating that they had become center-bound and were unable to stand up under the loads. The greatest difficulty, however, was with the fastenings, which consisted of bolts set in the concrete, with ordinary clips for holding the base of the rail. These bolts became loose in the concrete and the side thrust and working of the rail shattered the material under the rail seats, which consisted of a steel plate embedded in the concrete.

Encouraged by this experience Mr. Harrell redesigned the tie on improved lines. In the later pattern the metallic core or frame consists of a steel web plate $\frac{1}{4}$ in. thick, 7 ins. deep and 7 ft. 8 ins. long. The upper corner of each end of this plate is slitted and lopped over each way. The plate is also perforated at frequent intervals by punching out square holes and bending over the tongue of metal, to give the frame a firm hold in the concrete. The bearing for the rail consists of a plate 5 ins. wide, 14 ins. long and $\frac{3}{8}$ in. thick, resting upon the top of the steel web and upon the concrete. The fastening for each rail consists of a pair of straps riveted to the web plate and projecting up through the tie plate or rail seat. The rail is held to the plate by spring links which straddle the straps and are held in place by common track spikes run through slots in the straps after springing the links down with a bar. The tie is 8 ft. long, over all, and $8\frac{5}{8}$ ins. deep. Each end of the tie, for about one-third of its length, is 9 ins. wide on bottom and 5 ins. wide on top. The middle third of the tie is 5 ins. thick, and the bottom corners of this portion are rounded, to restrict the bearing surface and prevent center-binding. The tie weighs about 300 lbs., of which 55 lbs. is metal. The concrete is made of crushed limestone and Portland cement in a very wet mixture. The proportion of the materials is the result of a good deal of experimenting, and it differs materially from that of concrete for ordinary building construction, in that no sand is used. The stone for the mixture is "crusher run" of $\frac{5}{8}$ in. size and smaller, no attempt being made to separate the dust, which was found to produce a stronger concrete than could be made by the use of sand. Some of these ties are laid in a side-track of the Pennsylvania Lines, at Hegewisch, Ill.

In 1901 the Pere Marquette R. R. began experimenting with a composite tie of concrete and steel construction designed by Mr. Geo. H. Kimball, at that time chief engineer. The tie consists of two bearing blocks of concrete each 3 ft. long and shaped like a pole tie. Each of these blocks is 7 ins. deep and the face is 9 ins. wide. Each pair of concrete blocks is joined by two 3-in. channels placed 2 ins. apart, back to back, and molded in with the concrete. The general arrangement and details are illustrated in Fig. 484. The bearing of the rail is taken by a 4x9-in. white oak cushion block 18 ins. long. This block is secured to the concrete base by $\frac{1}{2}$-in. square bolts molded into the concrete block and jointed at the top surface thereof by means of a screw socket. The top head of the bolt is countersunk into the wood and the space around the same is filled with pitch, to exclude water. The wooden blocks are treated with carbolineum. To these blocks the rail is spiked in the usual manner, but the use of clips, as shown at the left of the middle engraving, has been considered. In places where a wooden block is used that is thinner than the length of the spike, elm plugs are molded into the concrete block and bored for the spikes. Against the outside end of each oak block there is a concrete shoulder, to prevent spreading of the gage should the block become loose. The method of connecting the anchor bolts to the channels is made clear in the sectional view. The pin for this connection projects into the concrete about one inch from the side of the channel, thus giving the channel a secure hold in the masonry. The exposed surface of the channels, between the concrete blocks, is protected by two coats of Portland cement mortar spread on thin, and to further protect the steel from corrosive action the space between the channels is filled with concrete. The concrete in the bearing blocks consists of two parts of Portland cement, one part sand and three parts of ¾-in. screened gravel. The blocks are molded to the ends of the channels under a pressure of 10 lbs. per square inch. The weight of the tie is about 452 lbs., including 68 lbs. of metal, 374 lbs. of concrete and 10 lbs. of wood block, and the cost was $1.46 each, including 50 cents for concrete and labor of molding. In 1902 three quarters of a mile of track in Jefferson St., Bay City, Mich., was laid with ties of this design without the channel bars. The Pere Marquette R. R. enters Bay City by this route, and as the street is paved, special construction of a permanent character was desirable. The ties were laid in cement mortar upon a bed of concrete 9 ins. deep, being set to a true grade with an engineer's level, and after the track had been put to surface the space between the ties up to the level of base of rail, was filled in with concrete. On this was placed a 1-in. bedding for the paving blocks. As the concrete ties or (properly speaking) supporting blocks abut against the foundation of the pavement, it is impossible for them to become separated or spread farther apart, and the steel channels were therefore omitted. The oak cushion blocks were the only perishable material used, and they are renewable.

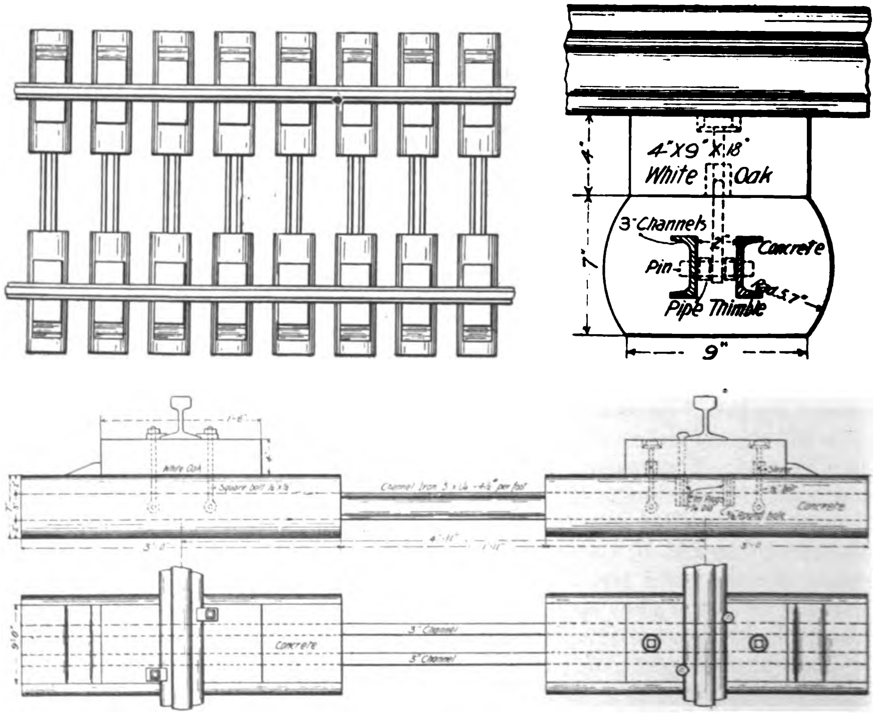

Fig. 484.—Kimball Composite Steel and Concrete Tie, Pere Marquette R. R.

Another idea applied in composite tie construction is to place a stiff steel member in the top of the tie, to take the bearing of the rails and hold the fastenings. The body of the tie then consists of concrete molded to the under part of this top member. This design is the invention of Roadmaster C. Buhrer, of the Lake Shore & Michigan Southern Ry., and in the spring of 1902 a number of ties so constructed were laid in the main track of that road, near Sandusky, O. These ties were made by molding a concrete body or base to the head of an inverted piece of old 65-lb. rail, but for economy of metal a lighter rail might be used, or an I-beam or other shape of lighter section might be found to answer the purpose. The first ties put into service are 5½ ins. deep and 8 ins. wide on the under face, except at the central portion, which is narrower, so as to avoid full bearing and liability to center-binding. The fastenings consist of bolts and clips applied to the upturned base of the rail, as is done with the Buhrer steel tie. Buhrer composite ties of later design are 6½ ins. deep and 8 ins. wide on the bottom face. Trial sections of main track have been laid with these ties on the L. S. & M. S. Ry., at many points; on the Chicago & Northwestern Ry., at Milwaukee; on the Lakeside & Marblehead R. R., at Danbury, Ohio, and on other roads mentionel in § 210, Supplementary Notes.

The Adriatic Ry., in Italy, is using a number of concrete-steel ties, the cross section of which is like a triangle with the corners cut off. The ties are 8.53 ft. long, the bottom width is 7.87 ins., and at the rail seats the top face widens out to the full bottom width. The concrete consists of a mixture of cement and sand in the proportion of 121 to 165. The reinforcement consists of 28 round steel rods running straight through the tie longitudinally. The aggregate cross-sectional area of these rods is 3 sq. ins., and they are distributed (as seen sectionally) in two horizontal rows, near the bottom face of the tie, and in three rows vertically along the middle part of the tie; in other words, the general shape of the reinforcement is like an inverted "T." Each tie weighs 287 lbs., including 88 lbs. of metal, and the cost ranged from $2.16 to $2.40.

One question which arises in connection with the use of concrete for tie material is the effect of derailments. It is not an uncommon occurrence for the wheels of freight cars to become derailed and run over the ties for several miles before the accident is discovered. In such cases wooden ties, although cut by the wheel flanges, are not usually rendered unfit for service, but the ties get severely bumped, and it is a question whether ties with exposed concrete in the top face would not be shattered or broken up by such rough treatment. In the Buhrer composite tie the top face of steel seems well designed to protect the concrete in case of derailment.

Although it seems unlikely that the day for the general introduction of metal ties in this country is near at hand, yet industrial conditions are continually changing, and the possibilities in the field certainly suggest the wisdom of careful study and experimentation along such lines. One serious obstacle to the general use of an all-metal tie would be found in the difficulty of insulating the rails for the track circuits of automatic electric block signals, which have been extensively adopted on American railroads. In such signal systems track circuits are much preferred to wire circuits. Possibly some means of overcoming this difficulty could be found, and the problem invites careful study. The solution might be found to satisfaction in some form of composite tie. The Kimball tie of the Pere Marquette R. R. (Fig. 484) insulates the rails. The experience with metal ties in foreign countries, in some of which they have been used extensively, is treated at some length in § 203, Supplementary Notes.

170. Lag Screws vs. Spikes.—Every now and then some ingenious man, casting about for opportunity to work an improvement in track construction, hits upon the track spike and finds something to say condemnatory of its use. It is a fact, however, that the shortcomings of the spike as a track fastening, such as they are, were discovered as long as a generation ago, or longer, and at an early date numerous attempts were made to substitute a better form of fastening. The result of it all has been that the old-fashioned hook-headed spike still remains practically the universal form of rail fastening for wooden ties, at least in this country; and, judging from the degree of satisfaction which it gives, the field for track improvements would appear to be wider in other directions. It is quite safe to say that if among track devices there be one that is remarkable for its simplicity, cheapness, durability, convenience of application and general efficiency, which has served its purpose from the first, and is still fully meeting that purpose, it is the track spike.

The principal objections urged against the use of the spike are two, namely: that it has less adhesion to the tie than some proposed forms of fastening, and in time is worked up from the rail flange by the undulations in the rail; and that in process of driving it crushes the fibers of the timber immediately surrounding it, which operates not only to destroy to some extent the adhesive qualities of the fiber, but also weakens the fiber against the lateral displacement of the spike, thus tending to permit spreading of the rails. It is worth while to analyze these objections and try to discern their real importance, for much needless anxiety and study arises from exaggerated ideas of the service required of a track spike and the conditions under which it is applied.

In the first place, the principal duty of a track spike is not adhesion to the tie, but to hold against lateral displacement—the tenacity with which the spike resists pulling from the tie is relatively of small importance. On tangents the duty required of the spikes is mainly to establish the alignment of the rails, and not so much to maintain it, for if such track be kept in fair surface there is little or no tendency for the rails to spread, and the spike is not subjected to lateral pressure of any account. Elsewhere in this volume it is pointed out that, so far as the safety of the track is concerned, under normal conditions, it would not matter if two-thirds or three-quarters of the spikes on tangents were pulled from the ties. On curves, however, the duty of the spikes in maintaining the alignment is of prime importance, for they must hold the rail against lateral displacement by side pressure from the wheels and the centrifugal force of the cars that is due to speed. Still this duty, important as it is, is imposed by only the one tendency to lateral displacement. The familiar supposition that the spikes must resist an overturning tendency in the rails is not warranted by the facts. If such was the condition imposed the spike would indeed be a poor form of fastening to prevent the overturning of the rail.

While it is true that the canting of the inside rail of curves is of frequent occurrence it is elsewhere explained that such tendency arises from the crosswise skidding of the wheel tread on the top of the rail, tending of course to overturn the rail, but being entirely too small a force to lift the inner corner of the rail flange. The resultant of the forces acting upon the rail always passes well within the rail base, and whatever tendency there is to overturn the rail is too small in comparison with the weight acting vertically downward to cause the lifting of one side of the rail flange. The result which the overturning tendency actually does accomplish is an unequal distribution of the weight on the rail base, which of course, acts more severely on the fiber under the side having the preponderance of weight, so that the compression of the fiber on that side is greater, and under certain conditions already made clear the rail gradually assumes a canting position, which is augmented with time. It should be noted, however, that it is the unequal wear or depression of the wood fiber which permits the tilting of the rail, and such action would take place just as rapidly with any other form of fastening, no matter how firmly the rail could be united with the tie. That it does take place without any apparent resistance from the spikes is therefore no indication that the spikes do not fully perform their duty. The gist of the matter is that on curves which are properly elevated the resultant of the forces on each rail passes through the center of the rail base, or very near to it, and under no conditions obtainable in ordinary practice is there an uplift on the inner side of either rail. The adhesion of the spike against an upward pull is therefore of no practical consequence, so far as concerns the point discussed. Ignorance of, or indifference to, this fact accounts for the sometimes needless practice of plugging the holes of spikes pulled and redriven in the same holes on the original line, as in renewing rails with same width of base. Some even go so far as to plug the old hole and set the spike in a new position, to obtain better adhesion, which is not required. If the alignment or gage of the rail is not to be changed by the spikes, it is better practice to redrive the spikes in the old holes without plugging, for while the adhesion is not so great as with a spike driven in a plugged hole or in undisturbed fiber, the lateral resistance to the spike is not impaired by pulling, if it is properly done.

The uplift of the rail in its undulations is resisted by the spike, and it must be admitted that to fully perform this duty the adhesion is not quite sufficient. Gradually the spike becomes lifted, even in ties of the hardest woods, especially after the tie has become somewhat deteriorated, until the head of the spike will sometimes stand ¼ in. or more clear of the rail flange. In ties sound enough to remain in the track, however, it is not usually the case that the lifting of the spikes becomes excessive. While there are those who claim that the rail should have free play vertically to the extent of its undulations from wheel loads, so as to prevent the lifting of the ties from their beds, it is doubtful if the supposed benefits from such practice can be substantiated. It must be considered that unless the rails are firmly anchored to the ties the amplitude of the undulations will be increased, which will facilitate creeping of the rails in two ways, namely, by accelerating their creeping action, and by removing an obstruction thereto, for if the spikes are kept tightly driven the ties will powerfully resist the creeping of the rails. To hold the spikes to their work it is necessary to go over the track at least once a year and drive down a large portion of them, which is, of course, a matter of some expense. It should not be understood, however, that such work becomes a pressing necessity.

It now remains to refer to some of the devices which have been contrived or introduced with a view to hold the rail firmly to the tie. The Bush interlocking bolts were devised and experimented with as early as 1882, on a number of roads, but have never come into extensive use. These bolts are shown as Fig. 490. They are inserted into holes bored in the tie at an angle of about 45 deg., and in such directions that their center lines nearly intersect in the interior of the tie, underneath the rail. The boring is done by means of a machine clamped to the rail, and the proper position and angle of the holes are fixed by the set of the bits. The lower portion of each bolt is notched out, to provide for the reception of the other bolt, so that when crossed and drawn home the bolts interlock. As it appears in the figure, to show the manner of interlocking, the right-hand bolt has not been drawn entirely home. One of the bolts must be turned after it has been driven across the other bolt, and by tightening down the nuts on the beveled clips the shoulder on each bolt pulls against a like part of the other. To remove the bolts the nut on the right-hand bolt is slackened and the bolt is driven in, to permit the withdrawal of the left-hand bolt, when the other can be freely withdrawn. The first cost of such a device is a considerable item, and it does not take a practical trackman long to discover that it is far from being a perfect track fastening, if indeed it amounts to any improvement at all over the track spike. While it is true that it ought to be capable of holding the rail very firmly to the tie, still any cutting of the rail into the tie removes the rail flange from the gripe of the clips, which cannot be made to follow up the recession of the rail without removing the clips and adzing the tie. Experience with track bolts also teaches that a nut placed upon a vibrating body, like a rail, is a difficult device to maintain in proper adjustment, so that, all things considered, a great deal of labor would be required to maintain the rail in close union with the ties with a fastening of this class.

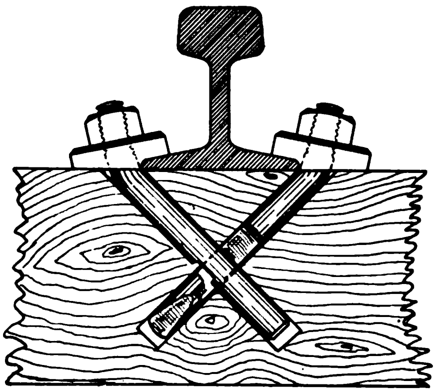

Fig. 490.

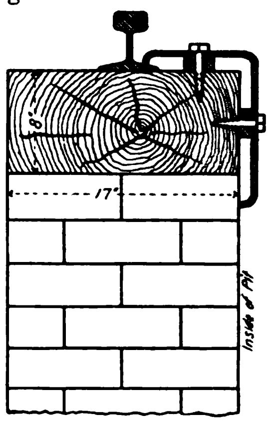

Fig. 490 A.

A simpler form of fastening which has been proposed, and tried to a limited extent on the New York Central & Hudson River R. R. and on some of the elevated railway tracks, consists in the use of clips and lag screws, on the arrangement shown in Fig. 491. Holes are bored in the tie at the proper slant and the lag screws are turned down upon the beveled clips. Each clip has a shoulder to oppose the lateral thrust of the rail flange, and the clip is slotted to permit a lateral movement of ½ in. in either direction, to provide for adjustment of the gage without resetting the screw. It is clear that the first cost and the cost of application of such devices would be greatly in excess of the cost of spikes, with no prospect of permanent results superior to those obtainable by the use of spikes. It is plain to be seen that any cutting of the rail into the tie would destroy the integrity of the fastening, and should the rail cut into the tie a depth equal to the thickness of the edge of the flange, the clip then presents no backing against the rail, and on curves the rail would cut under the clip and spread, as shown in Fig. 492, unless such cutting action of the rail was closely followed up by adzing the ties and resetting the clips. In this respect, therefore, the clip and lag screw device is inferior, in point of safety, to the spike, because the spike always maintains a backing for the rail flange. Unless used in connection with a tie plate it is difficult to see how any advantage could accrue from the use of clips and lag screws.

While it is generally considered that the track spike is not a perfect fastening it may be said without reserve that it answers the purpose better than any other device yet produced. It is the least expensive, and it may be applied and withdrawn with less labor than is required with any other form of fastening. It consists of but a single part and it cannot get loose and rattle. If on sharp curves or on curves with soft-wood ties the spike, or resort to double spiking, be not equal to the lateral thrust of the rail, the situation cannot be misleading to any competent trackman, and such devices as rail braces or tie plates may be brought to the aid of the spikes.

Considered by itself the lag screw, as a track fastening, is hardly superior to the common spike, for while it has greater adhesion in the timber, tests have shown that it meets with less resistance to lateral displacement from the wood fiber than a spike of square cross section presenting the same projectional area against the fiber. The results of some tests made in the Pittsburg testing laboratory, as published in the Railroad Gazette of Oct. 15, 1897, show that in pine wood a screw with sectional area of 0.45 sq. in. met with 67 per cent, and in oak wood 96 per cent, of the lateral resistance offered to a spike having a sectional area of 0.37 sq. in.; in cedar the lateral resistance to the screw was only 58 per cent of that offered to the spike. In European practice lag screws are very commonly used as track fastenings, in substitution for spikes, but it is quite commonly understood there that a fastening of square cross section offers more resistance to displacement of the wood fiber endwise the grain than a fastening of circular cross section. Accordingly, it is very largely the practice on European roads to use screws for gage-side fastenings and spikes for outside fastenings, as the latter afford better security against spreading of the rail.

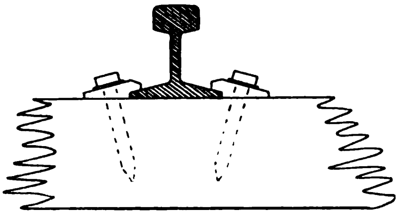

Fig. 491.

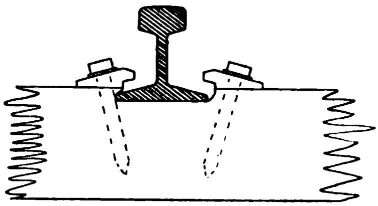

Fig. 492.

Although the adhesion of the spike in the timber has been shown to be of relatively small importance, it may nevertheless be of some interest to state briefly the results of some tests published in the journal of the Engineering Society of the University of Iowa, in September, 1891. It was found that the force required to draw spikes was somewhat variable, even with the same spikes in the same tie, due quite probably to variability in the density of the fiber in different parts of the wood. Discovery was also made of the fact, already very well known to any trackman or other person who has handled a claw bar, that while pulling a spike the adhesion in the wood decreases very rapidly after the spike has been started. In 20 tests with common track spikes newly driven 4⅜ ins. deep into a seasoned Missouri white oak tie, the average resistance to starting was 5514 lbs. The spike used for experiment was 5½ ins. long, and $^9/_{16}$ in. square, in section, with a point ⅞ in. long. In nine tests with spikes driven into the same tie in a ½-in. bored hole the average resistance to starting was found to be 4936 lbs. Compared with tests on an unseasoned white oak tie the results are quite interesting. In tests with seven spikes driven into this tie the average force required to start the spike was 4706 lbs., but when driven into a $\frac{1}{2}$-in. bored hole the average resistance to starting was 6140 lbs. The average force required to start spikes from unseasoned white cedar ties was 1140 lbs., and the average force required to start spikes driven into a $\frac{1}{2}$-in. bored hole in the same tie was 1400 lbs. The force required to start a $\frac{5}{8}$-in. lag screw set in a $\frac{1}{2}$-in. bored hole in a seasoned white oak tie to a depth of $4\frac{1}{2}$ ins., was 8037 lbs.; a $^9/_{16}$-in. lag screw set in a $^7/_{16}$-in. bored hole 3 ins. resisted starting with a force of 6480 lbs. A $\frac{5}{8}$-in. lag screw set in a $\frac{1}{2}$-in. bored hole in a yellow pine tie to a depth of 4 ins. resisted starting with a force of 3800 lbs.; and a $\frac{5}{8}$-in. screw set in a $\frac{1}{2}$-in. bored hole in a white cedar unseasoned tie to a depth of 4 ins. resisted starting with a force of 3405 lbs. While the number of tests performed and the number of pieces of timber selected for the tests were not sufficient to determine results which can be accepted as general, the results do give some idea of the relative holding powers of spikes and lag screws.

It is generally recognized that in driving the common spike having a blunt wedge-shaped point the fiber of the wood immediately surrounding it is injured to some extent, especially the fiber of soft-wood ties. While this injury to the fiber decreases somewhat the tenacity with which it holds the spike, as is shown by the above reports on tests with cedar ties, the most serious objection is found in the impairment of the fiber respecting decreased resistance to the lateral thrust of the spike, and in the greater rapidity with which such fiber will decay by rot; the fiber is also less able to support the spike in case it should be pulled and driven the second time, and the crushed fiber is in that part of the tie where the greatest pressure from the rail occurs. The difficulty may be overcome by boring holes for the spikes, somewhat smaller in diameter than the thickness of the spike. Whether or not such preparation would in all cases increase the adhesion of the spike, it is known that it would greatly improve the resistance of the spike to the lateral thrust of the rail, which is the principal duty of the spike, as already pointed out. In Europe the boring of ties for the spikes has been extensively practiced. Out of 44 European railways replying to an inquiry from the International Railway Congress in 1889, 26 reported that they were boring holes for the spikes.

There should be less difficulty in boring ties for spikes than is commonly supposed, in this country, and the extra expense should be inconsiderable. On divisions where the gage is not widened on curves the holes could be bored by machinery, in the yards, as the ties are being loaded for distribution. There need be no trouble about the joint ties, because a certain proportion of the ties—more than enough to cover the number required for the joints—could be left blank, to be bored by hand as they are placed in the track. Where tie plates are to be used it is only necessary that the holes should be staggered and gaged to correspond to the punching of the plates, which could easily be regulated by boring through templets, which would be required in any case, in order to readily locate the holes at the proper gage distance for the two rails. In boring holes where tie plates are to be used a machine, either hand or power driven, could be arranged to bore both holes for each plate simultaneously, the bits being set to correspond to the relative position of the holes in the plate. In order to embed the plates properly they might be made to follow drift pins fitting the spike holes loosely. On roads where the gage is spread on curves the boring can best be done on the ground, as the ties are placed in the track, using templets made for the particular gage desired. In this way the gage of the rails can be controlled with better accuracy than is the case with ordinary methods of widening it. Those who have experimented with spikes driven in bored holes recommend boring the hole $^1/_{16}$ in. smaller in diameter than the thickness of the spike, and not deeper than the length of the spike exclusive of the head and the portion tapered for the point. It would also probably pay to fill the holes, at the time they are bored, with some liquid wood preserver, thus rendering that part of the tie immune to water, fungi, bacteria or other agencies of decay.

171. Effects of Bad Counterbalancing.—It is generally understood that the wear and tear to track caused by locomotives is in much greater proportion than the ratio of their weight to that of the trains they pull. While the inequality of detrimental effects is not due entirely to the relative magnitude of the locomotive wheel loads, yet extent of loading is one of the important considerations in the case. To start with, then, it will be well enough to look at the wheel loads or static wheel pressures of some of the heaviest locomotives and cars in service. One-hundred-ton locomotives are no longer phenomenal. Road engines weighing 115 to 125 tons are numerous; and there are some (A., T. & S. F. Ry.) weighing 143.6 tons. Engines exceeding 100 tons in weight are in service on a good many roads. Average loads of 12 to 13 tons per driver are quite common, and they have even reached 14 tons (Bessemer & Lake Erie R. R. consolidation engines). The average driving-wheel loads of a large number of locomotives built during the years 1900 to 1902, inclusive, for 30 representative railroads, were as follows: for 4-driver locomotives, 11.1 tons per driver; for 6-driver locomotives, 10.7 tons per driver; 8-driver locomotives, 10.4 tons per driver. The weight of some freight cars of 110,000 lbs. capacity, loaded, is 76 or 77 tons, making a wheel load of about 9½ tons. The wheel load of heavy coaches, sleeping and dining cars is about 4½ tons. The average wheel load of freight cars, is, however, much smaller than the maximum, because a large percentage of the freight cars in transit are hauled empty or loaded under the full capacity. In consideration of this fact it cannot be far from general practice to put the average car wheel load at 5 tons and the average driving-wheel load at 10 tons, observing that driver loads remain constantly the same. Thus, to begin with, the average static loading of locomotive drivers must operate with much greater severity on track surface than the average static car wheel load. The average static driver load is, however, no safe measure of the actual pressure of that wheel on the rail at speed, for reasons now to be considered.

While a locomotive is using steam the distribution of its weight on the wheels is constantly undergoing change. When the engine is working forward the oblique push and pull of the main rod acts downward on the crank pin and upward against the guide bars, on both the up and down strokes, increasing the rail pressure of the main wheel and tending to lift the forward end of the frame from the truck and transfer some part of its load to the drivers; and this changing or shifting tendency is remitted at the end of each stroke of the piston. When the engine is working backward the same action of the main rods tends to pull the front of the engine more heavily down upon the front truck and reduce the rail pressure of the main wheels. Thus from front to rear of engine, while working steam, there are rapidly acting forces which operate to throw the loading of the front truck and drivers out of the normal distribution or balance, and so administer abnormal pressures upon the rails. While the actual fluctuation of loading on the drivers and truck wheels due to this behavior of the engine has not been definitely determined in any case, the matter has been studied to some extent in connection with the subject of rail stresses, and the distribution of the loading is considered to be quite variable.

There is, however, another source of impairment to the track, originating from the action of the moving parts of a locomotive, concerning the relative magnitude of which but little doubt can exist, for in extreme cases, under conditions to be discussed, great and positive injury is done to the track—and that is the action of the locomotive counterbalance. The necessity for balancing locomotive drivers to counteract the centrifugal forces produced by the rotation of the crank pins and side rods is plain. So far as these revolving parts are concerned there is no difficulty in putting the drivers in perfect balance, except for a certain "nosing" effect due to the counterbalance in the wheel and the revolving parts not being in the same plane, which has some tendency to turn the engine sidewise. In order to overcome a certain shaking effect on the engine frame due to the movement of the reciprocating parts, known as "plunging," it is necessary to place additional balance metal in the wheels, or an amount in excess of that required for the revolving parts. The centrifugal force of this excess balance is counteracted by the reciprocating parts only in the horizontal direction, thus leaving the wheels out of balance vertically. Such a condition exists in practically all well built locomotives. The effect of this overbalancing is a tendency in the wheel to revolve not about its geometrical center (the center of the axle), but about its center of gravity, or, providing the centrifugal force is sufficient to overcome the inertia of the wheel, there is set up what might be called a wabbling motion in the wheel. Such wabbling motion actually will take place with any ordinary locomotive driver at sufficient speed, causing it to lift from the rail at one point in each revolution and exert a very great blow or pressure on the rail at another point of the same revolution. The problem at hand in counterbalancing any locomotive is therefore to fully balance the wheels for all revolving parts and use as little additional balance for the reciprocating parts as will serve to overcome disagreeable motions of the engine and relieve the frame and working parts of undue stresses when running at the maximum speed for the service in which the locomotive is intended. In other words, it is impossible to completely balance all the moving parts of a locomotive of ordinary design. If only the revolving parts are balanced the engine will be out of balance horizontally, and if the reciprocating parts are fully balanced the engine will be badly out of balance vertically. Again, the revolving parts at any certain speed have a constant velocity, whereas the velocity of the reciprocating parts is necessarily variable in every stroke. Out of such considerations it is necessary to compromise. The effect of the overbalance vertically is stated above. The effect of the unbalanced reciprocating weight is a tendency at one quarter of the revolution to push one side of the engine forward and at the next quarter the opposite side; and at the third and fourth quarters the racking stresses are respectively backwards.

In actual practice only one half to two thirds of the weight of the reciprocating parts is balanced in the driving wheels. The parts considered as having a reciprocating motion are the piston, piston rod, crosshead and the front end of the main rod, the rear end of the main rod being considered to have a revolving motion. A rule favorably reported upon at the annual convention of the American Railway Master Mechanics' Association, in 1897, and which seems to have been followed quite extensively in general practice, requires the balancing of the drivers on each side for the weight of the reciprocating parts on that side less one four-hundredth of the total weight of the engine. This portion of the counterbalance is to be distributed equally among all the driving wheels on one side, adding the weight of the revolving parts for each wheel separately. This rule takes into account the weight of the engine and assumes that a heavy engine can stand more unbalanced reciprocating weight without detriment to its smoothness of working than a lighter one. Undoubtedly the design of the engine has also some influence on the matter of counterbalancing, as it is generally supposed that an engine with a given proportion of weight on the front truck will stand more unbalanced weight in the reciprocating parts without disagreeable motion or injury to the engine than one with less weight on the front truck. The length of the driving wheel base very likely has an important influence, also; the shorter the base the more readily would the machine be expected to plunge. Thus in some cases it has been reported that with eight-wheel engines in fast passenger service a larger proportion of the total weight of the engine than one four-hundredth has been taken as the allowable unbalanced weight of reciprocating parts on each side, and that an increase in the unbalanced weight can be made in proportion to the length of the engine. At a speed of the engine in miles per hour equal to the diameter of the drivers in inches the increase and decrease of the wheel pressure on the rail in each revolution, due to the overbalancing of the wheel for the reciprocating parts, has been found by calculation to be 38.4 times the weight of the excess balance. In order therefore that the wheel shall not leave the rail at the speed indicated, the portion of the counterbalance allowed for the reciprocating parts must not exceed the static pressure of the wheel on the rail divided by 38.4; and to insure safety such increase or decrease of pressure should be kept within an amount equal to the static pressure of the wheel on the rail.

It does seem like expecting a good deal of track to take for granted that it will stand any wheel pressure brought to bear upon it just so long as the wheel does not lift and drop upon the rail at each revolution, for very heavy rail pressures (approximating to double the static pressure of the wheel) may obtain before actual lifting takes place. It seems as though the matter should receive very careful attention at the hands of both the mechanical and track departments, for the increase of rail pressure from overbalanced wheels, even at moderate speed, must exert a considerable effect upon track surface. The amount of overbalance should therefore be reduced to the lowest possible limits consistent with satisfactory running of the engine and allowable stresses in the parts.

It has been stated that the pull and thrust of the main rod when the engine is working forward increases the rail pressure of the main wheel. This increase of pressure acts with the increase of pressure due to the overbalance of the wheel, and against the lifting force due to such overbalance; which is to say that while the counterbalance is passing below the center of the wheel the centrifugal force of the overbalance acting downward at that time is increased by the downward component of the pull of the main rod, while during the passage of the counterbalance above the center of the wheel the centrifugal force acting vertically as though to lift the wheel is counteracted by the amount of the downward component from the thrust of the main rod. Thus it happens that, so far as the main wheel is concerned, while the engine is working forward, the decrease of wheel pressure on the rail due to the centrifugal force of the overbalance must exceed the static pressure of that wheel by the downward component of the main rod pull before the wheel can lift; while as regards the increase of rail pressure at the downward throw of the counterbalance, the maximum pressure which takes place in the same revolution when the decrease of pressure is just sufficient to lift the wheel from the rail, cannot be less than twice the static pressure of the wheel plus the vertical component from the thrust of the main rod. When the engine is working backward the reverse obtains; that is, the vertical component of stress from the main rod is downward against the guide bars and upward against the crank pin, on both the up and down strokes, and such lifting force on the crank pin operates to diminish the increase of pressure due to the centrifugal force of the overbalance, and to augment the decrease of pressure due to such force; so that the action of the overbalance can pound the track with less severity while passing below the center of the wheel, but the wheel is able to lift from the track at a less speed than when the engine is running forward. Such considerations would make it appear that in the distribution of the counterbalance among the drivers on each side of the engine the main wheel should receive less than its proportionate amount of that part of the balance inserted for the reciprocating parts.

Fig. 493.—Rails Damaged by High-Speed Running, Mo. Pac. Ry.

This brief exposition of some of the forces exerted upon the track, as developed from locomotive operation, must show that all of the shocks or rail pressures which actually take place are very complicated of determination, if not practically indeterminate, for evidently there are many kinds of pressures acting simultaneously. Instances of damage to track by the action of excess counterbalance at high speed have been of more or less frequent occurrence and are sure to take place where locomotives exceed the speed for which they are balanced. Some details regarding damage of this kind will serve to indicate the magnitude of the forces acting. Figures 493 and 494 are views reproduced from photographs of track damaged at one time on the Missouri Pacific Ry., near Jefferson City, Mo. On this occasion the rails on three miles and 2780 ft. of track were badly kinked and had to be removed from the track. The rails on 2190 ft. of track were of 75-lb. section, and on three miles and 590 ft. of track they were of 63-lb. section. The engine was of the consolidation type with drivers (eight) 44 ins. in diameter., the weight on the drivers being 45 tons. At the time the damage occurred the engine was not pulling a train, and is supposed to have been running between 45 and 50 miles per hour. The rails were sharply kinked at intervals corresponding to the driving wheel circumference, the kink in all cases being vertically downward and inward toward the center of the track, as indicated by the loose rail in Fig. 494, which was removed from the inside of the curve and placed in the middle of the track for the purpose of photographing. The two views show that the damage was inflicted alike upon curves and tangents, and the view of the straight line forcibly reminds one that the stresses which must have acted upon the bridge shown were undoubtedly in excess of anything calculated upon in the design of its members. It is somewhat interesting to notice that in all cases of track damaged in this manner the lateral bending of the rail is inward, or toward the middle of the track. This phenomenon is probably explainable on the fact that the pressure from the wheels is applied inside the middle line of the rail head, thereby causing it to swerve inward as the rail is kinked downward.

Similar damage has been observed to take place in hauling "dead" locomotives with the side rods taken down, or when running engines with only one side connected, even at a moderate rate of speed; which is easily explained by the fact that the removal of the rods leaves the wheels very heavily overbalanced, the entire counterbalance then being excessive where the side rods are removed. By way of illustration, a six-wheel engine of the Wabash R. R. with side rods disconnected, in being hauled to the shop in a freight train, between Huntington and Andrews, Ind., pounded the track so heavily that 772 rails had to be removed, 10 of them being broken. The engine which did the damage had 56-in. drivers, and the train was running at a speed of 40 to 45 m. p. h. The rails were "kinked" or surface-bent at points a uniform distance of about 15 ft. apart, and the depressions were nearly all from the outside of the rail head, as though the engine had delivered a blow diagonally downward and inward to the track. The weight of the rail was 63 lbs. per yd., and out of the 772 damaged rails 600 were on one side of the track, none on this side escaping punishment; on the other side the indentations were scattered, and not generally opposite those on the other side. Some roads have a rule that the maximum speed of freight trains hauling "dead" or disconnected engines shall not exceed 20 m. p. h. It is required on a number of roads that side rods must be in position on locomotives while in transit, the rule having special reference to new engines hauled in the freight trains.

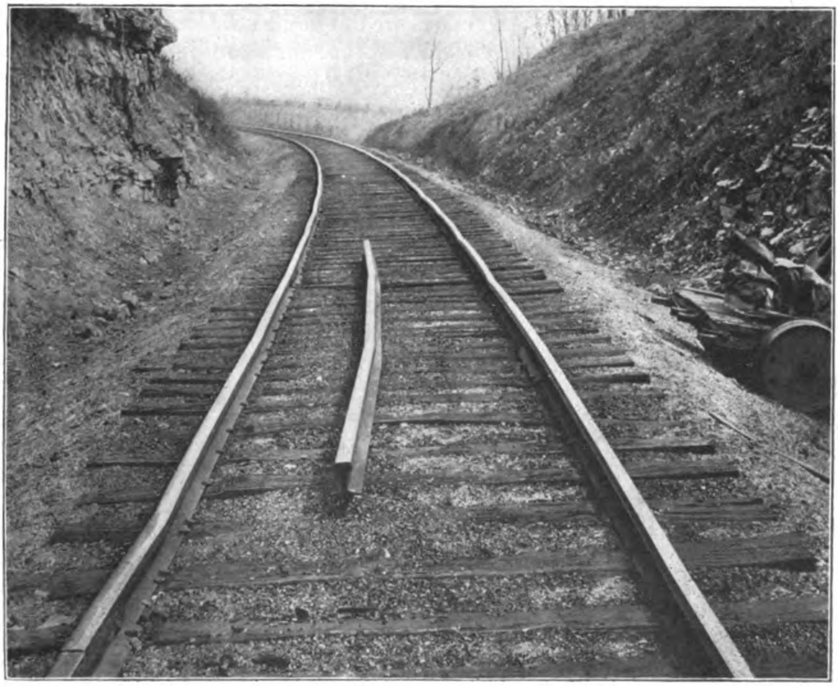

Fig. 494.—Rails Damaged by High Speed Running, Mo. Pac. Ry.

It is also to be expected that an improper distribution of the counterbalance among the drivers will lead to excessive pressure from the driver most heavily overbalanced under the conditions imposed. As a matter of fact it appears that in nearly all cases where injury has been done the track from counterbalance effects, the damage has come from only one wheel on each side of the engine.

That a wheel carrying excessive counterbalance will actually lift from its support at high speed was proved by Professor W. F. M. Goss in some experiments conducted in the mechanical laboratory at Purdue University. Lafayette, Ind., in 1893. The details of these experiments, which are exceedingly interesting from the standpoint of the maintenance of way engineer, are stated in § 204, Supplementary Notes.

In a preceding paragraph it is stated to be impossible to completely balance all the moving parts of a locomotive of "ordinary design." It is practicable to so design a locomotive that the reciprocating parts will be in balance, and for many years a few mechanical engineers have urged such construction. With the reciprocating parts in balance no overbalance of the driving wheels is necessary. In that case the drivers are counterbalanced for the revolving parts and all of the working parts are then in balance. The famous 20,000th locomotive of the Baldwin Locomotive Works, completed in February, 1902, and prominently known in connection with the seventieth anniversary of the operation of that institution, was built in this way. This was a 10-wheel passenger engine for the Plant System (No. 119). It is a four-cylinder compound machine, the two low-pressure cylinders being outside the frame, in the usual place, and the two high-pressure cylinders between the frames or between the two low-pressure cylinders, being cast with the saddle, so that the axes of the four cylinders are parallel and in the same horizontal plane. The pistons of the outside cylinders are connected with crank pins on the main wheels (which in this case are the front drivers), in the ordinary way, and those of the inside or high-pressure cylinders with cranks in the main axle. The crank in the axle and the crank pin on the driver for the corresponding high and low-pressure cylinders are set 180 deg. apart, so that the two sets of pistons, piston rods and cross heads on each side of the locomotive simultaneously move in opposite directions. As the weights of these reciprocating parts for the high and low-pressure cylinders are made nearly the same the working parts are almost perfectly balanced. As each driving wheel is counterbalanced for its own rotating weight and for no reciprocating parts there is therefore no unbalanced rotating weight in the wheels, and no "hammerblow" effect. In 1903 the Atchison, Topeka & Santa Fe Ry. had in service four balanced compound Atlantic type passenger locomotives built with a crank main axle and designed in this way; but it is questionable whether such features of design will come into general service in this country, for the crank axle has always been objectionable from the American point of view.

172. Longer Rails.—Just why 30 ft. came to be so universally adopted as the standard length for track rails in this country is not a matter of record, but it may readily be surmised that convenience of transportation had a good deal to do with it. For many years the length of ordinary flat cars was such that a rail longer than 30 ft. could not be conveniently handled thereon in shipment; and it is also probable that in the early rolling mills a sufficient quantity of metal for making a rail longer than 30 ft. could not be handled in a single ingot. However this may have been such difficulties no longer survive, but 30 ft. remains the general standard length of rail. The one great advantage to be obtained in the use of rails longer than 30 ft. is a decrease in the number of joints. In order to eliminate joints or the effects of the same, three lines of improvement have been proposed and experimented with to some extent, namely: (1) to rivet the rails together at the joints, continuously, without allowance for expansion; (2) to firmly unite the rails at the joints, in stretches several hundred feet in length, without allowance for expansion, by providing slip joints or devices to receive the expansion at the ends of the sections; and (3) to increase the length of the rail considerably, say 50 to 100 per cent.

Although it is commonly the practice in street railway construction to butt the rails closely end to end, with no allowance for expansion, no well informed trackman would be guilty of suggesting such construction for the ordinary type of track on steam roads. In street car tracks all except the top of the rail is covered by the earth or by the pavement, so that on a hot day the rail readily loses its heat by conduction. It is further to be considered that the street railway track is firmly held by the earth or pavement that is closely packed about it, so much so that it is quite impossible for the track to be moved out of line by rail expansion during a hot day; and the rail is compelled to undergo the stresses set up by the expansion of the metal, without lengthwise extension. On street railway track where the rail is not closely protected by earth or pavement one will observe that, unless there is allowance for expansion, the rail, on very hot days, is thrown into slight kinks, showing that the metal is under tremendous stress. Theoretically this stress is about 200 lbs. per sectional square inch of metal for each Fahrenheit degree increase of temperature. As the ties are solidly embedded, however, they cannot be moved out of line and the spikes are able to hold the rail to a safe general alignment. As such conditions do not obtain to any considerable extent on steam roads, however, the practice of the street railways is no criterion for general practice on steam roads. Experienced trackmen well understand the dangerous tendency of track on steam roads, especially on curves, where sufficient allowance for expansion (not to speak of no allowance at all) for the extreme temperature of hot weather is not provided for.

In this connection mention may be made of the famous "Noonan" experiment, on the Lynchburg & Durham Ry. (now part of the Norfolk & Western Ry.) in 1889. In June of that year three miles of track near Glady's Station, Va., was laid according to plans devised and patented by a section foreman named Philip Noonan. In laying this track the ends of the rails (56 lbs. per yd.) were brought into contact and firmly united in a continuous stretch over the whole section of three miles. The joint fastening consisted of heavy fish plates ¾ in. thick, drilled with round holes to correspond to the bolt holes in the rails, and secured by four 1-in. rivets, driven hot, with the aid of drift pins to tightly close the joints. This splice proved to be all that was expected of it, for it was found that the joint would not open in the slightest amount, and in this respect the rail was practically continuous. The spikes were not driven home, the heads remaining ⅜ in. clear of the flange, to permit undulations in the rail without disturbing the spikes or the ties. At each end of the 3-mile section the rails were turned out and switch points were laid to take care of the expansion. The track was ballasted with dirt and the ties were covered with earth, consisting of red clay and loam, extending to the under side of the rail head, between the rails, and to the top of rail on the outside of the track. To prevent dust, the filling material on part of this track was turfed over, and grass seed was sown over the remainder (unusual practice, indeed). While the riveting was in progress, and before the track had been surfaced, lined and buried, some trouble was had from expansion of the rails, but not afterward.

It was expected that this track would remain "self-surfacing," and after a test of 17 months the managing official, Mr. R. T. Gleaves, declared before the Engineers' Club of Philadelphia that there had not been the slightest buckling of the rails (the three-mile section included some curved track) and that the track had not been surfaced or lined since it was first put in running condition. Engines weighing 104,000 lbs. passed over the track at a speed of 50 miles per hour. Owing to the fact that the track was laid on newly-made roadbed it settled out of surface, to some extent, but on the whole the experiment was reported to have been very satisfactory. During the same period the expense for labor in keeping up an adjoining three-mile section was $1890. In due course it was ascertained that the ties decayed prematurely, and no report seems to have been made public of the expense of digging out and surfacing the track when such repairs eventually became necessary. Finally the experiment dropped out of sight, and, so far as has been generally known, has not been repeated. It is hardly necessary to add that such construction is not particularly enticing to trackmen; and it may be safely said that the expense of filling the track and the vast amount of labor required to remove the material when surface repairs and tie renewals become necessary present a forbidding aspect.

An experiment of the second kind above referred to was begun on the main line of the Michigan Central R. R., in the suburbs of Detroit, Mich., in November, 1894. At this point four consecutive sections of experimental track, each 500 ft. in length, were laid with 80-lb. rails butted end to end and firmly spliced together, without allowance for expansion. The rails were spliced with six-bolt 44-in. angle bars, in the ordinary manner, with four additional 1-in. machine-made bolts in the middle of the first, second, fourth and fifth spaces between the ordinary bolts. Harvey "grip" bolts were used, well set up, and the splices were made to hold the rails so firmly that no opening could take place at the joints. At each end of the 500-ft. stretch the rails were coupled by a slip joint of special design, with an outside reinforcement to carry the wheels. This slip joint was designed to provide for 4½ ins. of expansion. At the middle of the 500-ft. section two ties were held to concrete anchorage by U-shaped pieces of rail embedded in the concrete mass underneath the track, and the rails were held to the anchored ties by special splices and lag screws. Whatever expansion could take place, therefore, would have to be exerted from the middle of the section toward the slip joints at the two ends. The actual expansion at each slip joint—that is, between the middle points of each two adjoining 500-ft. sections—between the two extremes of temperature, was found to be about 3¼ ins., so that the expansion allowance was ample, and there was no tendency to buckling of the rails. After the experiment had been in progress eight years the track had remained in good surface without any tamping, except what was done soon after the rails were laid, to put the track in first-class condition. The results were so satisfactory that in 1901 a further experiment on a much larger scale was begun on substantially the same lines. At a point on the Bay City division of the road, a few miles out of Detroit, a mile of track was laid with 60-ft. rails tightly spliced together in 500-ft sections, without allowance for expansion. Slip joints are used between the long sections, as at Detroit, but the method of anchoring to prevent creeping track is somewhat different. The rail at the middle of each 500-ft. section is anchored to a piece of old rail about 15 ft. long set vertically in a mass of concrete deposited in a hole excavated into the roadbed. The top of this anchor rail rests against, and projects slightly above, the flange of the track rail, fitting into a notch in the horizontal leg of a splice bar. These experiments were planned by the late Chief Engineer A. Torrey.

Rails 33 ft. long are extensively used on a good many roads, and an increase in the standard length of rail to 33 ft. has been recommended by both the Roadmasters' and Maintenance of Way Association and the American Railway Engineering and Maintenance of Way Association. Rails longer than 33 ft.—mostly 45-ft. and 60-ft. rails—have been tried on but comparatively few roads. The results have been of a varying character, and the experimental stage in the use of such rails cannot yet be considered to have been passed. The objectionable features which have been found in the use of rails longer than 33 ft. may be summarized as follows: (1) surface kinks in the rails due to improper straightening at the mills; (2) excessive pounding at the joints, due to the increased allowance for expansion; (3) the rails are not as readily and conveniently transported and as cheaply handled as are rails of standard length. On the first point some mill men claim that, owing to the heavier weight to be handled, and other difficulties, it is impracticable to straighten 60-ft. rails as well as 30 or 33-ft. rails, and that the excessive gagging required by the long rail is liable to injure it. It is claimed that the best product is to be expected in rails not exceeding a length of 33 ft. Those who dispute these claims contend that some mills do straighten 60-ft. rails properly; that the matter of straightening is only a question of mechanical skill; and that rails as long as 60 ft. can be straightened as well as rails 30 ft. long, but necessarily at greater cost. Concerning the question of excessive pounding at the joints of rails longer than 33 ft. there is difference of opinion, as is also the case with the matter of handling and transporting the rails.

The Lehigh Valley R. R. began using 45-ft. rails with miter-cut or skew ends about 1890, and for seven or eight years they were the standard of that road. They were finally abandoned, however, as the standard, and the use of 30-ft. rails was again taken up. Mr. A. Morrison, at one time roadmaster with the Lehigh Valley R. R., has stated that in his experience with 45-ft. rails he found it was cheaper to handle and lay them than 30-ft. rails; that it was cheaper to maintain the track with 45-ft. rails than with 30-ft. rails, and that it was also easier to line out kinks in the 45-ft. rails. Previous to the time when 45-ft. rails had been adopted it was the practice to curve 30-ft. rails for laying on sharp curves, but with 45-ft. rails it was found unnecessary to do this, even for curves as sharp as 10 deg. The 45-ft. rails were unloaded from the rear end of the work train by means of a 15-ft. chain, hook and clevis, the rail being permitted to drop into the middle of the track as the train was pulled ahead, without injury to the rail. The rails were then thrown outside the track by two men with bars. His only unfavorable criticism of 45-ft. rails was the wider space necessary for expansion at the joints, for which reason the joints could not be maintained in as good condition as with 30-ft. rails. Experience with the miter-cut ends on this road was also unsatisfactory, one of the difficulties being that the long corner of the head overhanging the end of the web portion would break off. The battering and flow of metal at the ends of miter-cut rails is reported to have been as great as with ends squarely cut. The Buffalo, Rochester & Pittsburg Ry. began using 45-ft. rails to a limited extent about 1895, and after an experience of six years these rails, with both miter and square ends, were reported to be giving satisfactory service. The only defect which has been noticed with 45-ft.

rails on this road was the imperfect straightening found when the rails came from the mills. It is thought that better track has been maintained at the same expense as that required for track with 30-ft. rails. No trouble has been experienced with abnormal openings from creeping due to change of temperature, and there has been no battered joints.

In 1891 the Pennsylvania R. R. began experimenting with 60-ft. rails of 85-lb. section, and after 10 years this length was "condemned" as unsatisfactory. On straight track, where there were no grades, a measurable degree of satisfaction was obtained, but on grades, where creeping was troublesome, these rails gave poor satisfaction, even where two and three anti-creeping fastenings had been applied to each rail, besides slot-spiking at the joints. The chief difficulty was that the creeping of the rails caused them to "bunch," and in cold weather openings as wide as $\frac{5}{8}$ to $\frac{7}{8}$ in. were commonly found. Under these conditions the receiving rails at the joints were badly punished. Between the years 1892 and 1896 the Norfolk & Western Ry. laid 25 miles of track with 60-ft., 85-lb. rails with miter ends, and 60 miles with the ends cut square. These rails were laid on the heaviest grades and on sections of the road over which the heaviest traffic passed, and gave good satisfaction, the maintenance expenses being noticeably reduced. On 6-deg reverse curves 60-ft. 85-lb. rails carried 91 million tons in $7\frac{1}{2}$ years, when they had to be removed on account of flange wear. The grades were 70 ft. to the mile and trains were handled with pushers. The track was ballasted with furnace slag and the rails were connected with Churchill joint splices 23 ins. long, extending $3\frac{1}{4}$ ins. below base of rail. It is reported that no trouble arose from battering of the rail ends by reason of the joint space allowed for expansion. The Chesapeake & Ohio R. R., has experimented with square-cut 60-ft. rails, weighing 75 lbs. per yard, and after an experience of some years good satisfaction was reported. A number of other roads have tried both 45-ft. and 60-ft. rails. On the Philadelphia & Reading Ry. 45-ft. rails have been found advantageous.

The expansion allowance required for 60-ft. rails is double that for 30-ft. rails, under the same conditions, and for 45-ft. rails it is in the same proportion. The spacing for 60-ft. rails adopted by the engineering department of the Baltimore & Ohio R. R. progresses uniformly from a tight joint at 125 deg. and above, to an opening of $\frac{5}{8}$ in. at zero temperature. This allowance, it will be seen, is $\frac{1}{8}$ in. for each 25 deg. below the maximum temperature, or double the opening usually made for rails of 30-ft. length, which is $^1/_{16}$ in. for each 25 deg. difference of temperature. In long tunnels there is usually but little change in the temperature, and but little or no open space need be left at the joints for expansion. It would therefore seem that in such places 60-ft. rails should be well adapted, without any question. For 60-ft. rails it has been customary with the mill people to exact an extra charge, $2 per ton being the extra price paid in some cases. With some roads this extra charge has been the reason for discontinuing the use of "longer" rails.

In the transportation of long rails it is the practice with some companies to lay them over two flat or gondola cars, using bolsters, and in other cases rails as long as 60 ft. are loaded on alternate cars, the ends projecting equally past the loaded car, over the idle cars adjacent. In every case where the same rail rests upon two cars it is recommended that bolsters be used, in order to prevent injury to the rails by the side and vertical motions of the cars. The Lake Terminal R. R., operated by the Lorain Steel Co., has 100 long cars for the transportation of 60 and 62-ft. rails, built on plans prepared by Mr. F. H. Stark, master car builder of the Cleveland, Lorain & Wheeling Ry. The length of these cars over the end sills is 66 ft. 4 ins., the width 8 ft. 11 ins. and the capacity 80,000 lbs. The car is stiffened with eight under truss rods of 1¼ ins. diameter, passing through the end sills, and four other under truss rods of the same diameter passing up through stirrups straddling the side plank, and thence through the end plank. Passing through the stirrups straddling the side planks in the center of the car are four counter truss rods 1⅛ ins. in diam. passing down through a wrought iron plate held across the end of a block bolted beneath the side sills and abutting against the end of the needle beam. The cars have a permanent 6x8-in. floor bolster over each truck, and the cars are trussed to a camber of 4 ins., so that the long rails rest upon the bolsters nearly level.

In unloading long rails from cars by hand, a larger force is required than is the case when handling 30-ft. rails, but the ordinary work-train crew is easily able to do the work. Quite frequently 60-ft. rails have been unloaded by hooking a 30-ft. rope to the end of the rail and anchoring it to the track, the rail then being drawn off the car as the train is pulled ahead. The end of the rail is then lowered from the car to the track by a gang of men, as the car is pulled from under it, or in some cases it is allowed to drop freely on the ties, the long sag being so deep that the rail drops without injury. Two men with bars then throw the rail out of the track. In renewing rails the number of tongsmen required to handle 60-ft. rails is double the number for 30-ft. rails, but only half the number of bolters is required. It has been stated that, on the whole, there is a saving of fully 15 per cent in handling and laying 60-ft. rails as compared with the expense of handling and laying 30-ft. rails in the same length of track. The cost of unloading and laying 60-ft. rails on the Norfolk & Western Ry. is reported to have been 20 per cent less than the cost of handling 30-ft. rails in like manner, for an equal length of track.

In Germany the old standard length for rails was 29½ ft., and the experience from increasing this length seems to have resulted more satisfactorily than has been the case in this country. An increase of 33⅓ per cent or to 39 ft. 4 ins., seems to have met with general approval. On some roads the standard length has been increased to 59 ft.

173. Compound Rails.—The effort to produce a continuous rail has led to numerous proposed designs on the principle of dividing the rail into longitudinal parts to be bolted or riveted together so as to break joints. An old idea, and one which is said to have succeeded to actual trial, was to roll the rail in two parts separable vertically through the middle plane of the web and bolted or riveted together so as to break joints, without splices. If it were not for the necessity of allowing space for expansion such a design might have stood some show of success, years ago, because a joint extending entirely across the rail could have been avoided; but even then, without splice bars, the rail at joints between contiguous sections would have been weakened to one-half the strength or stiffness at intermediate portions. The necessity for expansion allowance, however, forbids a rigid union of the parts, so that it would not have been possible to get them to act together, the result of which would have been a shaky affair. At the present time such a design obtains no right to consideration, even if it was practicable to rivet the two halves rigidly together, because if allowance for expansion could be dropped out of consideration present methods of cast-welding or electrically welding rails could be applied with greater advantage and economy.

With the two-fold object of making the rail continuous and to provide a part which need not be scrapped when the head becomes worn out, it has been proposed to divide the rail into top and bottom parts. A familiar design which numerous inventors have worked upon consists of a rail head of ordinary form (*A*, Fig. 495) with a depending tongue or web portion, fitting into a grooved base; or, vice versa, a rail head with a depending grooved portion, into which is fitted a base with an upwardly projecting tongue portion. Some have proposed to make the base solid or in one part, like the Bargion rails, laid experimentally by the Southern Pacific Co., at Oakland, Cal., in 1890; while others, to facilitate rolling or to provide increased bearing surface for the head, have proposed to divide the base into two parts (*B* and *C*, Fig. 495). The top and base portions are then to be riveted or bolted together to break joints. In this case, also, the necessity for expansion allowance gives rise to a fatal defect in the design, for unless the parts could be riveted to make absolutely rigid connection, whether the base portion be solid or in two parts, the different parts of the rail could not be made to act together, and there would be simply the strength and stiffness due to the head and base portions acting independently. To show that such a design is extremely faulty from other considerations it is only necessary to point out that each part has but one flanged portion and each part is considerably shallower than the depth of the entire rail, thus greatly lacking in stiffness. Moreover, the holes provided for riveting or

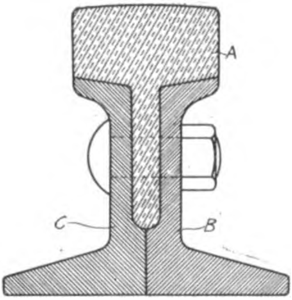

Fig. 495.

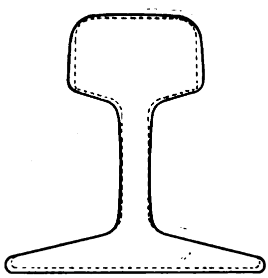

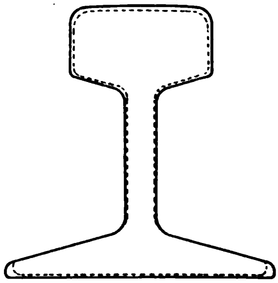

Fig. 496.—Rerolled Rails—Fig. 497.

bolting the parts together, being outside the neutral axis of the section, in each case, weaken those parts unduly and increase the liability to fracture or break at the holes. In order to make a rail of this design as stiff and reliable as the rail of simple section in ordinary use would require a base portion so enormously heavy that interest on the cost of extra metal would more than eat up any saving which could be effected in cost of maintaining track surface or in the prolonged service of a portion of the rail exempt from the scrap pile.

The Bargion rail, above referred to, had a solid grooved base of soft, tough steel, of a quality intended to withstand stress and shocks, and a head with a depending tongue, made of hard corbonized steel, for wear. The base or lower part was first rolled open, in star shape, until the last pass, when the double web was closed in to the proper shape. From the fact that it was rolled in one piece there were no flanges on the top edges of the double web, as in Fig. 495. The rail weighed 138 lbs. per yd., of which the base weighed 75 lbs. and the head portion 63 lbs. Head and base were fastened together with rivets. The rail was successfully laid on a $7\frac{1}{2}$-deg. curve. It failed by cracking and breaking through the rivet holes. The design of compound rail proposed by Mr. Walter Katte, formerly chief engineer of the New York Central & Hudson River R. R., was similar to Fig. 495, the difference consisting in an enlargement of the tongue portion of the head on line with the bolts, the inside faces of the double web being grooved out to correspond. The Haarmann compound rail is described in connection with Metal Ties, §203 Suppl. Notes.

174. Rerolling Rails.—It is familiar to the experience of many railway men that rails of inferior quality are rendered unserviceable for main track use more from flowing and roughening of the head than from serious loss of metal. In any case it is not practicable to use up more than 15 or 20 per cent of the metal in a rail, in wear, by the traffic, and it is seldom that the metal worn away in main-track service amounts to as much as 12 per cent of the weight of the rail. The limit of wear in main-track service is ¼ to ⅜ in. in depth of head. The rest goes to the scrap pile and, taking one year with another, will sell for about 40 per cent of the price per ton of new rail, after deducting freight charges. Thus, on a basis of 12 per cent wear, about 53 per cent of the price paid for the rail is lost by depreciation, the oxidation of rails usually being but very little. Some years ago it occurred to Mr. E. W. McKenna, assistant general superintendent of the Chicago, Milwaukee & St. Paul Ry., that the unworn portion of rails commonly taken up in renewals contains sufficient metal for a rail nearly as large in section as that of the original rail; and that if a cheap process of rerolling the worn rail could be devised, a new rail of but slight reduction in section could be produced at low cost, which would work an important economy in the expense of rail renewals. After some study of the matter machinery was fitted up in the North Chicago rail mill of the Illinois Steel Co., and in the fall of 1895 trial orders for rerolled rails were executed for the Chicago, Milwaukee & St. Paul; Atchison, Topeka & Santa Fe; Chicago, Burlington & Quincy; Michigan Central; and Baltimore & Ohio roads.

The experience with these rails showed that added serviceability to the rails could be cheaply gained at the cost of rerolling, and in 1897 a new mill was built at Joliet, Ill., specially equipped for the work. In this mill there are two furnaces for heating rails, so arranged that the rails can be charged in at one end of the furnace and drawn out at the other. Each furnace has a capacity for 21 rails, and the time required to heat the rails to the desired temperature—1700 deg. F.—is about 35 minutes. At this temperature the metal is a bright cherry red, which is below the decarburization point. The rails are withdrawn from the furnace one at a time, and as soon as seven have been withdrawn a new charge of seven rails is run in at the other end of the furnace. Each rail after being taken from the furnace receives three passes in the rolls, or one pass in each of three sets of two-high rolls in tandem. The first set, which operates directly in front of the furnace, and draws the rail out of the furnace, is known as the "upsetting" rolls, and through these the rail is passed workwise. The purpose of these rolls is to compress the rail vertically, so as to force the head and flange, and consequently the fishing surfaces, nearer together and reduce all the rails to a uniform hight. The rail then goes to the second set, known as the "roughing" or "forming" rolls, which have three grooves each designed to receive definite forms of worn rail. From the third and last set of rolls, known as the "finishing" rolls, the rail emerges at a temperature of about 1400 deg., whence it is taken to the hot saws, hot beds, straightening and drilling machines, in the usual way. The average time of the rolling process, from furnace to hot saws, is only 29 seconds. The capacity of this mill is 400 tons of rails rerolled in 24 hours. In Kansas City, Mo., there is another mill of equal capacity and similarly operated, built in 1898. At Tremley Point, N. J., there is a mill of 600 tons' daily capacity, built in 1902.

Before the rails are put into the heating furnace fins or slivers, resulting from flowing of the metal, are ground off with an emery wheel, as it is found that the metal composing such imperfections is extremely hard, and if rolled into the body of the rail distinct cleavage lines will remain and lead to slivering of the rail head under traffic. As each rail is drawn from the furnace it is passed through a set of revolving wire brushes, to remove scale before the first pass through the rolls, and in advance of the last pass the scale is removed by a jet of steam. It is found that the chemical composition of the rails remains practically unchanged and it is claimed (on good grounds) that the rolling which the metal receives at the comparatively low temperature actually improves the wearing qualities of the rail. Data of rails in service have verified this claim. The loss of metal from oxidation in heating and rerolling amounts to about 1 per cent, and the entire loss from the rails, including the crop ends, amounts to from 6 to 10 per cent, but usually 7½ or 8 per cent, in weight of the metal rolled—that is to say, the number of tons of serviceable rails returned from the mill will fall 7½ or 8 per cent short of the number of tons of rail sent to the mill to be rerolled. Of this shortage about 6 per cent is returned in crop ends. The charge for rerolling has been $5 to $6 per ton.

Some of the roads which have made use of rerolled rails are the Chicago, Milwaukee & St. Paul; Atchison, Topeka & Santa Fe and the Wabash. The road first named began using rerolled rails in main track that were rolled principally from rails weighing originally 67 and 75 lbs. per yd. The 67-lb. rails were worn down to about 65 or 65½ lbs. per yd., and were rerolled to a 60-lb. section, as shown by the dotted lines in Fig. 496, reproduced from a full-size drawing taken from templets of the rails. The full line shows comparatively the original section of the rail, or what it was when first laid in the track. It will be noticed that the shape of the rail has been changed somewhat by the rerolling process, the web of the new rail having straight instead of curved sides, and the sides of the head being vertical instead of sloping. The hight of section is decreased slightly, resulting in a slightly shallower and narrower head and thinner and narrower flange. Figure 497 shows comparatively the size and shape of section of rerolled rails weighing originally 75 lbs. per yd., the dotted line of course representing the rerolled rail. These rails had been worn to about 72½ lbs. per yd. and were rerolled to a 67½-lb. section. It will be noticed that all parts of the rail are reduced somewhat in size, the head being slightly shallower and narrower, the web and flange slightly thinner. It would have been equally as feasible to have retained the original depth of section by narrowing the head and other parts to greater extent. In both cases the fishing angle remains the same, but the rerolled rail provided for a slightly deeper angle bar of standard size. The general practice in laying rerolled rails is to use new splice bars, but, if desired, the rail may be rerolled to fit the old bars again. If the rail is curve worn the rerolling process will transfer metal from one side of the head to the other, to balance the section. In some cases the rail has been rolled to a section ⅛ in. deeper than that to which it had been worn.

A desirable feature of the rerolling process is that the loss in cross section beyond what is actually required to form a new section of maximum size is gained in elongation of the rail. Thus, some of the 30-ft. rails rerolled for this road were returned from the mills 32 ft. in length, while others were cut off at 30 ft. To give another illustration of the result of rerolling, in this respect, the net gain in length in a lot of 16,007 rails rerolled was 7350 ft., and the reduction in section was from an average of 75.27 lbs. per yd. to a uniform weight of 67.7 lbs. per yd. The length at which the rerolled rails are cut in the practice of this road depends somewhat on the location of the old bolt holes. It is not permitted to cut the rail so that an old bolt hole comes between the end and the first hole to be drilled, but the rails may be cut through an old bolt hole, providing that not more than half of the old hole remains in the end of the rail. It is also required that no hole newly drilled shall meet one of the old holes, which are made somewhat oblong by the rerolling process. The experience which this road has had with rerolled rails has been quite satisfactory. Some of the rails rerolled from the original 67-lb. rails, above referred to, laid in the Muskegon yards of the road at Milwaukee, Wis., where traffic is very heavy, lasted better than any other rails which had been in service in that place. In 1902 this company had about 50,000 tons of rerolled rails in the track.

The Atchison, Topeka & Santa Fe Ry. began using rerolled rails in 1898. Some of the rails then used weighed 60 lbs. per yd., and were rerolled from a rail the original weight of which was 66 lbs. per yd. The larger quantity, however, weighed 65 lbs. per yard and were rolled from rails which originally weighed 71 lbs. per yd. and had been worn down to 69 or 70 lbs. per yd. These rails had deteriorated to the point where renewing became a necessity, and no old rails were taken up expressly for the purpose of rerolling. In 1902 the Coast Lines of this road were using 307 track miles of rerolled rail, and the experience had been quite satisfactory. The rerolled rails had worn much better on the curves than the original rails. The percentage of breakage had been a little higher than with new rails, but not to an extent that gave cause for alarm. The Wabash R. R. has used a considerable tonnage of rerolled rails in main track, the first being laid in 1898. Of this rail part was of 63-lb. original section, rerolled to 58 lbs. per yd., and more were rails of 70-lb. original section, most of which had been damaged by improperly counterbalanced locomotives running at excessive speeds. In 1904 several thousand miles of track on various roads had been laid with rerolled rails. As an experiment, with a view to improve the wearing qualities of the metal, the Baltimore & Ohio and Wisconsin Central roads have each had 1000 tons of new 85-lb. rails rerolled to 80-lb. section.

175. Rail Trimming.—When iron rails were used in main tracks the battering at the joints was so excessive that the rails usually became unserviceable from this cause long before the head along the intermediate portion was worn down sufficiently far to call for a general renewing of the rails. It was, therefore, considered extravagant to scrap the rails for this defect alone, and it came to be quite generally the practice to trim the rails by cutting off the battered portion at the end and then lay them again in the track in the course of ordinary repairs. Rails shortened in this manner were continued in service until the head was worn down to the allowable limit or until the ends became battered again, or, perhaps, again and again. The work of cutting the rails was quite frequently performed by the section men, with hammer and chisel, but when large quantities of battered rails had accumulated they were loaded up and sent to the shops to be trimmed and drilled for bolt holes. As steel rails and angle-bar splices came into use, the battering of rails at the ends, on any such scale as had been the case with iron rails, ceased to be a trouble with trackmen. In course of time, however, slight battering or surface bending developed in steel rails at the ends, in some cases, due to one or all of several causes, among which may be mentioned flowing of the metal, owing to inferiority of the product and increase in weight of locomotives and car loading; excessive allowance for expansion, failure to keep the joint splices tightly bolted and failure to keep the track in proper surface at the joints. With rails of good quality, properly spaced and maintained in fair surface, battering of the head at the ends is seldom the case, but after years of service it is quite common experience to find the under side of the head considerably worn by the splice bars. Such is quite likely to be the case where thin splice bars are used or where the duty of keeping the splices tightly bolted has not received close attention. With splice-worn rails it is impossible to secure a close fit, even with new splice bars, so that if this defect or battered or surface-kinked ends exists there is no remedy except amputation,

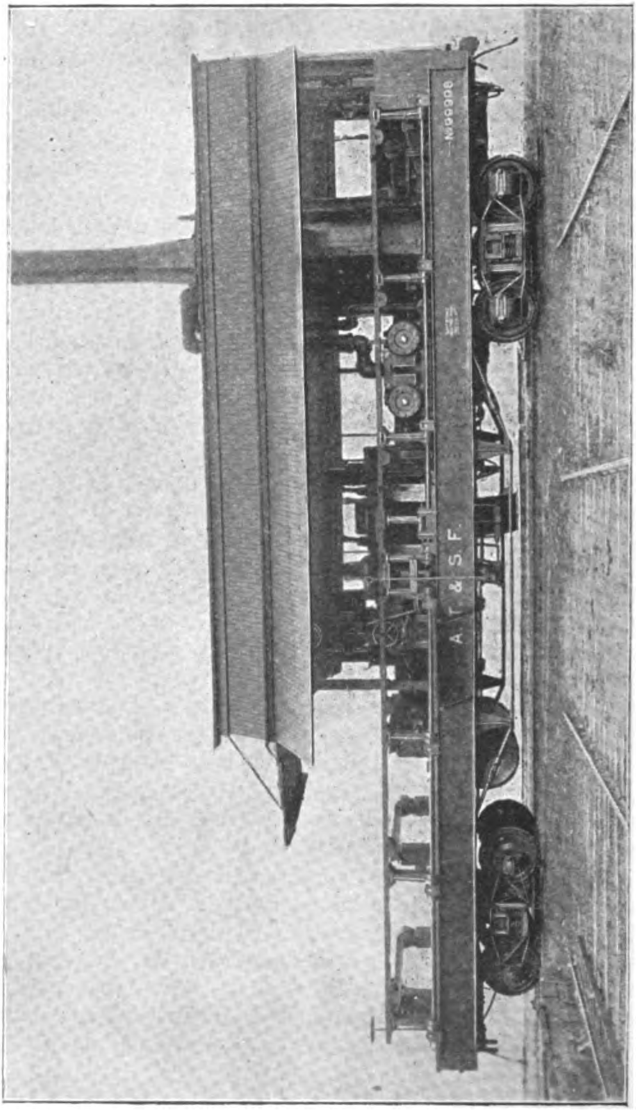

Fig. 498.—Portable Rail-Sawing Mill, Atchison, Topeka & Santa Fe Ry.

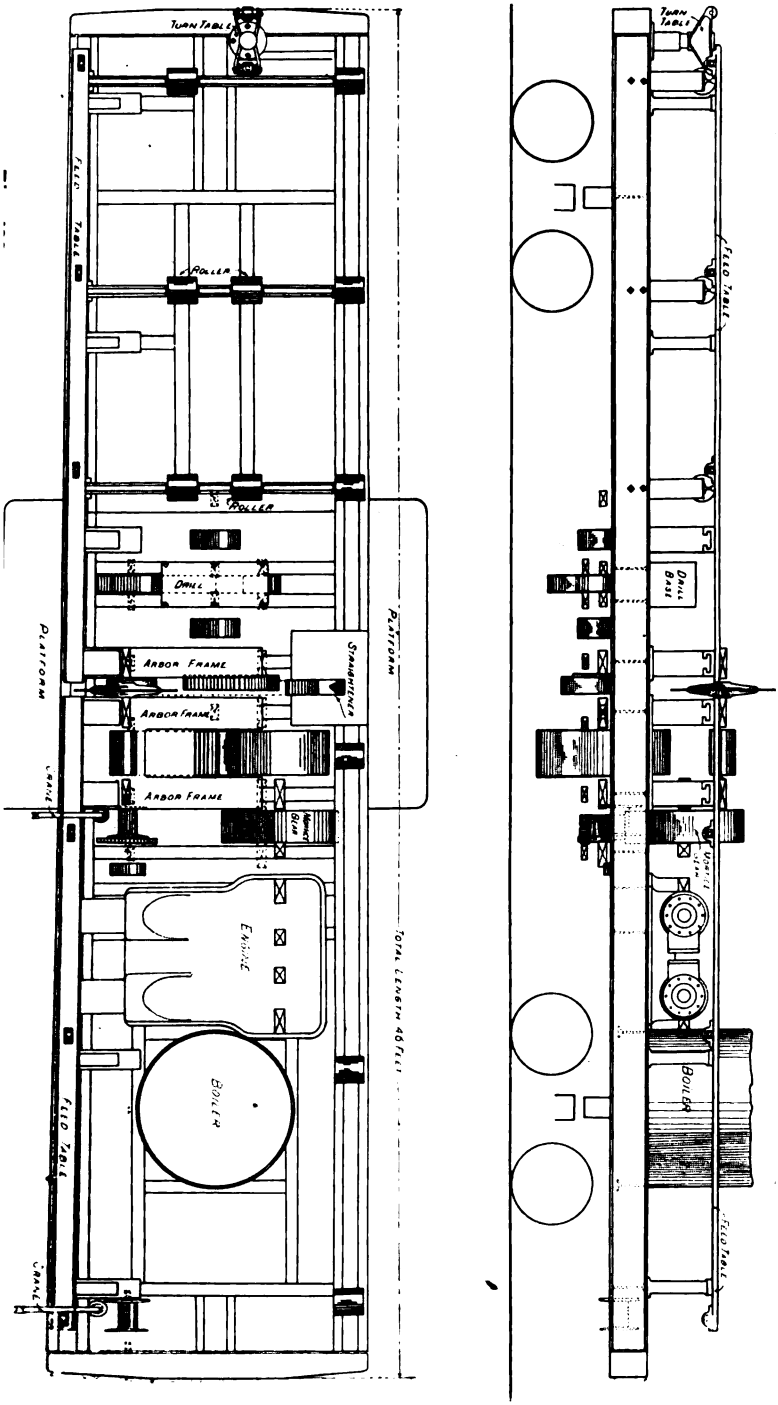
if it is expected to obtain further service from the rails in main track with economy in maintenance expenses. As the result of experience resort to trimming the ends of the rails has come to be the practice on a number of roads, particularly where rails are taken from the main line to be laid on branch lines.

The Michigan Central, the Atchison, Topeka & Santa Fe and some other roads have portable plants for trimming rails, the necessary machinery for sawing and drilling the rails being contained on a single flat car, vith auxiliary devices for lifting the rails from the incoming cars, and kidways for assorting the rails after they have been trimmed. The plant s set up at convenient points along the line, so that the cost of transporting he rails requiring treatment does not so largely affect the economy of the cheme as it otherwise would. The portable mills on the two roads named



are constructed alike and are operated in about the same way. Figure 498 shows the general appearance of the A. T. & S. F. mill and Fig. 499 the plan and elevation drawings. The car upon which the machinery is carried has a length of 46 ft. and a width over all of 10 ft. The car body is constructed in a very substantial manner, the frame consisting of 20-in. steel I-beams and channels thoroughly fitted and riveted together. The car body is carried upon two 4-wheel trucks of special design, to support the great weight, which, including the car and machinery, is 57 tons. The boiler is 10 ft. high, 63 ins. in diameter, with submerged flues 2 ins. in diameter. The engine operating the machine is of the horizontal type, of special design. It has double cylinders, 12x14. ins. each, and jacketed. The engine is connected directly with a mortise gear 48 ins. in diameter, which drives a cut steel pinion 20 ins. in diameter, thereby imparting a countershaft speed of 380 revolutions per minute. Upon this shaft is the band wheel driving the saw arbor. From the same shaft a 6 or 8-spindle drill is operated and, when necessary, the rail straightener. The disc or saw used in cutting the rails is 42 ins. in diameter and runs at 2000 r. p. m. About 150 h. p. is required to do the work properly. At the front side of the car (the near side in the illustrations) is arranged the feed table for conveying the rail to the saw. This table is constructed of steel channels, the channel side being placed upward and supported on arms keyed to a shaft journaled near the car floor. Within the channel are rollers for shifting the rail. The feed table is divided at the saw into two sections, and each section is operated by an air cylinder. For holding the rail securely while it is being fed into the saw there is a clamping device operated by an air cylinder provided with a quick release valve, as are also the feeding cylinders of the table. The rail drill is double, having three or four spindles on each side, provided with automatic or hand feed, as desired. These drills are independent and are connected by friction clutches to the main countershaft. Among the various miscellaneous machines included in the outfit is a steam turntable, upon which the rail is placed after one end has been drilled, so that it can be swung around for drilling the other end. There is a double rail clip hoisting mechanism for transferring the rails from the car to the feed table and systems of rail rollers for moving rails from one position to another. There is a water pump and tank for the use of the saw disc and for the drills. The machinery of the car is covered by a cab extending over two-thirds of its length, provided with swinging and sliding doors, so that all the machinery may be securely housed when not in operation, or while in transit from point to point.

The machinery for handling rails to and from the mill, as arranged on the Michigan Central R. R., is made clear in Fig. 500. The mill is placed on side-track between a siding for receiving the incoming rails, on the one hand, and a series of skidways or platforms for receiving the rails after they have passed the machine, on the other hand. It will be noticed that these skidways are graduated in width, the purpose being to receive the rails of shorter length on the skidways toward the left. These skidways hold about 100 rails each, in one tier. Just beyond the skidways there is a track for the cars upon which the outgoing rails are loaded. The operation of the mill may be described as follows: The car containing rails to be trimmed is placed at the front side of the mill. To begin with, the rail is seized near its two ends by the clips of two pneumatic cranes (Fig. 499) and lifted to the feed table. After the rail has been securely clamped to the first section of the feed table it is pulled against the saw, when it is swung back and run ahead past the saw to the other

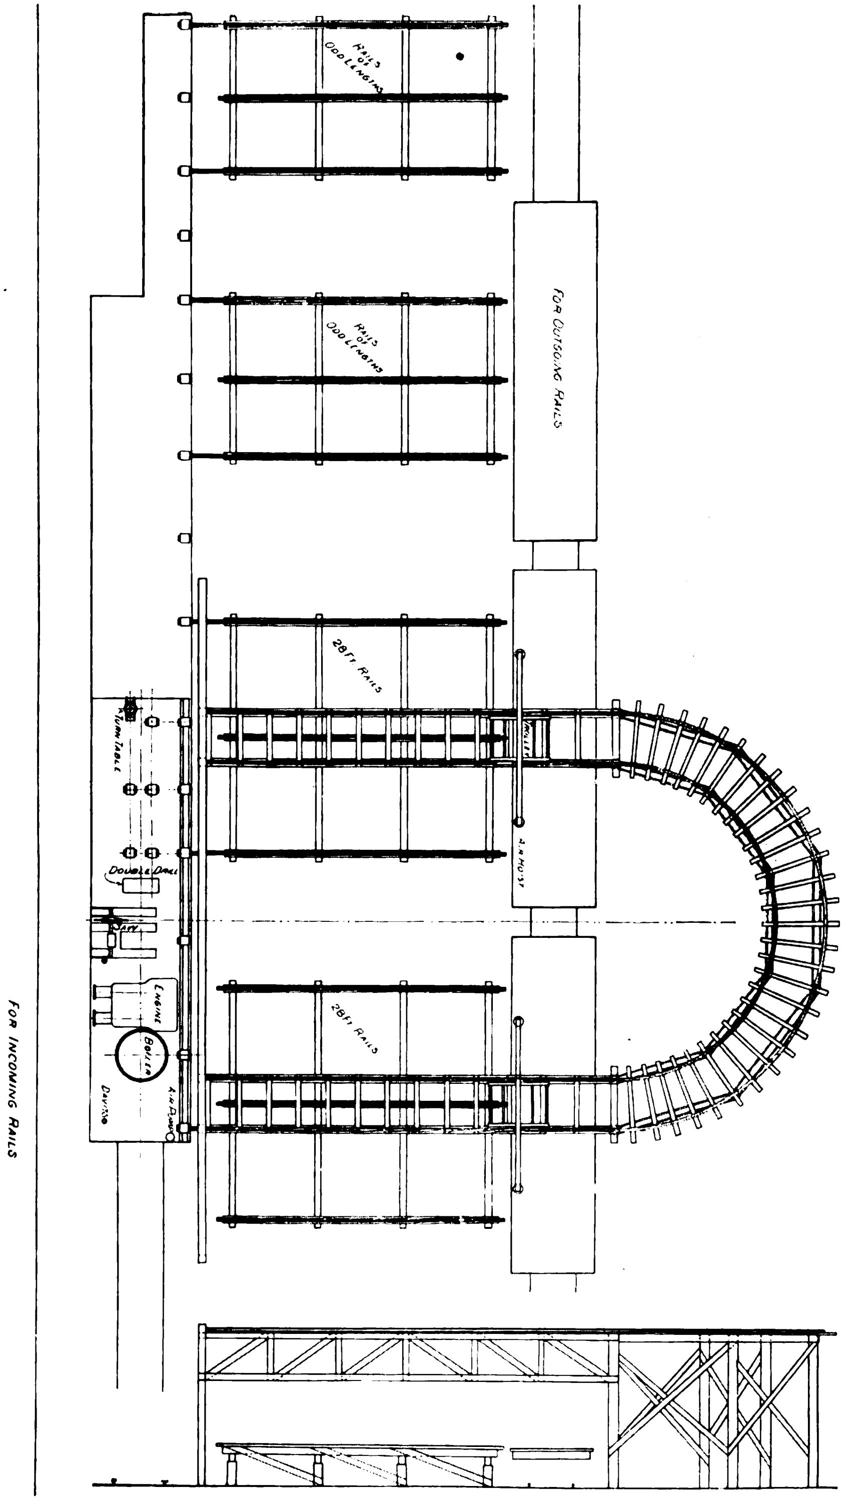


Fig. 500.—Arrangement of Portable Rail-Sawing Mill and Skidways, Michigan Central R. R.

section of the feed table, against a gage stub. In this position the rail is clamped and the other end is taken off; meanwhile the first section of the table is receiving another rail. Both ends of the rail being cut, it is then slid upon the storage space between the feed table and the first drill. It is next slid over to the drill and drilled. One side of the double drill does the drilling at one end of the rail, after which the rail is turned by the elevating steam turntable and the other end is drilled at the other side of the drilling machine. From the drills the rail is slid upon the long line of rollers (Fig. 500) for distributing to any of the skidways, its length determining the skidway to which it belongs. Unless the rail has to be straightened this ends the process, so far as the mill is concerned.

The means for transferring the rails from the skidways to the cars, or in handling the rails over for the purpose of matching, is very conveniently arranged. As will be seen in Figs. 500 and 501, there is an overhead structure or bridge, trussed over the skidways and loading track and trestled outside the track. The two trusses of this bridge extend over two skidways and are joined by a semicircular portion outside the loading

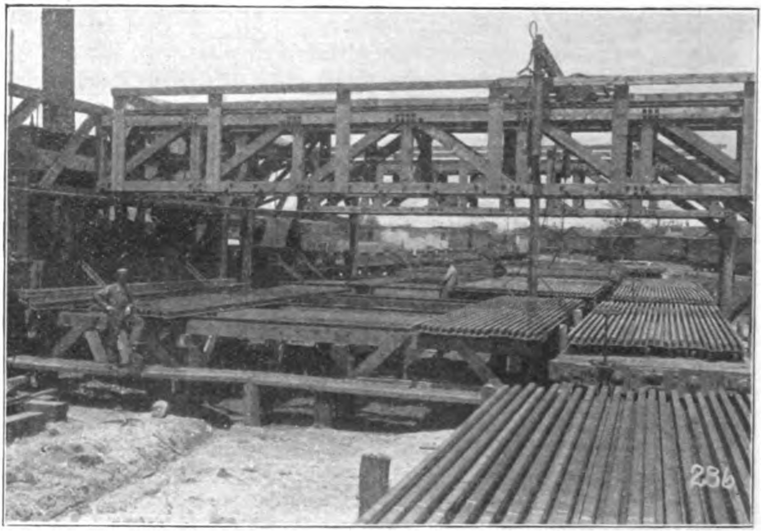

Fig. 501.—Skidways, Trolley and Air Hoist.

track. On this bridge there is a tramway carrying a trolley, which in turn carries a cross beam, on each end of which is an air hoist for lifting the rails. The trolley and hoists are operated by two men. To the piston of each air hoist there is fastened a chain with a rail clamp attached, for picking up the rails. After handling the rails on one of the skidways the trolley is run around the semicircle to the other skidway, as shown. The two skidways opposite the mill are intended for 28-ft. rails, which constitute the larger portion of the rails which leave the mill. Rails of odd lengths are run to the other skidways, where they are held until enough accumulate to furnish a car-load. On the A. T. & S. F. Ry. no rails are trimmed to a shorter length than 24 ft. The force necessary to handle the plant successfully is constituted as follows: One foreman, 1 engineer, 1 fireman, 1 sawyer, 2 drillers, 2 rail handlers at drill, 1 caliperer, 4 chippers, 2 men to load and 1 watchman; or a crew of 16 men, all told.

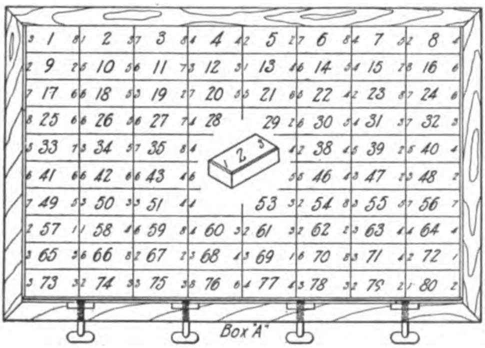
The overhead structure or tramway is arranged so that it may be readily taken down and shipped with the mill and erected at a new point of operation with but little trouble. A portable mill of later design is 59 ft. long and has an additional double drill, which dispenses with the steam turntable, so that opposite ends of the rails can be drilled at the same time by the two drills, thereby avoiding the necessity of having to turn the rail, as in the mill here described, wherein it has been found somewhat difficult to make the drilling operations keep up with the saw. In very fast work the rails are trimmed at the rate of one per minute. At the A. T. & S. F. mill two trolleys are employed—one over each skidway opposite the mill—and the framework supporting the trolleys is of riveted steel trusses and columns. The Chicago, St. Paul, Minneapolis & Omaha Ry. has a portable rail mill on a car 61 ft. long over all and 10 ft. 4 ins. wide. The equipment is similar to that above described, but includes two double rail drills 34 ft. apart centers. This mill will trim and drill 450 to 500 rails in 10 hours.

The Michigan Central trimming plant has been more or less in service since 1886 and has sawed several hundred miles of rail. After the rails are trimmed they are calipered as to depth of head, after which they are matched, numbered consecutively and so loaded that when the rails are taken off the cars the ends of the same depth of head will be together, so as to come in abuttal when laid. The calipering and matching idea originated with the late Mr. A. Torrey, chief engineer of the road, and is now recognized as a very important feature of successfully handling trimmed rails for relaying. Before this was done the variations in head depth of the rails as they were laid by chance made rough joints, and the use of trimmed rails was not satisfactory. Not more than 20 per cent of the rails in any lot trimmed are found to be equal in depth of head, and the difference in depth at the two ends of the same rail is often considerable.

Mr. Torrey's system of classifying the trimmed rails according to depth of head or hight, and in the order of laying, is simple but ingenious. The first thing that is noted is the itinerary of the cars on the loading-out track with respect to the direction in which they will head when arriving at their destination, the essential point being whether or not the rails in transit will get turned end for end from the way they are loaded. The sawing plant is so arranged that it is equally convenient to deliver the rails, after they are drilled, to either of the two skidways standing opposite (see Fig. 500). One of the skidways is set apart for rails to be laid on one side of the track and the other skidway for rails to be laid on the opposite side. In other words, if the track in which the rails are to be laid lies north and south, then one of the skidways will receive the rails for the east side of the track and the other skidway the rails for the west side. The rails are then delivered to the skids so that they will come reversed side to gage when laid; that is, the side of the rail head which stood to gage when the rail was first in service will come on the off side when the rail is relaid. As the burr from the sawing is clipped from the rails on the skids they are shoved along toward the loading track and arranged side by side, workwise, and chalk-marked consecutively from 1 to 80. The head at both ends of each rail is then calipered to the nearest 64th of an inch, record of which is taken, and then 60 rails from each set of skids (enough for a car-load) are selected and renumbered in the order in which they match end to end. They are then loaded upon the cars in this order, beginning with rail No. 60. A card is tacked upon the car indicating on which side of the track the rails are to be unloaded, and also indicating to which car-load for the same side of the track this car is the successor.

The foreman who unloads and distributes the rails at their destination sees that they are taken off the car in proper sequence—that is, from No. 1 to No. 60 seriatim, or in the reverse order from that in which they were loaded. The process of loading and unloading the rails is as simple as winding up a ball of yarn and then unwinding it: if the numbers are regarded there is no chance of getting the rails mixed up.

The system for recording the depth of the head at the ends of the rails and renumbering the rails in the order in which the ends match is as follows: A boy is given a shallow box in which are 80 sawed marble blocks $\frac{3}{4}$ in.x$1\frac{1}{2}$ ins. in size. The marking on the blocks is done with a common lead pencil, and before the boy begins work on a new set of rails he erases all the old pencil marks from the blocks and numbers them consecutively from 1 to 80, as shown in Box "A," Fig. 502. Each block represents one of the rails on the skidway, and the box is used like a map, the proper edge signifying the east or north end of the rails, as the case may be. As the boy calipers the east end of the 80 rails he marks the reading of the instrument for each rail on the east end of the block numbered to correspond to that rail; and when he calipers the west end of each rail he likewise marks the west end of the block which corresponds to that rail. When both ends of the rails have been calipered and recorded in this manner the



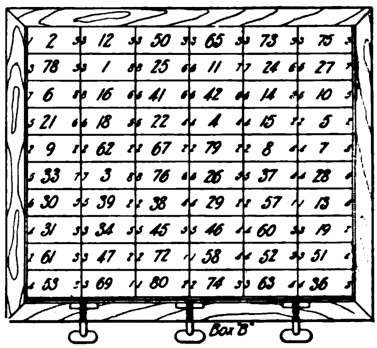


Fig. 502.—Matching Box for Classifying Rails—Fig. 503.

boy sits down and "plays dominoes" with the blocks into an empty box, until he gets 60 to match, as shown in Box "B," Fig. 503. To play the "game" fairly he must evidently keep all the blocks lying in the same direction, and not try to make them match by turning any of them end for end. It then remains only to renumber the rails to identify them with the matched arrangement in Box "B." This is done by painting on the middle of each rail the figure which represents the consecutive number of the space in which the block corresponding to that rail is found: figure 1 is painted on the rail marked 2 in chalk, figure 2 on the rail marked 12 in chalk, figure 3 on the rail marked 50 in chalk, and so on. The rails are then loaded in the order of the painted numbers. The 20 rails which are not matched or not loaded remain on the skids and form part of the next set of 80. The boy keeps a record of the caliper reading of the tail end of rail No. 60 in each car-load, and in starting the domino game for the succeeding car loaded from the same set of skids, he uses a block the head end of which is marked with the same figure.

The calipering instrument used in this work is shown as Fig. 504. The lower jaw is shaped to fit the fishing surfaces on the under side of the rail head and it carries two set-screws which can be adjusted to hold the caliper central with the web. The readings of the instrument correspond to differences of $^1/_{64}$ inch in depth of head. In using the caliper it is generally clamped to read 0 when it fits the head of an unworn rail of the original section, as then the readings on the worn rails will be the smallest numbers possible. Where the sawed rail is to be used with angle-bar splices account is taken of the depth of head only, as hitherto described, but if a type of splice is used which supports the rail at the base, then the total depth of the rails is calipered and they are matched on that basis. For such work a different caliper from the one here described is used.

By this plan of selection the sawed rails make as smooth joints as new rails—some say smoother than new rails rolled in mills where the rolls are permitted to run too long without dressing. The cost of sawing and handling, including matching, averages about 75 cents per gross ton. The product of the saw is found to be satisfactory when laid with new joint fastenings, but not when the old joint fastenings are applied. On this road the portable nature of the machine is found to be advantageous because of the fact that the company quite frequently finds itself short of equipment for hauling rails over long distances. At one stand where the Atchison, Topeka & Santa Fe mill was in operation, on the middle division of the road, it was used in trimming 6556 tons of 61-lb. steel rail. The rail handled was

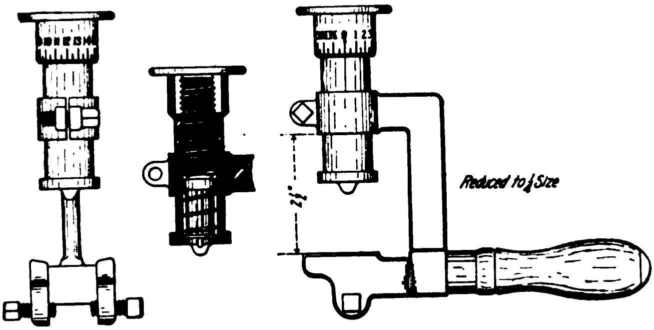

Fig. 504.—Rail Head Caliper, Michigan Central R. R.

in fairly good condition when taken out, notwithstanding that it had been in the track about 18 years. The rails were battered down $^1/_{16}$ to $^3/_{16}$ in. at the ends and the majority of them were splice worn under the head; in some cases also there was appreciable wear on the base. As a usual thing only 12 ins. was cut off each end, so that most of the trimmed rails which were returned from the mill were 28 ft. in length. The mill was run a total of 99 days, during which time it worked 784 hours, and the following is a list of the items chargeable to the expense of operation: Coal, 289 tons, $511.69; cost of repairs, including material, waste, etc., $410.83; cost of labor to operate the plant, $4138.69; total $5061.21. The average cost per ton for sawing, drilling, calipering and loading was, therefore, 77.2 cents. About 500 tons of crop ends were obtained as a by-product of the work, which were sold for $3800. When the mill is run at its full capacity it will cut rails for a mile of track per day and the proceeds from the sale of crop ends will nearly pay the cost of operation.

Figure 505 shows the end of a rail selected as a sample from a lot of 6000 tons of steel rails trimmed and redrilled for the Pennsylvania R. R. some years ago at a private mill in Wheatland, Pa. These rails had been in the main track of this line for fifteen years, the original weight having been 70 lbs. per yard. The rails had lost about $^1/_{16}$ in. in hight, pretty uniformly. The illustration shows the application of a straightedge to the top of the sample rail, disclosing that the rail end had been bent or worn downward $^3/_{16}$ in. The vertical white mark shows how much of the end had to be cut off to reach the uninjured portion of the rail. The rails as originally drilled were spliced with four bolts, but in drilling them after the shortening process, three holes were made in each end, for a 6-bolt splice. After trimming the rails they were sorted and kept together in sizes within a variation of $^1/_{32}$ in. in hight. In the lot of 6000 tons it was found that more than 80 per cent of the rails were of one hight. By the arrangement at this mill, operated by the Holland Company, of Pittsburg, Pa., the mill people took the rails from the cars, sawed, calipered, drilled and reloaded them, and disposed of the crop ends and applied the proceeds of the same to the expense of sawing. The plant comprised two toothed saws, 42 ins. in diameter, running at a peripheral speed of about 4 miles per minute. The rails were sawed dry—two rails at the same time by each saw. As a matter of record a rail was cut off in 8 seconds. Special apparatus had been arranged for lifting the rails to and from the cars and other parts of the equipment were adapted equally well to facilitate the work.

The Norfolk & Western Ry. has at Roanoke, Va., a stationary rail-sawing mill, equipped with a 46-in. friction saw, two three-spindle drills and a rail straightener, and large quantities of steel rails which have been removed from the main line for the purpose of relaying the track with heavier rails have been trimmed and straightened for use in branch lines. The time required to cut off a 75-lb. rail is from 15 to 20 seconds and the

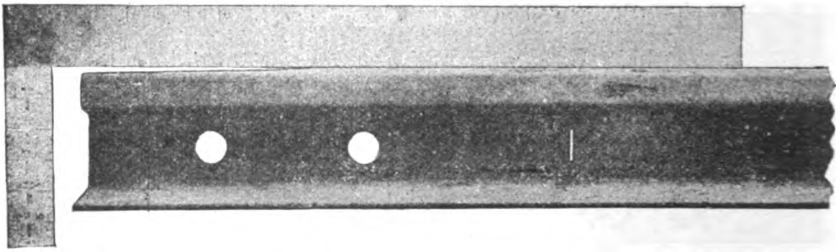

Fig. 505.

time required for drilling three holes in each end for splice bars is from 30 to 40 seconds. The mill has a capacity for sawing, drilling and straightening (such rails as require straightening) 300 rails in 10 hours, and the cost is about 12 cents per rail. There are rollers and skidways in rear of the mill, on which the rails are sorted and from which they are loaded to the cars. The Chicago, Milwaukee & St. Paul Ry. has a stationary rail trimming plant at Savanna, Ill. The Pennsylvania R. R., which has access to four stationary cold-sawing plants, has used trimmed rails in its light-traffic lines extensively. On the Western Railway of France the trimming of rails with battered ends for relaying is done by hand. The tool used is a hack saw, the blade of which lasts on an average for two cuts. Usually the rail is cropped 14 ins. at each end; that is, the rail is shortened 28 ins.

176. Track Elevation and Depression.—Track elevation or depression is generally understood to mean the work of raising or lowering track to a new level or grade line, on the same or practically the same location. Either term implies change of elevation, but the operations performed may or may not involve the lifting or lowering of the old track: a new track is sometimes built at the changed elevation and the old track is then abandoned and taken up. Of late years such work has assumed considerable importance, which will increase with time, owing to the growing tendency toward grade reduction and the abolishment of grade crossings in and about cities and in thickly populated districts. The work also derives importance from the engineering problems involved, which are usually of a high class and not infrequently very intricate. As a rule, the simplest problems attaching to such work are found in the country, where there are fewer highway crossings to deal with and where train movements are less frequent. Aside from the surveying the work in such locations is largely of the nature of track work, as a rule, while in the cities it is a combination of track and bridge work, and quite frequently it also involves the lowering of sewers and gas and water mains at the street intersections. While local conditions determine that the general work of track elevation or depression in any case is a special problem there are many details of the work, especially with reference to methods of handling the track, much the same or similar in nearly all cases, which are worth considering. It is to be remarked that while track elevation work is usually classed as engineering, skillful trackmanship (which is none the less engineering) is one of the essentials to the economical performance thereof.

The work of reducing grades on an old location usually consists in depressing the track at summits and elevating it in the hollows, the material excavated from the cuts being hauled to make the fills in the hollows. In cases where the quantity of excavation is not sufficient to do the filling it is customary to begin the embankments by scraping material from the side of the right of way with teams; or in some cases the central core of an embankment is put up by team work and a track is laid, from which material can be dumped from cars to widen out the earthwork to standard dimensions. If borrow material must be used to make the fills it will sometimes pay to purchase land on the inside of some curve, in cut, and take out the material with a steam shovel, thus making room to ease the curvature. The facility with which such operations can be carried on while maintaining the traffic of the road depends a good deal upon whether the road is single or double track. Large quantities of excavation are, of course, best handled with the steam shovel, unless the material is rock; and with the massive machines of modern construction it is frequently considered economical to handle even that material with steam shovels, after loosening up the rock by blasting. Where train movements are frequent, it will usually be found advisable, in deep cutting and high filling, to shift either the old track or the new grade line laterally a sufficient distance to enable the fill to be made from a temporary trestle of cheap construction, so that traffic on the main line need not be disturbed. The economy obtained in dumping the filling material from a trestle, as compared with the method of raising the track by stages and supporting it with the filling material, is found partly in the large saving of labor required in handling over the material; for every time the track is raised it must be at least roughly ballasted before trains can be permitted to pass. By the latter method there is bound to be at least some delay to the trains; a great deal of time is lost to the labor in waiting for trains to arrive and get out of the way; and as far as the construction of the fill is concerned, a great deal of labor goes for naught in continually preparing for the passage of trains. In dumping material from a trestle no hand labor is required until it becomes necessary to dress out the material at the top of the fill. In work of this kind carried out on the Illinois Central R. R. between Fulton, Ky., and Memphis, Tenn., the fills in various places were made from temporary trestles, as shown in Fig. 506, the new grade line being offset 18 to 50 ft., so that all portions of the fill could be constructed without interfering with main-line traffic. The top of the trestle was 3 ft. below the new grade line, so that the track in its final position would be

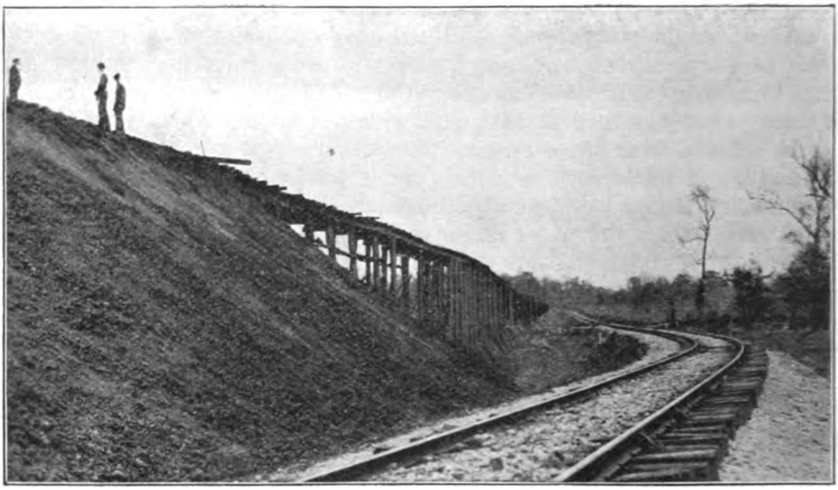

Fig. 506.—Raising Grade by Filling from a Temporary Trestle.

clear of the timber-work of the buried trestle. The material was handled by ordinary methods, being loaded in dump cars and run out onto the temporary structure by locomotives, on narrow-gage tracks in some instances and on standard-gage tracks in others.

In depressing a single track on the old location it is most commonly the practice to shift the track laterally a sufficient distance to permit the steam shovel to excavate the cut, thus providing for the traffic to pass undisturbed, meantime, and then to build a new track through the cut on the new grade, connect with the old track at the ends of the cut, and abandon the old track over the top. This was substantially the method followed in some very extensive work at grade reduction on the Chicago Great Western Ry., near Holcomb, Ill. The work involved a change of grade over a distance of five miles, with some deep earth and rock cutting at a point known as the "Holcomb Cut." At this place the grade was reduced from 1 to $\frac{1}{2}$ of 1 per cent, and by constructing overhead bridges across the cut the company was enabled to avoid five grade crossings with highways. The principal cut was one mile in length, with a maximum depth of 45 ft., the average depth for a distance of 1000 ft. being 40 ft. At one end of this cut the main line and some yard tracks had to be moved over to allow for necessary excavation, while at the other end the cut was excavated at some distance aside from the old location. While the cut was being made the trains used the old track over the top of the hill, and the new track was not laid through the cut until after its completion. The bulk of the material taken out of the cut was hauled in side-dump cars and used to raise the grade of the line to the west of the hill, the maximum haul being four miles. This material was handled with cars and locomotives of 3-ft. gage and the method of elevating the track was to widen out one side of the embankment at a time, by unloading from the side-dump cars, raising that side about 5 ft. above the main line; and then to throw the main line over on the new grade, when the other side of the fill would be widened out and raised 10 ft., or 5 ft. above the main line again. Temporary bridges were put in at the highways, where necessary. This method of procedure was repeated until the main line was thrown to final grade, when the balance of the embankment was brought to grade and the main line thrown to the center of the roadbed, which was finished off 24 ft. wide at sub-grade.

Another method that is commonly followed is to cut through with the steam shovel close beside the old track, completing the slope of the cut on that side, as illustrated in Fig. 507, and then to shift the track into the depression so made and later cut out the old bed and form the slope on the other side. Where the traffic is light the main line is sometimes used for the loading track, but if the traffic is heavy it is usual to build an extra track through the cut, either for a loading track, as shown, or for the traffic. In reducing the grades of the Grand Trunk Western Ry. the traffic through cuts that were being lowered was provided for on a "detour" track built at the side of the old main line, along the foot of slope, or by digging into the slope with pick and shovel a few feet in some places where it was necessary to make room. The old track would then be used for the loading track while one side of the cut was being lowered. By blocking up under the steam shovel as it progressed an excavation 15 ft. deep, in a single cutting, was sometimes made in this way, the material being loaded upon flat cars standing on the old track, as stated. The two tracks on the upper bench would then be thrown down into the new excavation and the steam shovel would take out the other side of the cut, the near track being used to load upon and the off track for traffic. In some locations, however, a new track was built in the bottom of the first excavation and ballasted up for the traffic, and the old main track thrown down to load upon when the steam shovel was ready to begin work on the other side. In that case the "detour" track was taken up.

Some characteristics of steam-shovel operation adopted by the St. Louis Southwestern Ry. in deepening cuts in grade reductions are shown in Fig. 508. The illustration shows the method of taking out the first cut in work of this character. The order of procedure is to throw the main track off the center as far as possible, through the cut to be lowered, this distance

Fig. 507.—Lowering Grade through a Cut.

usually averaging about 6 ft. The track so moved is still used as main track for passing the traffic, and at the same time is utilized as a loading track in connection with the steam shovel. After the first cut has been taken out traffic is diverted to the track previously used by the steam shovel, and the shovel is then put to work at taking down the other side of the cut; this operation being repeated until the desired depth is attained. In the particular piece of work illustrated by the sketch a summit cut having an original depth of 16 ft. was lowered an additional 16 ft. by the steam shovel, the first cut being 9 ft. in depth, as shown. In this case the new roadbed was graded to new centers to the right of the old line, and the tangents on each side were swung to a connection with a curve over the summit, after the same was thrown farther out to admit of the change. Under these conditions the material excavated from the right-hand side of the old track was in excess of that taken from the left-hand side, as indicated by the location of the new slope line. The summit was lowered the depth of 16 ft. with three cuts of the shovel, traffic being handled meantime without obstruction. The excavated material was hauled and dumped to raise the embankments over a distance of three miles on each side of the cut, resulting in a continuous ascending and descending gradient of 26 ft. to the mile over a distance of 6 miles, where a steeper grade had previously existed. In some places where work of this character was undertaken it was found to be advantageous to make the excavations on the inside of the curves and widen the embankments on the sharp existing curves, in order to improve the general alignment without having to shift the track very far.

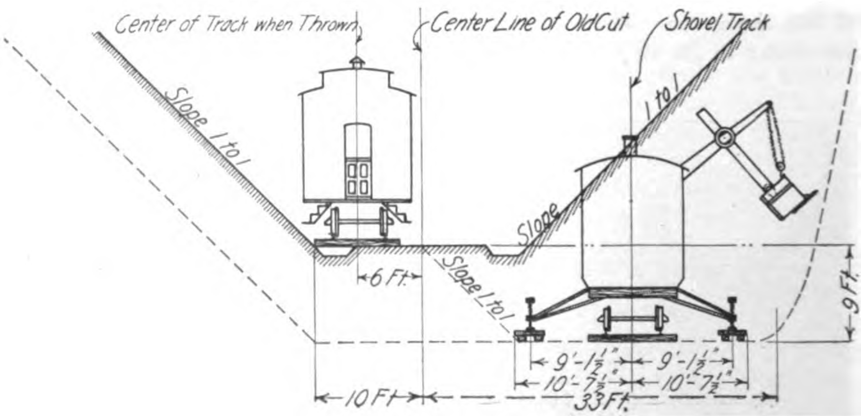

Fig. 508.—Method of Lowering Cut, St. Louis Southwestern Ry.

In elevating a double-track roadbed the inconvenience to the work in caring for the traffic is not so great as with single track, for one of the tracks may be abandoned temporarily, lifted 3 or 4 ft., filled in and roughly ballasted, the other track meanwhile carrying the traffic for both directions. The traffic may then be shifted to the higher track and the lower track lifted, filled in, the bank widened out on that side, and the track put in running order at an elevation of 3 or 4 ft. higher than the other track; and thus the embankment is carried up, the traffic being shifted from one track to the other as the work of filling proceeds from side to side. The service track is sometimes operated as a single-track block between semaphore signals established temporarily beyond the extreme limits of the stretch of work, operators being stationed at these points, in telegraphic communication with each other and with the train dispatcher.

The same arrangement is sometimes applied to the elevation of a single track. Part of the time the service track is used by the work trains, from which the material is unloaded and placed under the raised track. If a telegraph operator be stationed at the steam shovel, or if telephone connection be had between that point and the nearest telegraph station, so that the whereabouts of the main-line trains can be ascertained, the movements of the work trains can be much facilitated.

After the filling has been brought to the final grade the tracks are thrown to the permanent alignment and ballasted. It is not worth while to spend much time dressing off the ballast between the rails and on the shoulders, for on newly-made fills the track must necessarily settle quite rapidly; and not until some time has elapsed is it possible to maintain the track to an even surface at the desired grade. In lining the track, from time to time as the filling progresses, ordinary lining bars are found to be of but little use, being too narrow to obtain a firm hold in the loose material; and handspikes are usually substituted as being better adapted for the purpose. In the track elevation work of the Chicago, Burlington & Quincy Ry. the handspikes for throwing track were neatly made of oak 6 ft. long and of a section 3x3 ins. square for the first 2 ft. in length from the point, whence the stick was rounded and tapered to a size convenient for the grasp of the hand at the end. These handspikes had a crow-bar or wedge-shaped point.

In depressing double tracks it is usual to abandon one of the tracks and use it as a loading track for the steam shovel. After the first cut has been made this track can be thrown into the depression and serve as the loading track for a second cutting of the steam shovel, under the old bed. When the final grade is reached the track in the depression can be put in shape for the traffic and the steam shovel can be set at cutting out the remainder of the material to be excavated. In depressing three tracks at 12 ft. centers, over a stretch of 1¼ miles on the Chicago, Burlington & Quincy Ry., near Kirkwood, Ill., the middle track being a passing track, the method of doing the work was to throw the outside tracks outward to 14 ft. centers from the middle track, and then to cut down between the tracks by hand to a depth of 3 ft. The middle track was then taken up and the remainder of the excavation made with a steam shovel, using one of the tracks for traffic and the other for loading the material, until the middle core was taken out, when first one of the tracks was shifted into the excavation and put in running order, and then the other. Later on excavation was made for the third track, the passing track this time being placed on the outside, so as to enable the straightening of the two main tracks.

Change of Grade in Cities.—The elevation and depression of tracks in cities has received most attention in and about Boston, in Philadelphia and in Chicago; but especially in Chicago, where several hundred miles of steam railroad tracks have been elevated, resulting in the abolishment of several hundred grade crossings with streets. As the work has been carried out in that city the tracks pretty generally have been elevated about 10 ft. and the streets depressed at the subways to give a clear headroom of 12 ft., except in subways carrying street car tracks, in which case the clear headroom has been made 13½ ft. Retaining walls of stone masonry or concrete have been used where the width of the right of way has not been sufficient for a fill with natural slopes. The filling material in nearly all cases has been sand, of whitish color, excavated from sand dunes in Indiana and hauled about 35 miles.

The controlling feature in the work of elevating tracks in cities is the erection of the bridges (temporary and permanent) at the street intersections, which, in connection with the frequency of the train movements and the number of tracks to be elevated on the same roadbed, are the conditions which determine the method of handling the tracks. In nearly all cases the plan followed has been to abandon part of the tracks temporarily while they are being elevated, diverting the traffic to the remaining tracks, partly or wholly, or partly or wholly to tracks built temporarily to carry the traffic. Thus in elevating $4\frac{1}{2}$ miles of four-track road on the Providence division of the New York, New Haven & Hartford R. R., in Boston, in 1895 and 1896, strips of land were purchased on each side of the original right of way (66 ft. wide) and temporary tracks were laid thereon to carry part of the traffic. Over part of the way two high-level tracks were also laid, on trestle, to carry the traffic, this trestle being so located that it was afterwards filled in and made part of the elevated roadbed. The tracks were elevated 18 to 20 ft. above the original grade line without closing the streets and without interfering with the trains, which averaged 206 per day. The two westerly tracks were raised first, the retaining wall and the filling on that side being carried up simultaneously. The abutments for the bridges were built across half of the street at a time, and the bridges were completed and the tracks laid thereon and put in running order, so that trains could be moved over the two elevated tracks before taking the other two tracks out of service. Temporary trestles were used to make the approaches to the bridges on the tracks which were being elevated. After the two westerly tracks had been put in running order at the new elevation the east retaining wall was constructed and the two tracks on that side were taken out of service and elevated. A similar method was followed in elevating the two tracks of the St. Charles Air Line, between Clark street and Michigan avenue, in Chicago, in 1898. The retaining wall on the north line of the right of way (the tracks running east and west) was first laid, when a trestlework was constructed close to the wall to carry an elevated track. After the traffic was diverted to this trestle the retaining wall on the south side of the right of way was constructed, and the space between the retaining walls was filled with slag from gondola and side dump cars, first filling under the trestle and then widening out the embankment by building an additional track and dumping the material therefrom. Before the tracks were ballasted the stringers and caps were removed from the trestlework.

In elevating eight main-line tracks of the Illinois Central R. R. between Forty-seventh and Seventy-first streets, in Chicago, in 1892 and 1893, the work was begun on the east side of the company's right of way by the construction of a sand fill raised as high as was practicable in the middle of the blocks between the street crossings, with steep grades down to the crossings of the several streets, which had to be kept open for highway travel. Pile trestles were then constructed at the street crossings and one track was carried over the same, filled in and put in running order. In this manner the filling was gradually widened out toward the west and the tracks elevated, additional lines of trestle being built across the streets as the tracks were raised. The work of building the masonry abutments and the erection of the plate-girder bridges to replace the temporary trestles was an after consideration. In elevating the four tracks operated jointly by the Chicago, Rock Island & Pacific and the Lake Shore & Michigan Southern roads, in Chicago, two tracks were elevated together, in stretches over four blocks. The method pursued by these companies was to lift the tracks gradually, supporting them on blocking or cribs at the street crossings, until the full elevation was reached, when framed trestle bents and stringers were placed for the support of the track until the abutments were built and the plate-girder bridges erected. In some cases two of the tracks were first elevated to the full hight and put in service over bridges laid on abutments built in halves, and in other cases all of the tracks were first raised to the full elevation before the abutments were built or the bridges erected.

In the track elevation work of the Chicago, Milwaukee & St. Paul Ry., in Chicago (four tracks), the tracks were lifted to the final elevation in three stages, one track at a time, but all of the tracks more or less together, so that all the tracks were brought to the full elevation and supported upon temporary structures at the streets before the masonry work of the abutments was commenced. The method followed was to drive three-pile bents at the streets before the tracks were raised. These bents were located to span the abutment site at either side of the street, dodge the sewers, water pipes, etc., keeping within a span length of 15½ ft. These piles were then cut off at the elevation of the base of rail, and at the first lift, usually about 4 ft., the track was supported on two 12x12-in. caps (one on top of the other), upon which were laid the stringers and ties. The purpose of driving the piling for the support of the caps was to permit excavation for the depression of the street without weakening the support for the track. In the second and third stages of lifting the track, jacks were used under the uppermost of the two caps and at each stage the cap was supported by 12x12-in. posts, until the track was raised to the final hight and posts of the proper length were placed and braced to form framed bents. The piles used were second hand, 12 to 18 ft. long, some of which were tops cut from piles driven in the ordinary work of the road, the only requirement being that they should be sound enough to stand driving and last two years. Fir stringers 8x16 ins. x32 ft. long, were used, lapping by each other on the trestle caps. The posts were cut to standard lengths and this timber was used over and over, continuously, throughout all of the track elevation work of the road. The cost of this falsework per lineal foot of one track was $2.10, of which $1.30 was for labor and 80 cents for loss and deterioration of timber and iron. In order to facilitate the erection and removal of the timber the caps and sills were doweled to the posts and the brace planks were bolted. In this manner the track elevation work could progress independently of the masonry work and the erection of the plate-girder bridges. The abutments in all the bridges of this work were built of concrete. In elevating a two-track line of this company two temporary tracks were built at one side of the right of way to carry the traffic trains while the work of elevation was in progress.

In elevating the four tracks of the Pittsburg, Ft. Wayne & Chicago Ry., in Chicago, two tracks were abandoned and raised at a time. The method pursued differed from the foregoing, in that the bridges at the street intersections were erected, in place, on timber bents before the tracks were raised out of the old bed at the streets, although to some extent the tracks were raised in the middle of the blocks, under traffic. On portions of the line where bridges were so close that an appreciable elevation could not be had by raising the tracks in the middle of the block a cribbing of old ties, about 8 ft. high, was built to permit the two tracks which were being elevated to be placed at their full hight, the purpose of the cribbing being to retain the filling material which otherwise would have encroached upon the clearance of the adjacent running track. Tie cribbing was also constructed to serve as bulkheads to retain the filling at the ends of bridges until the abutments of the same were built. After two of the tracks had been elevated and put in running order over the permanent structures the traffic trains were diverted to them and bridges were put up for the other two tracks, which were then elevated. As far as possible the old ties forming the cribbing between the two middle tracks were dug out of the sand filling and removed as the third and fourth tracks were elevated.

In elevating the lines of the Chicago & Northwestern Ry., in Chicago, each track elevated was first raised to a summit in the middle of the block. The pair of girders for each (alternate) track were assembled at a distance, in a yard specially fitted up with derricks for the purpose, and brought to the crossing on flat cars, with the floor riveted up in position, complete, and the rails in place. Previous to the arrival of the bridge two piles would be driven on each side of the track to form

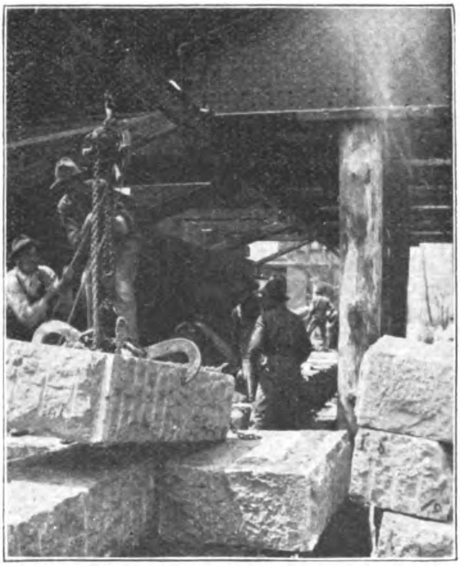

Fig. 509.—Trolley for Laying Stone, C. & N. W. Track Elevation.

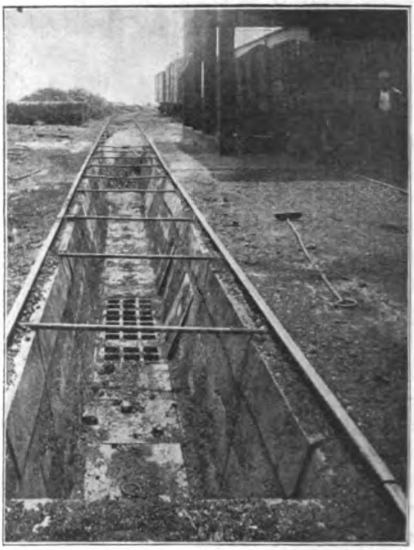

Fig. 509 A.—Cinder Pit for Conveyor Plant, Ill. Cent. R. R.

a two-pile bent of 9 ft. clear span, or a pier of four piles, for the temporary support of each end of the bridge while the abutments were being built underneath. Each pile bent was capped with two 15-in. I-beams, and the bent spanned the site of the abutment. In some cases the piles were cut off to place the bridge at an elevation of 7 ft. and in other cases to place it at the full elevation of 10 or 11 ft.; and in bridges of more than one span resting upon posts or columns the girders were unloaded from the cars directly to the posts, at the full elevation. Upon the arrival of the bridge it was jacked up on the cars, which were run between the pile supports, and let down upon the I-beam caps, and then the cars would be pulled from underneath. After landing the bridge on the pile supports in this manner, the track on the approaches to the bridge was raised, connected across the bridge and filled in, timber cribbing being placed to retain the filling at the abutment sites and at the high portions of the approach, at the sides. After a number of bridges had thus been placed and the approaches built on one of the tracks (of a three-track line) or on two of the tracks (of a five-track line) the traffic was turned onto the same. The work of track elevation and of placing the bridges thus progressed independently of the masonry work of the bridges, which was laid as best to suit convenience, at some time thereafter. The track at the middle of each block remained in a depression, not being raised as high as the bridges at the intersecting streets until the remaining parallel tracks were raised and filled in, thus avoiding the necessity for cribbing, which would have been necessary had the tracks been raised to the full elevation throughout the entire distance between the streets, since the slope of the filling material would have extended beyond the clearance line of the running track adjacent thereto. In elevating the five tracks of the Galena division of the road, three tracks, consecutively from one side, were abandoned and two retained in service. Bridges were placed on the first and third tracks and the intermediate floor for the second track was riveted in and all the filling made for the three tracks before traffic was turned over any of them. After traffic was turned onto the three tracks the other two tracks were abandoned, when the third pair of girders was placed and the intermediate floor put in. In elevating the three-track line on the Milwaukee division, the bridges were placed first for one of the outside tracks, which was elevated and put in running order, when the other outside track was abandoned, the bridges put in, the tracks elevated, and the intermediate floor riveted in between the bridges on the outside tracks. The stones for laying the abutments under the temporarily supported bridges were placed by a trolley running upon an 8-in. I-beam suspended from the lower flange of the girders to extend crosswise the bridge and over the middle of the abutment wall. The ends of this I-beam, which projected beyond the girders a sufficient distance to cover the length of the abutment, were held up by posts. The trolley arrangement straddled the web of the I-beam and ran upon the bottom flange. From the trolley was hung a Duplex block and fall which would hold its load at any point to which the same had been hoisted. Since the bridge seat casting was about 17 ins. high, all except the top course of stone could be lifted and run to place by this device, which is shown in Fig. 509.

A five-track line in Rockwell St., Chicago, consisting of two tracks of the Pittsburg, Cincinnati, Chicago & St. Louis Ry. and three tracks of the Chicago & Northwestern Ry., were elevated by methods much the same as those followed in the work of the C. & N. W. Ry., just referred to. To begin with, the bridges over four streets were erected for the two tracks of the P., C., C. & St. L. Ry., the traffic meanwhile being diverted to the three C. & N. W. tracks. After the filling had been completed between these four bridges and on the approaches the traffic was then handled over the P., C., C. & St. L. tracks, and bridges for eight blocks of the C. & N. W. tracks were erected and the track elevated to them. Traffic was then diverted to the C. & N. W. Ry. over these eight blocks and the elevation on the P., C., C. & St. L. extended four blocks on either end of the four blocks first elevated, thus making 12 blocks of completed work on these tracks. After diverting the traffic to these 12 blocks, the elevation on the C. & N. W. tracks was then extended eight blocks more, making 16 blocks in all. In this way the work progressed, using the tracks of one company while the work of elevation was being prosecuted on the tracks of the other. The average force was 300 men at raising and filling in the tracks and 200 men at putting in abutments and excavating and lowering the streets by contract.

Some very difficult engineering of a special character, encountered in changing the grade of tracks in the business centers of cities, including the depression of the Philadelphia & Reading Ry. tracks in Pennsylvania Ave., Philadelphia, and the elevation and depression of a network of tracks at Sixteenth and Clark streets, Chicago, is described in § 205, Supplementary Notes.

The best filling material for use in track elevation is sand, for many reasons: It is easily and cheaply handled, not only in loading and unloading the cars, but in putting it under the track; it does not become muddy or impede the progress of the work during wet weather, nor is its condition so changed during rainy weather that it cannot be worked to advantage, or so as to endanger the stability of the track; it serves as a fair material for ballast while the track is being raised; and it is readily compacted under the pressure of trains to form a firm embankment. In cities, therefore, where filling material for track elevation must usually be hauled from a distance, it is, if available in the locality, undoubtedly the most economical material to be obtained. The work of depressing the streets in subways under elevated tracks is usually performed with teams and scrapers, and the material obtained from such excavation is usually hauled around and dumped to form part of the filling material for the elevated tracks.

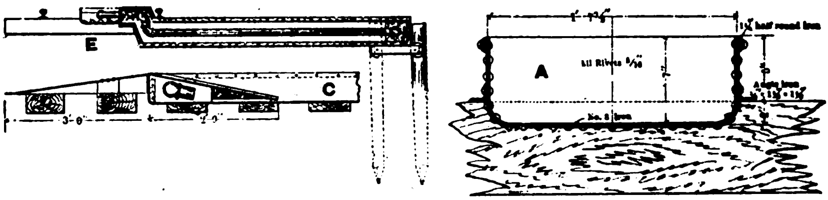

Fig. 516.—Track Tank, Chicago, Milwaukee & St. Paul Ry.

Most of the sand filling used in Chicago for track elevation work has been hauled in gondola cars and unloaded over the side of the car with hand labor. Where this has been done the trains have been unloaded from a track adjacent to the one being elevated, which was usually raised and blocked or otherwise supported at a good hight, so that the material as it was unloaded from the car was thrown to place under the track. In the track elevation work of the Chicago, Rock Island & Pacific and Lake Shore & Michigan Southern roads, unloading plows were used in at least part of the work. As dry sand in heavy winds is of fugitive character, the Chicago, Milwaukee & St. Paul Ry. has found it advantageous to throw a layer of loam about 12 ins. thick on the slopes of unretained sand filling. Such material on the slope is also less subject to washing down by rains than is sand. The sand filling is topped out with gravel or broken stone, to serve as ballast for the tracks, and during the first year after the tracks have been elevated some attention is required to keep the tracks in fair surface. Tracks elevated 10 ft. on sand filling, on either retained or unretained embankments, will settle about 7 ins. during the first year, when the settlement of the retained embankments practically ceases. On unretained embankments, however, the surface of track does not remain in as good condition as it does on embankments confined within retaining walls, after such settlement.

177. Track Tanks.—The track tank or track "watering trough" is a metal trough usually 6 or 7 ins. deep, 19 to 24 ins. wide and about ½ mile long, placed in the middle of the track. Water is taken into locomotive tenders, at speed, by means of a hinged scoop dropped into the trough by means of a lever manipulated by the fireman or worked by compressed air. Such tanks are used on but comparatively few roads in this country, as the necessity for the same arises only where fast trains must make long runs between stops. For a usual thing only passenger engines are equipped with scoops for taking water from the track, but on the New York division of the New York, New Haven & Hartford R. R., on the Canadian line of the Michigan Central R. R. and on some other roads where it is especially desirable to keep the freight trains moving, the freight engines also take water from the track. The Pennsylvania R. R. and the Lake Shore & Michigan Southern Ry. have a good many freight engines equipped with water scoops.

The trough is usually built of iron or steel plate $^3/_{16}$ in. thick and delivered on the ground in sections, to be riveted together as they are placed in the track. The Chicago, Milwaukee & St. Paul Ry. has two track tanks built of cast iron, in sections 6 ft. long. The track must, of course, be level, and the ties are dapped out $1\frac{1}{2}$ or 2 ins. to make room for the trough (Engraving A, Fig. 516), the top of which is placed even with top of rail. It is not necessary that the track should be straight. At several places on the Pennsylvania R. R. the track tanks are on curves. The top edges of the trough are stiffened by half-round irons and the trough is secured to the ties by ordinary track spikes driven to hook over (as they do the flange of a rail) the horizontal leg of a small angle iron riveted to the side of the trough at the top of the tie. This arrangement permits the trough to expand or contract without disturbing the spikes. The trough is usually anchored to the ties at the middle, and allowed to expand or contract at the ends. At the ends the bottom of the trough slopes upward (Engraving C, Fig. 516), to lift the scoop out of the trough should the fireman fail to raise it at the proper time; and outside the end of the trough there is an inclined plane laid with the intention of protecting the end of the trough from dragging parts of cars, or anything hanging lower than the top of the trough. The incline for lifting the scoop in case of tardy attention on the engine is usually made too abrupt, in this country, and the end of a trough is occasionally torn out by a train running at high speed. A slope 20 ft. long is perhaps none too gradual. It has been recommended that a piece of plank bolted to the end of the trough in lieu of a sloping end would answer every purpose and in case it was torn out it could be quickly and cheaply renewed.

Water is supplied the trough by pumping or from a reservoir, under head. It is usually brought to the trough through a main with branch pipes entering the trough at intervals, so that it may be filled quickly after the water has been scooped out by a locomotive. Where track tanks are used on both the tracks of a double-track road the two troughs are usually interconnected by pipes at frequent intervals, so that the supply of water in both troughs is made quickly available for either track. The usual arrangement for preventing the water from freezing in winter time is to pipe live steam from a boiler plant located near the middle of the trough and admit it into the trough at intervals of 40 or 50 ft. To prevent trouble with pipe connections at points where the trough is permitted to expand or contract with change of temperature, the connection is usually made with a piece of rubber hose, or with some form of expansion joint in the pipe.

On the Baltimore & Ohio R. R., between Philadelphia and Baltimore, the distance of 92 miles is divided into three stretches of approximately 31 miles each, and track tanks (for double track) are placed at the two intermediate points. The troughs of these tanks are each 1200 ft. long, laid on sawed white oak ties 8x9 ins. in section. The inclined planes outside and inside each end of each trough are each 6 ft. 10 ins. long. The trough at one of the points referred to is supplied with water from a 40,000-gal. tank and at the other point from a 30,000-gal. tank, elevated 28 ft. above the track, in both cases. Water enters the trough through three 3½-in. pipes connecting with the bottom of the trough at its middle point and at points 200 ft. from the ends, these 3½-in. inlet pipes connecting with a 6-in. main leading from the pump house, to which the water is brought from the elevated tank through an 8-in. pipe. The valves controlling the admission of water to the trough are placed in the 6-in. pipe at the pump house, and an attendant is on hand at all times to see that the trough is kept full. The time consumed in filling the trough after a locomotive has taken water is from four to six minutes. To prevent the water from freezing in winter live steam is led into the side of the trough at intervals of 45 ft. through 1-in. pipes connecting with a 2-in. pipe running midway between the tracks, which connects with a

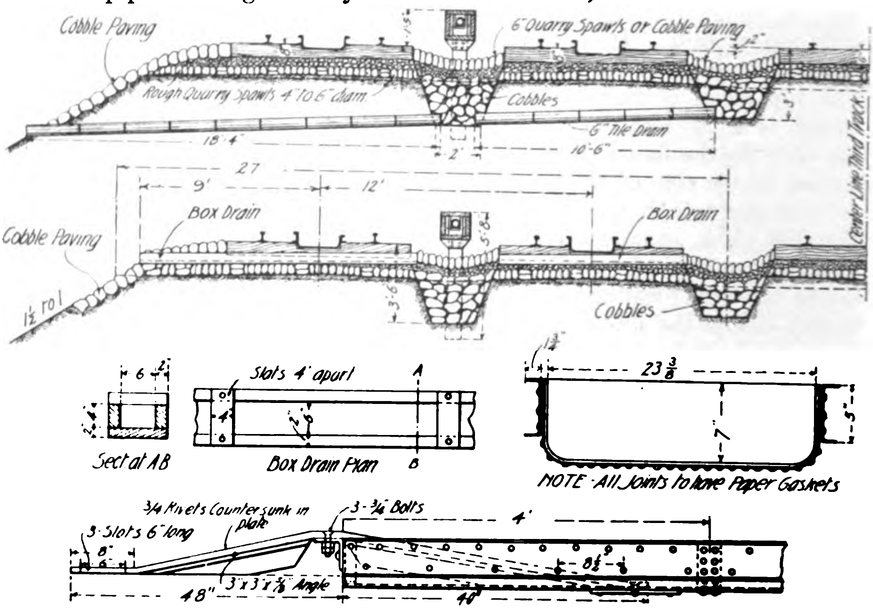

Fig. 517.—Track Tank, New York Central & Hudson River R. R.

2½-in. pipe leading from the steam dome of a large boiler in the pump house. To prevent condensation of the steam the pipes are wrapped and boxed, and 1-in. check valves are used to prevent back flow of water into the steam pipes when the steam is turned off. The connection with the trough is made with a nipple 3 ins. long, tapped and plugged with a stop which has a hole ⅛ in. in diameter inclined downward. The pressure of steam necessary to prevent freezing in the coldest weather is about 80 lbs. per sq. in. Full particulars regarding these tanks, including illustrations and itemized statements of cost of construction and operation, may be found in a paper read before the Association of Railway Superintendents of Bridges and Buildings, in 1892, by Mr. Geo. W. Andrews, supervisor of bridges, buildings and water stations, on the Philadelphia division of the road named.

In the arrangement for operating track tanks on the Baltimore & Ohio R. R. there is, at the end of the trough nearest the approaching train, a signal similar to a high switch stand, to indicate to the fireman when he may lower the scoop, and 100 ft. ahead of the far end of the trough there is a similar signal placed to mark the point where the scoop should be raised. The spout which conveys the water taken up by the scoop is oblong in section and is "goose-necked" into the top of the tender, so that the water enters the tender from above. The scoop is usually 12 or 13 ins. wide, and there is a stop to prevent it from dropping far enough to touch the bottom of the trough. In the scooping position it usually reaches 3 to 5 ins. below the top of the trough. As water may be taken at a speed of 45 miles per hour trains are not usually required to slow down very much in taking water from track tanks. Water has been taken from track tanks by engines running 70 m. p. h.

In a track tank on the Chicago, Milwaukee & St. Paul Ry., at Wadsworth, Ill., about half way between Chicago and Milwaukee, it was found impossible to keep the trough free of ice by the usual method of conducting live steam thereinto, and this experience led to the substitution of a new arrangement, by which the water is heated at the pump house and kept in circulation through the trough. Sectional drawings of this trough are shown in Fig. 516. The trough is 19 ins. wide inside and 7 ins. deep, setting into the ties 2 ins. The joint rivets in the bottom of the trough have countersunk heads. Water enters each end of the trough through a 3-in. pipe, the discharge taking place back of a casting underneath the end slope, whence it flows out into the trough through five semi-circular openings of 1½ ins. radius, through the bottom of the casting, as shown in the sectional drawings *C* and *E*. From both ends of the trough the water flows toward the middle, where there is a 5-in. pipe leading from the bottom of the trough, through which the water is pumped and delivered into an 8-in. pipe at the pump house, into which live steam is admitted from the boiler through a 1-in. pipe. From this 8-in. pipe the 3-in. feed pipes are led to the ends of the trough, as above explained. Thus, after the trough is filled, the water is kept in circulation through the trough and to and from the pump house, where its temperature is raised in the manner described.

Owing to the frequent splashing of water at track tanks the work of maintaining the track in even surface is much more difficult than at points where the conditions are only ordinary. The ballast for the track at track tanks should be broken rock of good depth and the drainage should be well provided for. In very cold weather the constant attention of the trackmen is necessary to keep the flangeways from being obstructed by ice formed by the freezing of the water thrown out by the scoops of the locomotives. The standard track tank of the New York Central & Hudson River R. R. and the arrangement of the drainage is shown in Fig. 517. The top of the roadbed and the top of the ballast are cobble paved, and between the two tracks on which the troughs are laid and between the second and third of the four (main) tracks there are blind ditches 3½ ft. and 3 ft. deep, respectively, filled with 6-in. quarry spawls or cobblestones. At intervals of 100 ft. these ditches are drained from the bottom with 6-in. tile pipe, and every 50 ft. the top surface of the ditch is drained by a 4x6-in. open box made of creosoted 2-in. plank and laid between the ties, as shown. The standard length of the trough is 1400 ft., the width 23⅝ ins. and the depth 7 ins., inside measurements. There are two inlet boxes under the trough, each being 18x12 ins.x2 ft. deep, located 104 ft. apart, near the middle of the trough. The water is fed through a 10-in. main and enters the boxes through 6-in. branches. Each inlet box has a strainer made of No. 14 wire woven to a No. 5 mesh. In the bottom of the trough, near the middle and also near each end, there is a 4-in. washout plug with a 4-in. pipe connection. The steam for heating, in winter, enters the bottom of the trough through $^3/_{16}$-in. brass nozzles 33 ft. apart. The main steam pipe is 3 ins. diam., reduced by sections to 1½ ins. at the ends, and the branches leading to the nozzles are ¾ in. diam. Some of the track tanks of the Lake Shore & Michigan Southern Ry. are 2500 ft. long, being of sufficient length to water two locomotives running as a "double-header." Each engine takes water while running half the length of the trough. Track tanks should not be located near interlockings or at other points where the train is liable to be stopped while taking water.

178. Ash Pits.—At terminal points it is desirable to have sections of track entering roundhouses or lying opposite coaling pockets or water stations built with reference to the convenient removal of ashes and cinders dumped from locomotives. While the construction of ash pits is usually taken in charge by the bridge and buildings department of railways, it is usual to find the clearing of the pits and the loading of the ashes in charge of the section men, and unless the arrangement for such work be planned with a view to convenience too much time will be spent on the accumulated ash heaps. From the trackman's standpoint it is, therefore, pertinent to consider the various types of ash pits, with the

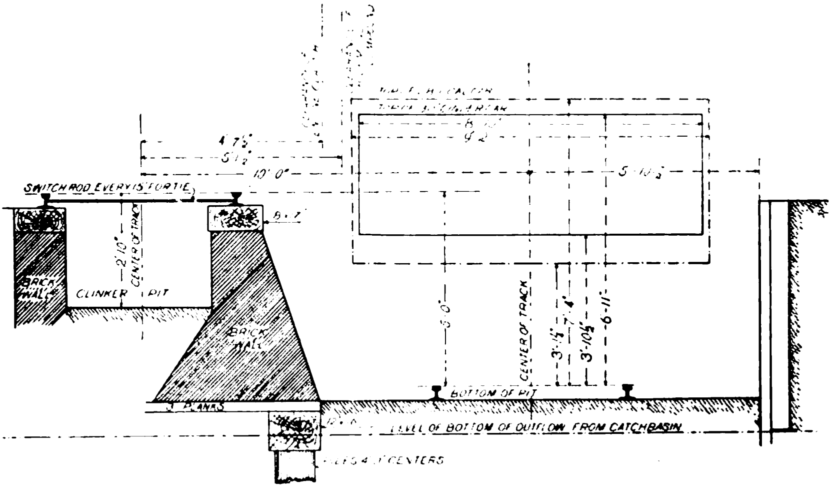

Fig. 518.—Ash Pit and Depressed Track, C., B. & Q. Ry.

attending facilities for clearing away and loading the ashes, if not the details of construction. It is too frequently the case that the ashes from a considerable number of locomotives are dumped upon the ties, to be shoveled out of the track daily by one or more men detailed from the section crew. While such an arrangement may be satisfactory at water tanks on main line, where high speed is made, the scheme is not an economical one for side-tracks or yard tracks where a number of locomotives are taken care of, for the ash heaps rapidly accumulate close to the track until the hostlers are discommoded in their work, for lack of room; and at last it becomes necessary to clear away the obstruction in some way, and it is frequently done by throwing part of the heap farther back. In any case the ashes have to be handled at least twice by the time they are loaded upon the cars, and where heaps are permitted to accumulate it sometimes happens that they are rehandled several times before they are finally loaded and hauled away.

To facilitate the removal of the contents of the ash pans a pit is sometimes constructed in the track, from which the ashes are shoveled out into heaps and afterwards loaded onto cars standing upon a parallel track, or run to place over the pit; but, so far as the cost of handling the ashes is concerned, such an arrangement is but little if any better than that of dumping the ashes upon the ties. The only improvement at all worthy of consideration is some arrangement whereby the ashes may be loaded onto the cars at the first handling; and if they must be loaded by hand, the only satisfactory arrangement is a depressed loading track, on which cars may be kept standing to receive the ashes as they are thrown out of the track or pit. An elevated dumping track, of course, corresponds to the same arrangement. It will be understood that the term ashes, as used in connection with the present subject, is intended to include cinders and clinkers as well.

The ash pit most commonly found in this country is a pit in the track, about 4 ft. wide and 3 or 3½ ft. deep, enclosed on both sides, with a depressed parallel track about 3 ft lower than the bottom of the pit, at convenient distance for loading the cars. Such pits are walled up with stone or brick laid upon a suitable masonry or concrete foundation and coped with stone, timber stringers, or wrought or cast iron plates. Ordinary hard-burned brick is the material most commonly used for paving, being set on edge, either in concrete or in a bed of sand, and sloped longitudinally and transversely for drainage, which is usually effected by means of 4 or 6-in. sewer pipe, with catch basins. Fire brick are sometimes used for paving the bottom of the pit and facing the side walls, but they are too soft to withstand the pressure from the weight above and the wear from the workmen shoveling in the pit, and hence ordinary hard-burned brick or ordinary brick faced with paving brick, are preferred. For the bottom, paving brick grouted with cement are used a good deal. It is also very commonly the practice to protect the bottom and sides of the pit from the heat of the cinders by a lining of old boiler plate, or cast iron plates about 1 in. thick, leaving an air space of about an inch between the plate and the wall. Where timber stringers are used for coping they are usually anchored by bolts passing down into the masonry, and the rails are spiked to them with ordinary spikes having the point turned 90 deg., so as to cut crosswise the grain of the timber. To protect the coping timber from fire the Chicago, Burlington & Quincy Ry. uses a sheet iron cover placed as shown in Fig. 490A. The material for these covers is obtained by cutting up old tank iron and bending it to such shape that when anchored against the timber there will be a 1-in. air space all around. To maintain this air space old nuts are placed between the wood and iron, at intervals, through which are run the lag screws securing the plate. The air space is closed in by bending down the edges of the iron plate, top and bottom, thus preventing cinders from filling up the opening. Where an iron or steel or cast iron plate is used for a coping the rail is riveted to the plate or fastened to it with bolts and clips and the plate is secured to the masonry by anchor bolts. In some cases, however, the rail rests directly upon the masonry and the fastenings consist of anchor bolts and clips or ordinary track spikes driven into wooden plugs about 2 ins. in diam., which are set in holes drilled in the masonry.

At a pit of this kind it is, of course, necessary to run the locomotive off the pit before the ashes can be shoveled out, and in case locomotives follow in rapid succession a small pit of the kind is liable to become clogged before the shovelers can get into it. While, as above stated, pits of this type are more numerous than any other, the design does not meet with as much favor for new construction as it formerly did. Figure 518 is typical of this style of pit construction. For convenience of loading the cars the pit and loading tracks are laid at only 10 ft. centers. The cost of loading cinders at a certain pit of this kind has averaged 97 cents per car-load of 27 cu. yds. (heaped). Before the depressed track was used the cinders were first shoveled from the pit to a platform, and from this platform into the car, at an average cost of $1.77 per car-load, same capacity as stated above. This comparison shows the economy of loading direct from pit to car.

A style of pit which meets with a great deal of favor is one that is open on the side toward the depressed loading track, as then the ashes may be raked out of the pit and loaded into the cars without hindrance from locomotives standing over the pit. It is desirable to have a clear space or platform 5 or 6 ft. wide between the open side of the pit and the side of the ash car, or a spacing of 14 or 15 ft. between the centers of pit track and loading track; and, to aid the shoveler, the bottom of the pit and floor of the platform should be sloped toward the loading track. The rail on the open side of the pit is usually supported upon cast iron pedestals or columns, or cast iron piling, and the rail on the closed side by the same means or by a wall with suitable coping and fastenings for

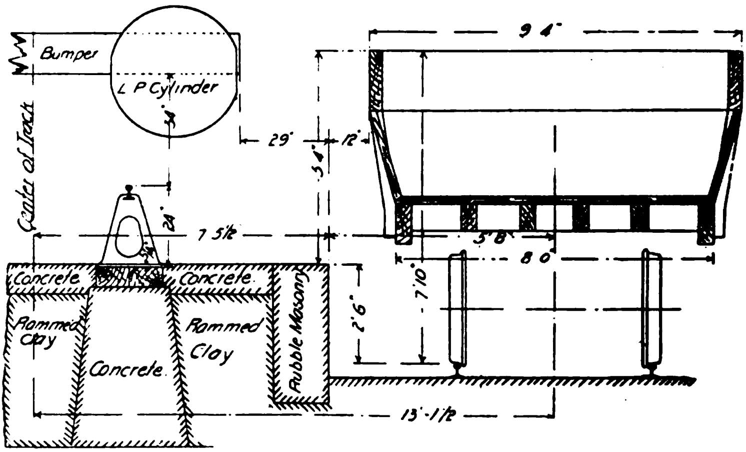

Fig. 519.—Ash Pit and Depressed Track, Northern Pacific Ry.

the rail. The pedestals are usually supported upon a longitudinal masonry pier, or upon the concrete bed on which is laid the paving of the bottom of the pit. Where the span between the pedestals is more than 3 ft., but does not exceed 6 ft., the running rail is usually reinforced for support by riveting it to an inverted rail fitting a suitable bearing or seat in the casting; but where the span exceeds 6 or 7 ft. the immediate support for the running rail is usually an I-beam, varying in depth according to the span. It is frequently selected from scrap bridge material. The rails are usually held to gage with switch rods or with long bolts through pipe struts. In order to cause the ashes to slide out upon the loading platform as they are dumped from the locomotive, inclined plates are sometimes placed against the back side of the pit or the bottom of the pit is laid to a slope. The edge of the loading platform is sometimes curbed with a line of old rails.

Figure 519 is typical of the foregoing style of ash pit. The track over the dumping pit is carried on cast iron pedestals 24 ins. high. The distance from the center of this track to the center of the depressed track is 13 ft. 1½ ins. The top of the car into which the cinders are loaded is

5 ft. 4 ins. above the level of the clinker pit. The difference of level between the loading platform and the depressed track is not as much as it ought to be to make the loading of the cinders easy. An ash pit of similar construction on the New York Central & Hudson River R. R. has six lines of old rails embedded in the concrete under each row of pedestals. To prevent the concrete floor from being cracked or broken up by the hot ashes, there is a galvanized netting of No. 8 wire, 1x2 ins. mesh, embedded in the concrete near the top surface.

It is obvious that the deeper the depression for the loading track the better is the work of loading the ashes facilitated. At East Tyrone, Pa., on the Pennsylvania R. R., there is an ash pit 120 ft. long and 3½ ft. deep, with a loading track depressed 8 ft. below the floor of the ash pit, the two tracks being 11 ft. 7 ins. centers The top of the masonry retaining wall for the pit of the loading track is corbeled out on a level with the top of a gondola car, and the ashes are loaded by raking them out of the pit and shoving them directly into the car. The floor of the pit, which is paved with hard red brick set in cement, slopes toward the car. In cleaning 131 freight engines and 21 passenger engines at this pit, daily, it was found that on an average 1¼ cu. yds. of ashes were handled per engine. At San Luis Obispo, Cal., on the Southern Pacific road, there is a pit of this type 3 ft. deep with the loading track depressed 9 ft. below the ash-pit floor, and the loading and pit tracks are located 9½ ft. centers. The rail on the open side of the pit is supported every 3 ft. upon cast iron pedestals, and in each span there is suspended across the pit an iron chute 3 ft. wide, under the pit, 5 ins. high and about 10 ft. long, extending out over the ash car. The width of the chute between the pedestals and outside of them is 2 ft. 5½ ins. and the chute is set at a slope of 1 in 9. Six of these chutes are placed closely side by side, making a solid length of 18 ft. under the pit. The ashes are dumped from the locomotive into these chutes and washed down into the car by water from a spray pipe under a pressure of about 80 lbs. per sq. in. It is said that the arrangement requires but little water and works successfully.

Another very common type of ash pit, and one which requires no special drainage, is formed by raising the track above the general level of the ground, supporting the rails upon low iron pedestals or chairs, the spaces between which are left open on both sides of the track. At some pits of this kind the ashes are shoveled and loaded into cars standing on parallel tracks at the ground level, but the most commendable arrangement is to depress the loading track, as in the cases aforementioned. Cast iron pedestals for such pits are made from 12 to 24 ins. high, and a common form or arrangement for the foundation is to stand the pedestals upon longitudinal stringers supported upon cross ties, or upon cross ties supported upon longitudinal stringers, the woodwork being protected from the live coals by a covering of earth, gravel, concrete, or by a brick paving. The pairs of pedestals may be tied across the track at their bottoms by riveting to channels or by bolts and web pieces, or by bolting to old rails, but the more usual arrangement is to cast the two pedestals and the tie between them all in one piece. In pits of this kind on the Union Pacific and Southern Pacific roads the pedestals are formed of old rails bent to form an "L" for each side of the track, each pair being tied together across the track by a piece of rail bent into a U-shape. These pedestals are set 6 ft. apart and the running rails are supported directly upon an inverted rail resting upon the vertical leg of the U-shape. Where the running rail at a pit of this kind must be assisted in its support by another rail or by an I-beam underneath, some headroom is lost, thereby obstructing to some extent the work of drawing the ashes out of the pit sidewise. An arrangement which practically obviates this objectionable feature is in service on the Atchison, Topeka & Santa Fe Ry., where two 7-in. I-beams are used for the support of each rail, over cast iron pedestals spaced at 9 ft. centers In this case the I-beams are separated about 6 ins. and the rail is supported upon blocks placed between the beams and bearing upon their lower flanges, the top of the rail coming flush with the tops of the I-beams.

By carrying the chair-supported type of pit (above ground line) a little farther another type of pit is recognized, whereby the track is elevated on an iron trestle, open on both sides, underneath, the ashes being dumped on the ground and shoveled up and loaded at convenient times onto cars standing on parallel tracks. The purpose of this arrangement is, of course, to afford storage space for the ashes and to obviate the necessity of having to attend closely to the removal of the ashes. A pit of this kind is in service on the Central R. R. of New Jersey, at Jersey City, N. J. The track is elevated 7 ft. above ground level, on trestle bents at 15-ft. spans, the rail being carried on girders, each of which is formed by two 15-in. I-beams weighing 150 lbs. per yd. On each side of the

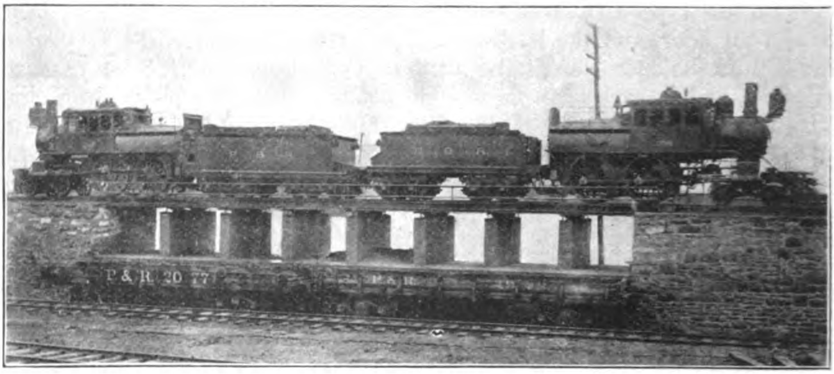

Fig. 520.—Ash Dump, Philadelphia & Reading Ry.

track there is a plank walk supported upon brackets extending from the girders. The loading tracks are located each side of the trestle, the center of each track being 16 ft. from the center of the trestle. This trestle is 225 ft. long, with filled approaches on 5-per cent grades at each end. The loading tracks are at the ground level.

Figure 520 shows this style of ash dump carried one step farther, providing a depressed loading track for the elevated dumping track. This dump is at Reading, Pa., on the Philadelphia & Reading Ry. The pits into which the ashes are dumped from the locomotives are arranged under a track elevated to such a hight that 6 ft. of clear headroom remains between the floor of the pit and the under side of the girders supporting the rails, while the floor of the pit is on a level with the top of a gondola car standing upon the loading track, at the side of the dump. The retaining wall for the elevated track is 444 ft. long, of rubble masonry laid in cement mortar. The dump is approached at each end with grades of 5 per cent, eased by vertical curves at the points where the grade changes. The top of the rail over the dump is 8 ft. above top of rail on main tracks, while the loading track is depressed to bring the top of rail 5½ ft. below top of rail for main track. The dump is 72 ft. in length, divided into eight pits, each 9 ft. in length between centers of partition piers. Each track rail rests directly upon the top flange of a 12-in., 170-lb. I-beam, in lengths of 17 ft. 11½ ins., or long enough to extend over two panels and leave ½ in. for expansion at the joints. At the panel points the I-beam girders are connected across by a 9-in. I-beam, and the joints are spliced by a cast iron plate inside the girder, and a wrought iron plate outside the girder, tied together by long bolts reaching across both girders. The I-beam girders at the panel points rest upon an inverted channel weighing 100 lbs. per yd., filled with cast iron blocking and supported upon a bent composed of four Phoenix columns, which form the actual support for the track. These columns are bricked in to form piers, but the brickwork has no office to perform other than to protect the iron columns from the heat and the action of the sulphur in the ashes, and to afford transverse support for the bent. The top of the brick pier is coped with cast iron and the columns are filled and rammed with concrete. The columns, caps and bases were of old material, in stock, and were used to enable the construction of narrow piers, thus saving room. On each side of the track there is a concrete walk 3½ ft. wide, formed upon three T-rails laid longitudinally and cross connected with bolts trussed to support the concrete. The length of each brick pier is 12 ft., crosswise the pit, and the floor of the pit is 20 ft. wide, or 10 ft. each way from center, sloping from center toward either side. The pit and loading tracks are 15½ ft. centers. The floor of the pit is laid with brick set on edge in Portland cement mortar, floated with grout as laid. The edge of the pit floor next the loading track is curbed with a T-rail laid on side with the base against an upturned bead on the L-shaped coping of the side wall. The brick used in this work is low in silica and burned very hard.

With a view to cheapen the cost of loading ashes where large quantities have to be handled, as at roundhouses, power machinery has been quite extensively applied. One system that is in service on a number of roads, with evident satisfaction, consists of an ordinary depressed, closed pit with ash buckets lifted out and in with a crane. One style of arrangement has buckets about 8 ft. long, 3 ins. narrower than the pit, and holding about 3 cu. yds or about 5000 lbs. of wet ashes. The bucket is made of old tank iron, and the top part fits the pit so closely that practically all of the ashes dumped from the locomotive fall into the bucket. The post of the crane is usually located about 9½ ft. from the center of the pit and the crane can be swung to handle two buckets. In order to obviate the necessity of multiplying cranes at a long pit it is the practice in some cases to set the ash buckets upon wheels, which run upon a narrow-gage track in the pit, on which the buckets can be pushed to a point within reach of the crane. In some cases the crane is operated by a hand winch, but there are various ways of securing power for working the crane, one of which is to utilize the locomotive which has been cleaned, to hoist the bucket as it leaves the pit. A chain is attached to the locomotive when it is ready to leave and the bucket is hoisted, when the locomotive is released. The crane and suspended bucket are then swung around to bring the bucket over a loading car upon a parallel track and the ashes are dumped by tripping the hinged bottom of the bucket. In a number of instances the hoisting and the turning of the crane are worked by compressed air piped from the shops or obtained by a connection with the air-brake apparatus of the locomotive. In handling and loading ashes by this method no force is needed besides the hostlers, or the men who clean the fire-boxes. According to figures reported officially from the Baltimore & Ohio Southwestern R. R. the cost of handling ashes with buckets and cranes, as ascertained by trial on that road, was only one third the cost of handling the same by shoveling from a depressed pit. On this road the cranes have been worked by both systems of power —locomotive and cable, and compressed air. One of the plants operated by air (at Chillicothe, O.) is illustrated in Fig. 521. The hoisting is done by means of a 12-in. cylinder with a 14-ft. stroke and the crane is turned by a double-acting cylinder 8 ins. in diam., with a stroke of 4½ ft The hoisting cylinder is anchored to the ground in a horizontal position, and power is applied to the crane by attaching the hoisting chain to a hook on the end of the piston rod. This cylinder is also used to pull the cars into position for loading as the work of filling them progresses. The air pressure is 65 lbs. per sq. in.

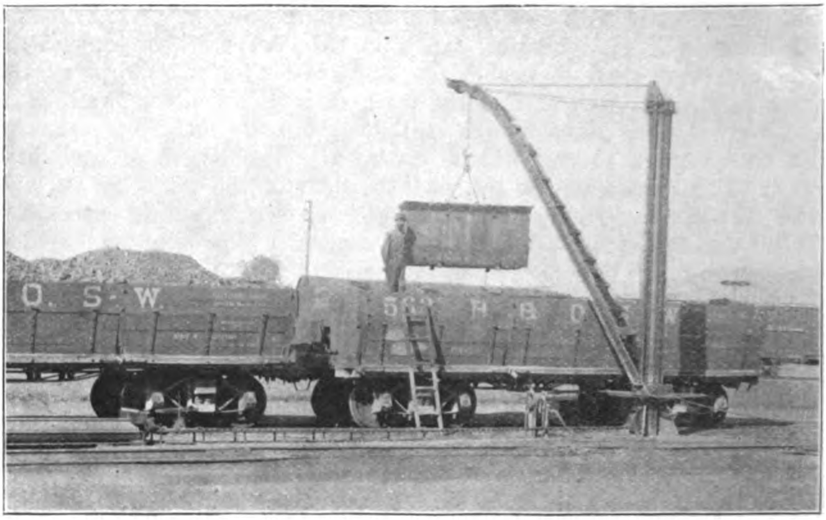

Fig. 521.—Ash-Handling Crane and Bucket, B. & O. S. W. R. R.

For lifting cinder buckets in its yards in St. Louis the Missouri Pacific Ry. uses a portable crane mounted upon a truck or small flat car. The crane is operated by air from a storage reservoir on the car. Instead of using a pit as a means for placing the buckets under the locomotives, the dumping track is elevated 2½ ft. above the ground and supported on cast iron pedestals 7 ft. apart, on which are placed two lines of inverted rails to serve as stringers for the support of the track rails. The buckets are of cast iron 18 ins. deep, and are suspended by means of flanges at each end which rest upon the tie rods between the track rails. There is a series of buckets suspended one after another to cover the length of the dumping track, and the portable crane is run upon this track, lifting the buckets one at a time and swinging them into position for dumping into cars on a parallel track. The time required to lift and dump the 27 buckets at one of the roundhouses is 40 minutes. The Robertson cinder conveyor, in use on the Grand Trunk Western Ry., at Elsdon, Ill., consists of an iron car running upon an incline track which enters the ash pit at the side. This incline track extends laterally over a depressed track which is parallel with the pit and 18 ft. distant, center to center. The ash car is hauled up the incline by a cable and compressed air cylinder, and as it arrives over the depressed track its bottom is automatically tripped and the ashes drop into a gondola or other car spotted under the incline for loading.

Ash pits should be located on a double-ended piece of track, or a siding which has an outlet at both ends, so that after an engine has been cleaned it may pull straight ahead off the pit and not be prevented from leaving by some engine which has come in behind it. The depressed loading track usually descends into its pit on a steep grade and it usually has a dead end. It is not infrequently the case that two short pits are used instead of a long one, and in such event the depressed loading track is run between the two ash pits. At any style of ash pit water should be available, with hose connections for wetting down the ashes, so as to relieve the walls of heat and enable the speedy removal of the ashes from the pit.

Ash pits should not be put in main track outside of yard limits or wherever trains run at full speed. In such places they are equivalent to pit cattle guards as an ever-present menace to trains running with a derailed truck. The standard main-line ash pit of the New York Central & Hudson River R. R. is 5½ ins. deep from base of rail The foundation is a bed of cinder concrete 12 ins. deep and 8 ft. wide, on which are placed 12x12-in. longitudinal creosoted yellow pine sleepers to support the rails. These sleepers are tied together at intervals of 3 ft. with ¾-in. rods, and to protect them from fire the top corners inside the rails are covered with angle irons. Between the sleepers the concrete bed is 18½ ins. deep, extending as high as the middle line of the stringers, to cover the tie rods. The bottom of the pit is faced with a 1½-in. layer of cement mortar. For further information on ash pits of a large variety of designs, regarding full details of construction, cost, economy of operation etc., the reader is referred to a lengthy committee report to the Association of Railway Superintendents of Bridges and Buildings, in 1894. The subject is also treated quite fully in Berg's "Buildings and Structures of American Railroads."

Wherever ashes and cinders are frequently dumped on the ties, as at stations, water tanks or in side-tracks, it is best, when cleaning up the track, to leave a layer about 1½ ins. deep to protect the ties from being burned the next time hot ashes are dumped. Where considerable quantities of ashes have to be cleared away daily it is well to keep coal scoops at hand for this purpose, as it is slow work handling such material with track shovels. At water tanks on busy roads, where ash heaps in the track should be cleared away promptly, a hose should be arranged for cooling off hot ashes.

Conveyor Plants.—The most modern arrangement for handling large quantities of locomotive ashes and cinders is a conveyor plant, which takes the ashes from the bottom of the pit and deposits them in an elevated hopper-bottom bin placed over a loading track, from which they can be discharged into cars by gravity. Such facilities are frequently combined with a coaling station plant, to be operated during intervals when coal is not being elevated. There is usually a hopper-shaped pit, under which there is a spiral or a bucket-and-chain conveyor carrying the ashes to an elevator line which delivers them into the elevated bins or pockets. An example of such a plant is illustrated in Fig. 522. There is an ash pit 70 ft. long on each side of the house and an elevated bin over each of the two loading tracks inside the house. There is also a sand bin on each side of the house. The pits are solidly constructed with concrete walls 8½ ft. deep and 8 ft. wide, out to out. The walls, which are 3 ft. thick at the bottom of the pit, taper to a thickness of 12 ins. at the top. The pit is 4 ft. wide at the top, 2 ft. wide at the bottom and 3 ft. deep to the top of the conveyor. To protect the corners of the concrete walls from being chipped off by bars and scrapers thrown against them they are faced with steel plates which hang down 16 ins. from the top. A view looking into one of these pits is shown in Fig. 509A. In the bottom of the pit there is a cast iron grating, to prevent clinkers of too large size from getting into the conveyor, and the grating is covered with steel plates provided with rings for convenient handling. The cinders drawn from the fire boxes fall on these plates and are quenched, and when the pit is full the plates are successively removed, allowing the cinders to fall into the conveyor below. Full details and illustrations of the

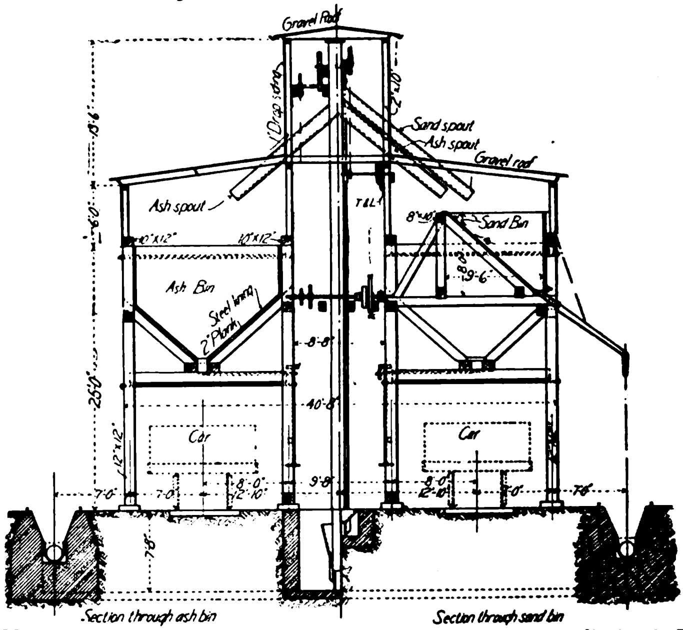

Fig. 522.—Cross Section of Ash and Sand-Handling House, Ill. Cent. R. R.

construction and operation of typical modern ash-handling plants were published in the Railway and Engineering Review for July 29, 1899, and March 15, 1902.

179. Track in Tunnels.—The roadbed in tunnels is usually a rock surface, dressed off to give proper drainage, or an invert of brick or concrete masonry arched downwards to prevent the bulging of the bottom of the tunnel, in case soft or yielding material is encountered. For the track the usual construction of cross ties and ballast is the rule in this country. In Europe longitudinal wooden stringers are used to some extent as supports for the rails, without ballast, the stringers being laid directly upon the masonry of the invert or upon a bed of concrete. Engineers who favor the stringer construction contend that the maintenance work is much facilitated, particularly in renewals; that the drainage can be better provided for and better inspected; and that where ballast is dispensed with there is a considerable saving in hight of tunnel, which effects a saving in excavation, and also in masonry construction if side walls have to be built.

Drainage of track in tunnels is usually provided for by a blind drain of box form built of stone and overlaid with flagstones, placed underneath the track, where there is but one track over a masonry invert, or in the bottom of the tunnel midway between the two tracks, in case of double track. In other cases there are narrow open ditches next the side walls of the tunnel, with curbstones to retain the ballast, or lines of stoneware pipe are laid and covered with ballast, so that the floor is available its entire width. Where springs or large quantities of water are encountered it is customary to lay drain pipe behind the side walls. The necessary fall for drainage purposes is usually provided for by running the tunnel to a summit at the middle or by a grade the whole length. The St. Clair tunnel, on the Grand Trunk Ry., is circular in section and lined with flanged cast iron plates or sections bolted together. In this tunnel the ties are supported upon four 6x12-in. longitudinal sleepers laid directly upon a concrete bed. Guard timbers are bolted to the ties, outside the rails, as on a bridge floor, and a drain 18 ins. wide is formed in the concrete bed, between the two middle timbers supporting the track.

The best ballast for track in wet tunnels is broken stone, as it forms less obstruction to the drainage than other kinds. In dry tunnels gravel ballast does very well. In tunnels through shale rock the disintegration of the shale on exposure to air and moisture is sometimes a source of considerable trouble in the way of maintaining the ballast. On a wet bottom of this kind, especially where water has come through the roof, it has happened that the disintegrated material of the floor would work up through the ballast in the form of clay and mud. The remedy applied in such cases has usually been to remove the softened rock and replace it with a layer of concrete.

As a rule the metal parts of track in tunnels deteriorate rapidly from corrosion, at any rate much more rapidly than with track in the open. This is due to the corrosive action of smoke and gases from locomotives, and in many cases also to dampness. The severity of these conditions depends, of course, a great deal upon the length of the tunnel, which has to do with the ventilation, and upon the amount of water dripping from above. The loss of metal to rails takes place all around the section. In some cases rails in tunnels have lasted only half to a third as long as rails under the same traffic conditions out in the open; and some writers have speculated on the rate of corrosion, but owing to the varying conditions of ventilation, dampness, nature of the fuel burned by the locomotives, the frequency of the train movements and the length of the tunnel it is not possible to deduce useful rules from the data presented. Owing to the fact that the ballast takes in a good deal of smoke and gas and becomes mixed with cinders it is desirable to dress it off clear from contact with the rails, so that the latter may get full benefit of whatever ventilation there is. In wet tunnels, where there is usually a bad rail, a good deal of sand must be used, and this causes excessive wear from the top. To protect rails in tunnels from rusting some of the English railways, including the Midland and the London & Northwestern roads, paint them with four coats of red lead before they are put into the track. A paper on "The Wear of Steel Rails in Tunnels," written by Mr. Thomas Andrews and presented at a meeting of the Institution of Civil Engineers, on April 10, 1900, treats of the subject somewhat thoroughly from the standpoint of English railways. In one tunnel 3000 ft. long the average loss in weight of rails from corrosion and wear was 2.8 lbs. per yard per annum, as compared with an average annual rate of 0.324 lb. per yard for rails under the same volume of traffic in the open air.

The life of ties in tunnels is also another important matter for consideration. As tie renewing in tunnels is much more expensive than in open space, the ties for such places should be selected with a view to obtain the longest life possible. Undoubtedly the best plan is to use creosoted ties of best quality. In damp tunnels the moistened ties are rapidly cut under the rails, and where sand is frequently used this action is much augmented. The use of tie plates improves the situation, but by corrosion and the grinding action of the sand they do not last as long as on open track, and are therefore more expensive than ordinarily. In long or damp tunnels steel ties rust out rapidly and are not found to be satisfactory. On the St. Gothard Ry., in Switzerland, where 70 per cent of the track is laid with metal supports, wooden ties are used in the long tunnels. Metal ties have been tried there but in every instance their life was short.

Owing to the restricted space and to darkness, track work in tunnels is necessarily more difficult of performance and more expensive than is ordinarily the case with track on the outside. In renewing ties in single-track tunnels of ordinary width (15 ft.) there are several ways to get the old ties out and the new ones in. The easiest method is to draw the spikes on one of the rails and lift it up and block it or throw it laterally off the ties. Sometimes this is done with both rails, as then some digging may be saved, but it is not necessary to take the rails up; that is, to uncouple them at the joints. When the work is done in this way it is necessary, of course, to send out flagmen, but if the frequency of the traffic will not admit of this the ties have to be handled without disturbing the rails. By digging a downwardly slanting trench the old tie may be pulled to one side, one end lifted and the tie pulled out between the rails, and the new tie may be put in by the reverse process. Another way to get the old tie out is to dig a trench and cut the tie in two, when it may be taken out between the rails, in separate pieces. Another way to get ties out without digging deeply into the ballast is to remove the filling from between them, bunch four or five together and then slew the bad one at an angle of about 45 deg. and lift it out between the rails. New ties may be put in by reversing the process. This plan of renewing ties in tunnels is followed quite extensively. If there are no obstructions at the ends of the ties they may be taken out or in by slewing them outside the rails. Two ties are handled together. The ballast is removed from three spaces between ties and then one of the ties is pulled to one side of the track and slewed out under the rail and the other tie is pulled over and slewed out under the opposite rail. Both ties may, however, be slewed out under the same rail, by first pulling one of them back in the opposite direction far enough to make room to slew the first tie taken out; or only one of the ties need be taken out, the other being simply slewed to let the bad tie out and the new one in. For reasons presently explained trackmen are not usually permitted to lift track bodily when renewing ties in tunnels. In single-track tunnels it usually pays to renew ties out of face, as often as conditions may require. On this plan it is necessary to engage in the work only once in a period of years, which is more economical of labor than that of renewing part of the ties under difficulties each year. On roads where the renewing is done out of face the ties taken out that will see further service are used in side-tracks.

The work of track maintenance in single-track tunnels is also impeded by the necessity for the men to run to cover when trains approach. Alcoves, niches or manholes, as they are variously called, are usually built in tunnels at suitable intervals for workmen to secure a place of refuge from passing trains. In the Boulder tunnel, on the Montana

Central branch of the Great Northern Ry., which is 6112 ft. long, an arched hand-car recess 7 ft. wide is built into the side wall in two places, each 2000 ft. from either end of the tunnel, so that a hand car in passing through the tunnel is at no place farther than 1000 ft. from a place of safety. Trackmen should not enter dark tunnels without lights to signal trains, and when engaged in such places they must have lights to work by. Where only slight repairs have to be done trackmen can get along with hand torches, but where extensive work is going on it pays to have large pot torches, or lights of the Wells or Buckeye kind. The latter are used a great deal. When lining track in dark tunnels a torch or lantern may be held over the rail to give light, but when track is being surfaced it is desirable to have the tunnel lighted up so that 150 to 200 ft. of rail may be seen distinctly. It takes a good many hand torches to do this.

Methods of track work in tunnels apply in a general way to snow sheds, except that torches or other artificial lights are not usually needed, although in winter the working days are shortened an hour or two. The ventilation openings or screens that are sometimes left in the side of the shed, near the top, let in a good deal of light, and more or less light comes in through cracks between the planks on the roof and sides. For lining track in snow sheds a dull day is selected, as in bright weather the sun shining through the cracks strikes the track in streaks and patches and bothers the man sighting the rail. In snow sheds and at the ends of wet tunnels it is important to keep close watch of ice that may freeze and obstruct the ditches or accumulate around the rails from water dripping from above. Whenever such danger is threatening a watchman should be detailed to visit the place at proper intervals to keep the ditches open and pick or chop the ice clear from the rails.

Clearance.—In lining or surfacing track in tunnels and snow sheds it is important for trackmen to observe the established clearances. In such places the general surface of track cannot be raised without reducing the vertical clearance, and as this is of record in the office of the engineering department, such changes should never be made without permission or orders from that department. The rules of the road department of most railways forbid trackmen to raise the general surface of track in tunnels, or under overhead structures that come anywhere near the established clearing distances. This rule, of course, permits raising low joints and other low places in the track, but not higher than is necessary to bring the rail to an even surface on the existing grade. For measuring clearance in tunnels and snow sheds, at bridge openings and at side structures that are close to the track some roads use a special flat car carrying a templet or framework built approximately to the outlines of the supposed clearance. This is arranged transversely on the car, with a platform high enough to enable the inspectors to use foot rules or measuring sticks to take the clearance, measuring from the templet as a reference.

The clearance-measuring car of the Pennsylvania R. R. is a specially constructed long flat car with a platform about 9 ft. square erected over one of the trucks and standing about 5 ft. above the floor of the car. Railed stairways lead to the platform on two sides, and there are substantial railings around the platform and all around the car. Each end of the car is equipped with a platform and steps of the passenger-coach pattern. The templet from which the measurements are taken was built approximately to the outlines of the existing minimum clearance records, and stands 15 ft. high above the rail, being graduated every 3 ins. The vertical leg of this templet, on either side of the car, extends as low as the ordinary car step, and is hinged so as to trail with the car in case it should meet with an obstruction. To provide against meeting with an unexpected obstruction overhead, the arched part of the templet is also hinged to fall backward in case it should strike anything. To prevent any possibility of passing an obstruction within the required clearance without observation, as might happen in a tunnel or after dark when the vision is obscured by smoke or steam, the perimeter is set with wooden pegs about 3 ins. apart and projecting 6 ins. from the edge of the templet. Should any of these pegs be broken off while the car is in inspection service it is then known that some obstruction has been passed which requires investigation. Coupled in behind this car in the clearance-measuring train there is a dining and sleeping car for the crew, and there are storage batteries to supply current to electric lights of high candle power on the platform of the clearance-measuring car, for use when taking measurements in tunnels, or when work is continued into the evening in order to reach some desirable point for lying over night. The measurements taken at any point are recorded on a printed diagram of the templet, and obstructions met with are sketched thereon. This car is used whenever new lines, tunnel or through bridge work are completed. Between times the car is dismantled, the templet and platforms being stored in the shops and the car put into ordinary service.

To get measurements of the cross section of a tunnel with reference to the track it is necessary to erect the templet frame over the center of one of the trucks, but sharp curves sometimes occur in tunnels and quite frequently in snow sheds, and in such places record should be taken of the clearance at the middle of long cars, as affected by the overhang. For this purpose there might be an additional templet at the middle of the clearance-measuring car; and the length of the car and the position of the trucks should correspond to similar measurements of the longest sleeping car or other car of maximum length liable to be hauled over the road.

In a paper on "Maintenance of Railway Tunnels," by Mr. Arthur Watson, read before the Institution of Civil Engineers (extracts were printed in the Railway and Engineering Review, Apr. 13, 1901), that author calls attention to an instrument for measuring the contour of a tunnel cross section, that is designed on the pantagraph principle. There is a bar or piece that is placed across the rails of the track, or across the two inside rails of a double track, to center with the center line of the track or tracks, and on this there is a fixed drawing board 27 ins. square standing vertically. Attached to this drawing board on its vertical center line there is a telescopic shaft or pointer of light construction, carrying a small wheel at the end which is passed around the soffit of the tunnel arch and side walls. This shaft or pointer is attached to an arrangement of crossed bars of the familiar proportional divider style. At a fixed place on the drawing board there is a piece of drawing paper which shows, in firm lines, the minimum clearance profile. Attached to the pantagraph bars (at the first crossing point) there is a pencil held to proper contact with the paper by a spring. When the cross section of a tunnel is to be taken at some point a sheet of tracing paper is pinned to the face of the board, over the drawing paper and diagram referred to, and on it are traced the rail level and vertical center line of the tunnel section. By traversing the telescopic pointer around the soffit or roof and sides of the tunnel a correct contour of the same is produced on the tracing paper, one twelfth full size. Having the minimum clearance profile already drawn the comparison is graphically shown, and the clearances can be readily scaled off the drawing.

The general purpose in taking car clearances is obvious, but one specific purpose is to collect data to govern the issuing of special permits for the transportation of merchandise freight carried on flat cars, but which may be a few inches wider than the cars or slightly higher than the general standard. The minimum clearance on each division or between certain points of a division is usually represented by a diagram, and the various diagrams for a road are of record in the general offices of the engineering and transportation departments.

180. Resurveys.—Many of the railroads of this country were hurriedly constructed, without careful surveys or the filing of proper records. As a consequence irregularities in track alignment and surface become more and more noticeable, with time, no reference points being available, so that the re-establishment of center and grade lines becomes a necessity, if the track is to be maintained in good condition. It is also to be considered that the attention of maintenance of way engineers is being more and more directed to the relocation, in part, of many of the old lines, to secure more favorable grades and curvature, thereby making it possible to increase the tonnage of trains, or to equalize the tonnage over all points of the same division of the road, and to increase the speed of the trains. In connection with work of this character good opportunity is found for the establishment of the surveys throughout on a more accurate and enduring plan. One of the principal objects is, of course, to establish points of curvature, which should then be permanently marked with substantial monuments, which are treated in § 48. It is quite common experience that changes are made which shorten or lengthen the line, as the case may be, after the permanent location has been run, and resort is had to equated stations, in order that each change so made need not affect the station numbers of the entire line beyond. Such changes also occur in the relocation of a line for the reduction or elimination of curvature. In the resurvey of a railway such equations should be taken out and the line measured continuously from the starting point, changing the positions of the mile posts as occasion may require. Such was done in the resurveys of the Detroit, Grand Rapids & Western and the Chicago & West Michigan roads, and a piece of old rail 5 ft. long was set 30 ft. to the left of each mile point, the base facing the track, with the number of miles stamped thereon.

The resurvey of a railway should be thoroughly carried out, taking note of all matters pertaining to the roadbed and right of way which are liable to become of use to the company's officials. While it will not be necessary here to go into the details of surveying it should be said that all the physical features of any consequence on the right of way and for some little distance off the right of way, should be located and platted on right-of-way maps, or made matters of record by descriptive data of some sort. Thus it is important to accurately locate all fence lines and the boundaries between lands of separate owners adjoining the right of way, as well as state, county, township and town boundaries, and section lines of government surveys. In work of this character it is also customary to locate all buildings within 200 ft., on each side of the center line, and in towns and cities all property is sometimes mapped as far out as 400 ft. each side of the line. Accurate data should be obtained regarding the important features and measurements of bridges and culverts along the road, and in respect to all tracks, locating the point of switch where one track diverges from another. High and low water marks should be indicated on the profile at points where the line of the road crosses streams. It is customary also to locate the banks of large streams for a distance of ¼ mile or so from the point where the track crosses the stream. It is quite largely the practice to make use of photography in connection with the surveys of the line, taking a view of every company building, bridge, culvert or other structure and of each road crossing. Photographs are mounted for filing and the negatives are retained.

In relining track that has strayed from the original center stakes efforts should be made to find as many of the old reference marks as possible, particularly the points of curvature. If these cannot be found the whole line must be rerun, keeping as near the existing alignment as may be practicable. Of course there are many points which it is desirable or obligatory to consider fixed, such as the center line at bridges, points of crossing with other railways, the existing center line opposite station platforms, at water stations, through yards, etc., and these are taken for governing points on the new line. When such points come on curves where the original P C.'s have been lost some study may be required in order to get a true curve to follow the old one approximately and pass through the required points. One way to do this is to plot points on the curve at convenient intervals, as offsets from one of the tangents produced, and then to cut and try with various calculated curves until one is found to fit the conditions. In rerunning an old tangent that is found badly out of line it may pay to first plot it with reference to a preliminary tangent, using an exaggerated scale for the offsets measured from this tangent to points on the track center 400 or 500 ft. apart. By means of this plat the position for the new line which will require the least work of realigning the track from its existing location can be readily determined.

In connection with the subject of resurveys reference may be made to track information or data sheets, which are used by the maintenance of way department of most well regulated roads. These sheets or charts consist of blue prints or other drawings on which are delineated a plan and profile of the track, together with all data useful to the engineering, track and bridge departments, put down in the order in which they come. For instance, the width of right of way is shown, usually on an exaggerated scale, with intersecting line fences and the intersection angle in each case, and the names of the landowners; the kind of right-of-way fence, when built or rebuilt, and the location of snow fences; the location of stations and other buildings on the right of way, and of buildings near the right of way; the location of bridges, with their numbers, and all openings in the roadbed; the headroom at through bridges; the location of highway crossings, farm crossings, track signs, cattle guards, cuts, tunnels, culverts, ditches, switches and turnouts, with the number or angle of the frog, and various measurements between side-tracks and structures located in nearness thereto; the true bearing of tangents, the data relating to curves; the dividing points between sections, with the number of the section and the name and residence address of the section foreman; the kind of ballast, and its depth; the character of the material in cuts and fills, and the slope; other important natural conditions on or near the right of way; the weight of the rails and the date when the same were laid; the kind of joint fastening, if different kinds are used, or any devices which may be in use for experimental purposes; the location of water tanks, track tanks, mile posts, mail cranes, stand pipes, telltales, signals and in-interlocking devices—in short, the location of each thing along the track which can be of interest in any way to the maintenance of way department, should be shown and the thing described as fully as is feasible. For this purpose the drawings should be made to such scale as will allow the data to be inserted without presenting a confused appearance. The use of conventional signs aids very much in elaborating on details and in confining descriptive data to the smallest possible space; as, for instance, the kind of material in buildings and other structures or the kind of fence may be clearly indicated by conventional signs or symbols. The profile is usually drawn along the bottom of the sheet, and broken as often as is necessary to keep it from running up on or off the sheet. It shows the grades and the altitude of particular points above sea level. There should also be shown upon the sheet the location of bench marks for leveling.

The standard profile sheet of the Cleveland & Pittsburg division of the Pennsylvania Lines West shows, in addition to the grade line of the track or top of rail, a "ground line" taken 20 ft. out on each side of the track. The grade line of the track is shown in blue, the ground line on the north side in full black and the ground line on the south side in broken black. Wherever the elevation of the track varies from the established grade line a black dot is made every 100 ft. to show what that elevation is. These profiles are made in long rolls, each roll covering about 20 miles of track. The purpose of the ground lines is to enable one to make a rough estimate of the grading to be done in building a second track or a siding, or of the amount of earthwork necessary for a contemplated reduction of grades.

These drawings, sheets or charts, as they may be called, should be revised yearly, or from time to time as changes are made. For office work such a drawing can be conveniently used in the form of a scroll in two rolls, one rolling out as the other rolls up, but for outside use it may be folded into pocket size or preferably be divided into separate sheets which are bound under covers. The New York, New Haven & Hartford R. R. uses data sheets 22 ins. long and 10 ins. wide bound in book form. They are drawn to a scale of 300 ft. to the inch, showing 5000 ft. of track on each sheet. The information shown on each sheet is of a more elaborate character than is usual with most companies, giving, in addition to features already named, a great deal of information useful to the operating department, such as the taxable value of all property adjoining the right of way and the character of the land, as to whether cultivable, wooded, etc.; a list of the names of agents and other permanent employees; a list of the industries in each town furnishing business to the road; the names of hotels, and whether express wagons or carriages may be found at the station; a list of the newspapers, etc. The Pennsylvania R. R. uses a long sheet 6 ins. wide, which is folded into a form 4x6 ins. in size, for the pocket. Drawings for a right-of-way atlas are usually made to a scale of 100 to 200 ft. to the inch. The atlases of the Pennsylvania R. R. are made to a scale of 100 ft. to the inch They are drawn on tracing linen sheets, 24x36 ins., which are mounted on thin cloth, like cheese cloth, and bound into books. When maps of this kind are put up in book form they should be bound loosely or in such manner that sheets may be easily removed for correction, from time to time, and then replaced.

181. Rail Deflection.—One of the aims of engineering is to reduce the problems of practice to a basis of computation. Especially is this true of structures, where it is desired to know what duty each member must perform, in order that it may be proportioned with a view to the safety of the structure and economy of material. In modern railway work all construction is designed as nearly as possible on this plan. There are, however, certain structures environed by conditions so far removed from satisfactory analysis that calculation beforehand of the stresses from loads imposed and the determination of the behavior of the structure under stress become impracticable. In such cases the investigation of the problem is conducted along experimental lines, usually in observing the behavior of the structure and in taking measurements while the same is under stress. The track comes within this category of engineering problems, for all that we can know about the stresses to which the parts are subjected is what we are able to see and deduce from the behavior of those parts in service. In fact it may be said that, so far as railway engineers have given attention to this matter, but very little is known.

The development of railway rails and fastenings has not advanced on designs formed to meet certain known requirements of stress and deflection, because not until comparatively recent years was it known what these stresses and deflections were, with any degree of approximation. From experience it was known that rails weighing 50 lbs. per yard were strong enough for the loads when that weight of rail was in common service, and it being known that an increase in the depth of the rail, with a corresponding increase in the amount of metal, made a stronger rail, it only remained to increase the weight of rail; and such has been done, the increase in weight of rails taking place in about the same proportion as the increase in weight of rolling stock, although perhaps a little tardy at times. During comparatively recent years some information has been obtained concerning rail deflection and stresses in the same, but it has had only a passive effect, at most, so far as rail design and track construction are concerned; for beyond the mere matter of ascertaining such stresses and deflections from the few experiments performed no attention has been given to the matter of making use of the data in practical ways.

It would seem that track deflection experiments could be made a fruitful field of investigation. In connection with what is said above regarding development in the weight of rails it may be stated that, generally speaking, rails have been strong enough against breakage, but the main question always has been, and is still, as to what is the most economical weight of rail for maintenance of track surface. There is some certain amount of money which can be expended for metal in the rails which will yield a maximum economy in track maintenance, but as to just what the proper weight of rail is for an assumed volume of traffic is not known with any close degree of approximation. We know that it costs less to maintain the surface of track laid with 80-lb. rails than track laid with 60-lb. rails, but just how much less is not definitely understood. It would seem that a carefully conducted series of track deflection experiments with rails of different weight per yard, laid at different times on the same ties and roadbed, taking observation of the deflection and rate of recovery of the ballast and roadbed and the amount of permanent deflection of the same during certain intervals, might lead to more definite knowledge of the relation of rail deflection to track settlement than we have at present. There are other matters of investigation of measurable importance referred to further along. In the mechanical department of railways, tests are made of fuel, engine working, axle grease, etc.: why should not tests be made of the track and roadbed, which represent a larger investment than all other railway property?

A number of track deflection experiments carried out under the auspices of Mr. James E. Howard, of the United States arsenal testing plant at Watertown, Mass., are of record and are prominently known. The first of these were made on the Boston & Albany R. R., in 1889, and later on others were conducted as follows: On the Chicago, Burlington & Quincy Ry., in 1893; on the Pennsylvania R. R., in 1894; and on the Boston & Albany R. R. again, in 1895. It is interesting to review the data obtained from these experiments, not so much in contemplating the actual deflections observed and the ascertained stresses in the rails, as in the study afforded by the variation of the deflections under different conditions, and the irregularity of the results from like causes acting at different points on the same rail and on different pieces of track.

Experiments on the C. B. & Q. Ry.—The experiments conducted on the Chicago, Burlington & Quincy Ry. were under the supervision of Mr. Howard, assisted by Mr. F. A. Delano, at that time superintendent of freight terminals of the road. They were made at Hawthorne, Ill., during the month of October, when the ground was in settled condition. The experiments in track deflection were of two classes: First, the deflection of the rail was measured at a certain fixed point on the same, under each wheel of the locomotive, which was made to change its position at each observation, and also when the locomotive was in position to bring the point on the rail midway of the space between each two adjacent wheels. In the other class of experiments the level of the unoccupied rail was carefully taken, after which the locomotive was run into position and the level of the rail taken at various points while under load. At first the depression of the rail was taken by leveling with an astronomical spirit bubble and micrometer screw from bench marks established on stakes driven into the roadbed 31 ins. from the rail, but it was soon found that the depression of the ground extended beyond the stakes, when the bench marks were dispensed with and the leveling was done from a cantilever supported 10 ft. from the rail. The levels taken from the stakes were then corrected for the depression of the same due to the proximity of the locomotive. As the result of careful measurements it was found that opposite the main driver of a mogul locomotive weighing 125,000 lbs. the cinder ballast at a point 31 ins. from the rail was depressed .047 in.; at a point 61 ins. from the rail it was depressed .013 in. and at a point 91 ins. from the rail the ground was depressed .001 in. At a point 10 ft. from the rail no noticeable depression could be detected. At a point 31 ins. from the rail, in gravel ballast, the depression was .036 in. The rail in this track weighed 66 lbs. per yard. It should be explained that the ground underneath the track where these experiments were made was of firm clay and the spikes were redriven before the experiments began.

The fiber stresses in the rails were determined by measuring the amount of elongation or compression of the rail flange by a micrometer (Fig. 523) extending over a gaged length of 5 ins. on the top of the rail flange, observations being taken of the strains when the wheels were directly over the micrometer and in all positions of the engine when the micrometer stood midway of the spaces between the wheels. On an assumed modulus of elasticity of 30,000,000 lbs. per sq. in. the stresses were computed for the fibers on the top of the rail flange and it was then assumed that the fiber stresses on the bottom of the flange (which are the ones referred to in connection with these experiments) were proportional to their distance from the neutral axis of the rail.

Before taking observations of the depression of the rail under load measurements were taken of the wave in the rail running in advance of the locomotive. With a mogul locomotive weighing 125,000 lbs., on track laid with 66-lb. rails on oak ties, in cinder ballast 8 ins. deep it was found that an upward movement of the rail began when the leading wheel was 15 ft. away and the crest of the same (about .0035 in. high) was reached when the locomotive was 8½ ft. away from the point observed. Then followed a sudden depression and when the locomotive had approached to a point 7½ ft. from the point of observation the rail had subsided to its normal level or hight.

One of the locomotives (No. 336 Class H) used in these experiments was a mogul weighing 110,000 lbs., with wheel spacings and weight distribution as shown in Fig. 403. With this engine standing in one position on main track laid with 66-lb. rails, 17 oak ties to the rail, gravel ballast, in such position that the truck wheel and first driver spanned the joint, the depression of the rail was as noted on the diagram. The maximum depression was .156 in., under the main driver. The depression at points between the drivers is recorded on the diagram. The line below the shaded part of the diagram measures the correction of each observation for the depression of the bench mark due to the proximity of the locomotive. With the same engine in different positions on the same piece of track it was found that at a point 26 ins. from the joint the rail was depressed .111 in.—.160 in.—.161 in.—and .151 in. as the truck wheel and each of the drivers respectively were run into position over the point observed. With the wheels spanning the point (that is when the engine was in such

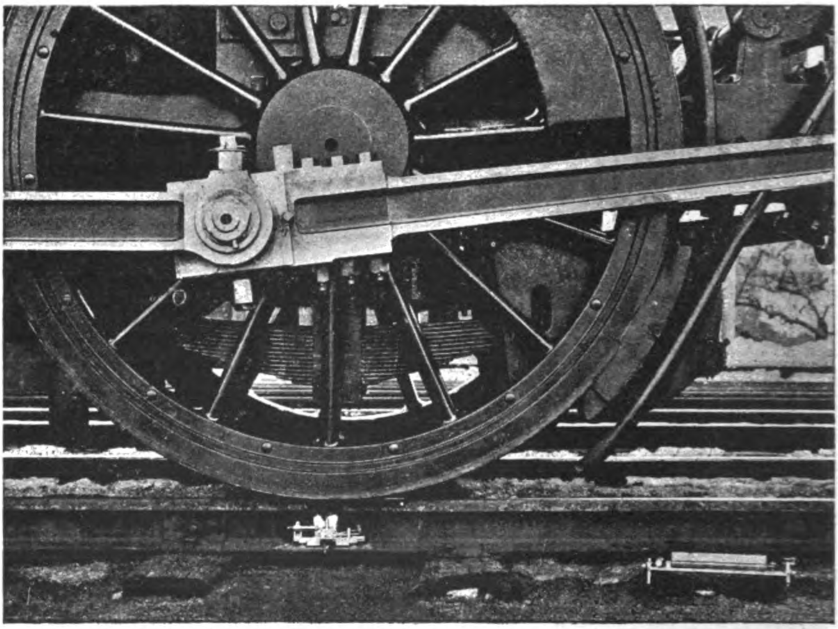

Fig. 523.—Micrometer for Measuring Strains in Rails.

position that the point observed was midway of a space between wheels) the deflection was .035 to .045 in. less in each case than the average of the deflections under the two adjacent wheels. The bottom of the rail was in tension as each wheel passed over the point observed, and either in compression or in a state of neutral stress as each two adjacent wheels spanned the point. The deflection of the rail under each of the tender wheels was quite uniform, the maximum being .112 in. for the first and second wheels each from the engine, and the minimum .092 in. for the rear wheel. The depression of the rail when each two of the adjacent tender wheels spanned the point of observation averaged about .009 in. less than the average of the above depressions in each case. With the rear driver and front tender wheel spanning the point the depression of the rail was .097 in.

With the same engine on the same piece of track, in different positions, the fiber stresses per square inch, as measured at a point on the base of the rail 9 ft. 9 ins. from the joint, were as follows, beginning with the truck wheel over the point observed and referring to each position of the engine when the point observed was under each wheel and midway of each of the wheel spacings: 7470 lbs. tension—750 lbs. compression—10,450 lbs. tension—0 lbs. stress—10,450 lbs. tension (middle driver)—10,450 lbs. tension (under rear driver).

With another mogul locomotive (No. 524) of the same class weighing 125,000 lbs., on the same piece of track, observations being taken at a

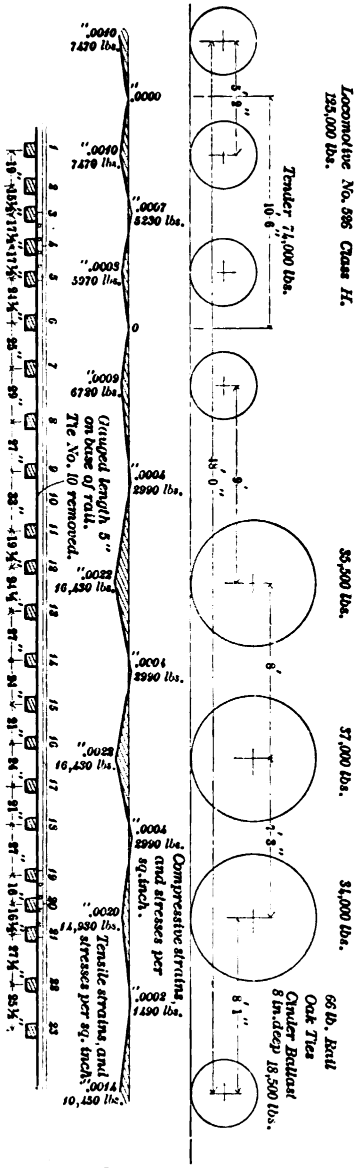

Fig. 525.—Experiments in Track Deflection (For Depressions See Fig. 452).

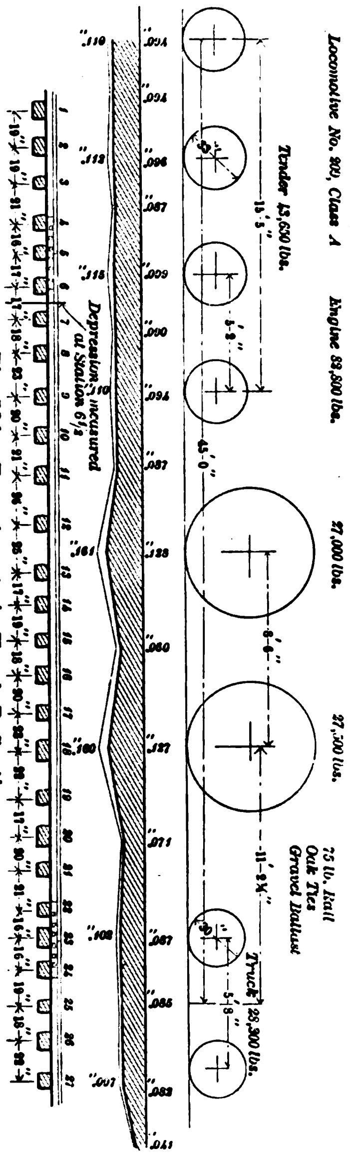

Fig. 524.—Experiments in Track Deflection.

point 8 ft. from the joint, there was a maximum depression of .182 in. under the middle driver, and about the same deflection for each of the other two drivers, The distribution of the weight and other details are shown in Fig. 476.

Another mogul engine of the same class weighing 110,000 lbs was run upon side-track laid with 66-lb. rails and oak ties (16 to the rail length) in cinder ballast 8 ins. deep. The depression of the rail at a point 8 ft.

2 ins. from the joint was .218 in., .230 in. and .206 in. under the three drivers respectively, front to rear. The depression from the truck wheel was .155 in.

With another engine (No. 526) of the same class weighing 125,000 lbs., on the same piece of cinder-ballasted track, there was a maximum deflection of .252 in. at the first driver, the point of observation being at a point on the rail 11 ft. 7 ins. from the joint, where a tie had been removed, leaving a space of 33 ins. center to center of ties. It is to be regretted that no observations were taken at this point before the tie was removed. The deflections as each of the drivers passed this point were practically the same, being .250 in. and .244 in. for the middle and rear drivers, respectively, as shown by diagram in Fig. 452. The maximum stress in the rail at this point was 16,430 lbs. per sq. in., tension, being the same for both the main and rear drivers (Fig. 525). The tensile stress under the truck wheel was 10,450 lbs. per sq. in. The maximum compressive stress was 2990 lbs. The data in inches on the strain diagram shows the amount of stretch or compression of the rail flange. Observations taken 6 ft. 4 ins. from the joint on the same piece of track with the same engine showed a maximum tensile stress of 13,810 lbs. per sq. in. when the middle driver was over the point, and a maximum compressive stress of 4480 lbs. per sq. in. when the front and middle drivers were spanning the point. The tensile stress under the truck wheel was 8960 lbs. per sq. in.

Observations made on rails weighing 75 lbs. per yd. were with locomotives of different type and weight, so that comparisons are not as instructive as would be the case had the same locomotives been used on both the 66-lb. and 75-lb. rails. Observations were taken with an 8-wheel passenger engine weighing 82,800 lbs. (Fig. 524). The track was a stretch of main line laid with 75-lb. rails and oak ties (18 per rail length) in gravel ballast. The point of observation was 25½ ins. from the joint and the depression under the front and rear drivers was .160 and .161 in. respectively, or the same as were observed for the mogul locomotive No. 336 (Fig. 403), and under practically the same track conditions, thus showing the relative severity of this class of locomotives. In all of the above experiments the point of observation was taken on the rail midway between ties. The depressions under a 6-wheel switch engine (No. 466) are shown in Fig. 480.

From these experiments it appears that the leading truck wheel develops a higher average unit fiber stress than the other wheels, in proportion to the weight on the same, and it is not always the case that the greatest depression or the greatest stress takes place under the heaviest wheel load, as either may depend to considerable extent upon the spacing of the wheels, the distribution of the weight, the spacing and tamping of the ties, and earth conditions. It was found that the recovery of the roadbed from the depression was not complete immediately upon the removal of the locomotive from the vicinity. While the principal part of the recovery took place at once a small portion of the depression was very sluggish in returning to the normal hight. The length of time required for the complete return of the roadbed to its normal state was not determined.

Experiments on the P. R. R.—The track experiments on the Pennsylvania R. R. were made during the months of October and November, 1894, with two eight-wheel passenger engines (Nos. 809 and 1515) and a consolidation freight engine, No. 557. Engine No. 809 weighed 127,050 lbs. of which 87,300 lbs. was about equally distributed on the four 80-in. drivers. The wheel spacings, from front to rear, were 6 ft. 7 ins.—8 ft.

5½ ins.—7 ft. 9 ins. (between drivers). Engine No 1515 weighed 145,500 lbs., of which 95,200 lbs was carried on the 84-in drivers, the first pair carrying 48,500 lbs. and the second pair 46,700 lbs., which, it will be noted, is very heavy, the load on the front drivers exceeding 12 tons per wheel. The wheel spacings, front to rear, were 7 ft. 8 ins.—8 ft. 3¾ ins.—8 ft. (between drivers.) Freight engine No. 557 weighed 124,800 lbs., of which 113,800 lbs. was carried on the 50-in drivers, distributed 26,500 lbs.—27,500 lbs.—31,300 lbs.—28,500 lbs., on first, second, third and fourth driver axles, respectively. The wheel spacings, front to rear, were 7 ft. 11 ins. (between truck wheel and first driver)—4 ft. 7 ins.—4 ft. 8 ins.—4 ft. 7 ins.

The object of these experiments was to determine the fiber stresses in the rails, measure the depression of the rails and find the slope or inclination of the rails caused by their depression under the weight of the different wheels. The observations for depression and data for the computation of stresses were taken in the same manner as in the experiments on the C., B. & Q. Ry. the year previously. The slope or inclination tests were made by means of a sensitive level bubble (Fig. 523) mounted on a frame 12 ins. long, having at one end a fixed support drawn to a conical point and at the other end a screw micrometer, as a means of adjustment. The method of using the instrument was to place the conical points in center punch marks 12 ins. apart on the rail flange, adjusting the instrument to level before and after the rail came within the influence of the locomotive pressure, and then note the difference in the readings. The rails examined ranged in weight from 60 to 100 lbs. per yard, being supported on oak pole ties, in stone, gravel and cinder ballast. The observations on the various rails were all made at a point on the rail quarter, with the engine in different positions. Altogether 45 distinct sets of observations were taken and diagrams were recorded from the data obtained.

Among the numerous observations were a number taken to compare the unit fiber stresses on the under side of the rail flange, under the wheels of the same locomotive on rails of different weight per yard. Thus, the average tensile stresses per sq. in. under each of the drivers of locomotive No. 809 for 60-lb., 70-lb. and 85-lb. rails, respectively, were 10,985 lbs., 17,930 lbs. and 11,820 lbs. The track in each case was ballasted with gravel. From these results it appears that the stresses in the 60-lb. rails were less than in either the 70-lb. or 85-lb. rails. With the same engine on stone-ballasted tracks laid with 60-lb., 70-lb., 85-lb. and 100-lb. rails, respectively, the corresponding average tensile stresses for each of the two drivers were 19,540 lbs., 14,390 lbs., 9675 lbs., and 9840 lbs., per sq. in. The peculiarity in this set of observations was that the stresses in the 100-lb. rail exceeded those in the 85-lb. rail. The average tensile stress per sq. in. under each of the four drivers of freight engine No. 557 corresponding to 60-lb., 70-lb., 85-lb. and 100-lb. rails in stone-ballasted track, were 14,125 lbs., 7910 lbs., 7160 lbs., and 5090 lbs., respectively.

The fact that the lighter of two rails in the first two sets of experiments underwent smaller stresses for the same loading is not necessarily an indication of disproportionate stiffness. It must be taken into consideration that underneath a locomotive or car there are four supports which undergo depression and stress: the rail, the tie, the ballast and the roadbed. In view of the variable stability of the roadbed it is not surprising that a rail of given weight per yard should undergo smaller stresses than a heavier rail on another piece of track, for the conditions of earth support in the two cases may have been entirely different, and it does not necessarily follow that increased stiffness in the rail could produce a greater stiffness for the whole supporting structure, as between the two locations compared. In fact such results are just what an experienced trackman would expect. It should be borne in mind therefore that in any investigation of the depressions in track or stresses in the rails, not only must the relative stiffness of the rail be considered, but the relative supporting powers or properties of the ballast and roadbed, in each case. As a means of illustration, the variable resistance found in driving piles at different locations in the same vicinity may be considered.

For the purpose of determining the relative supporting power of various kinds of ballast observations were taken of rails of the same weight laid on tracks in different kinds of ballast, the same locomotive being used in each case. With locomotive No. 809, on 60-lb. rails, the order of rigidity was with gravel, stone and cinder, the corresponding average depression under each of the two drivers being .073 in., .162 in., and .230 in. In another set of observations on tracks laid with 70-lb. rails the order of rigidity was found with gravel, cinder and stone, the average depression under the drivers, corresponding to the different kinds of ballast, being .138 in., .230 in., and .277 in. These observations would seem to make it appear that gravel is a more rigid ballast than either stone or cinder, but in some observations with the same engine on tracks laid with 85-lb. rails the order of rigidity was stone and gravel, the corresponding average depression for the drivers being .144 in. and .233 in. Thus again are we obliged to fall back upon the variability of earth support at individual rails in order to account for the phenomena observed.

It may be of interest to compare the stresses in the rails under the two passenger locomotives Nos. 809 and 1515, as showing the effect of increase in wheel weights. On cinder-ballasted track laid with 85-lb. rails the average tensile stress per sq. in. under each driver of engine No. 809 was 10,030 lbs., while under each driver of engine No. 1515, at the same point on the same piece of track, it was 11,820 lbs. On gravel-ballasted track laid with 85-lb. rails the average tensile stress under each driver of engine No. 809 was 11,820 lbs. per sq. in., while under each driver of engine No. 1515, at the same point on the same piece of track, the average tensile stress per sq. in. was 16,800 lbs.

It is also instructive to compare the stresses produced by the drivers of freight and passenger engines of about the same weight, and as passenger engine No. 809 is but 1.8 per cent heavier than freight engine No. 557, a good opportunity for a fair comparison is here afforded. On cinder-ballasted track laid with 85-lb. rails the average tensile stress per sq. in. for each driver of the passenger engine was 10,030 lbs., and the maximum tensile stress the same. The average tensile stress under each driver of the freight locomotive at the same point on the same piece of track was 5910 lbs. per sq. in., and the maximum stress 10,030 lbs. per sq. in. On gravel-ballasted track laid with 85-lb. rails the average tensile stress per sq. in. under each driver of the passenger engine was 11,820 lbs. and the maximum stress 12,180 lbs., while the average tensile stress per sq. in. under each driver of the freight locomotive at the same point on the same piece of track was 7700 lbs., and the maximum stress 10,030 lbs. On stone-ballasted track laid with 85-lb. rails the average tensile stress per sq. in. under each driver of the passenger engine was 9670 lbs., and the maximum stress 10,750 lbs.; while for each driver of the freight locomotive, at the same point on the same piece of track, the average tensile stress was 7160 lbs., and the maximum stress 10,030 lbs. The compressive stresses for the rail between the wheels are not mentioned, owing to the fact that in each case they were far less than the tensile stresses under the wheels, the average ratio of the two kinds of stress for the passenger engine being 37 to 100 and for the freight engine 36 to 100. It thus appears that in each comparison of the effects produced by the two engines on the same piece of track the average stresses produced by the freight engine drivers were far less than those produced by the drivers of the passenger engine (ranging from 60 to 75 per cent), while in no case did the maximum stress for the freight locomotive exceed that for the passenger engine. The conclusion to be drawn from these results is that locomotives of the eight-wheel type exert greater pressures upon track than consolidation locomotives of the same weight.

In this series of experiments several sets of observations were taken to show stress effects under special conditions. Thus in one instance a tie was removed from stone-ballasted track laid with 100-lb. rails, leaving a space of 52 ins., between centers of tie supports. The maximum tensile stress per sq. in. in the flange of the rail, developed under one of the drivers of engine No. 809, was 18,970 lbs., while the maximum stress per sq. in. on another rail of the same section (in stone ballast), where the ties were spaced 26 ins. centers, was 9840 lbs. In a test on a 34-in., six-bolt angle bar at a suspended joint between 70-lb rails, with joint ties 21¾ ins. centers, the bottom leg of the splice bar underwent a maximum stress of 22,140 lbs. per sq. in. when one of the drivers of passenger engine No. 809 stood directly over the joint. With the drivers spanning the joint there was a compressive stress of 8300 lbs. per sq. in. In a test made with the same engine on track laid with 70-lb. rails and oak ties 12 ins. apart in the clear, on an iron girder deck bridge, a maximum tensile stress of 18,180 lbs., per sq. in., was found in the flange of the rail when one of the drivers stood over a point midway between ties.

Experiments on the Boston & Albany R. R.—The experiments on the Boston & Albany R. R. were made in February, 1895, on track laid with 95-lb. rails on yellow pine ties, with shoulder tie plates, in gravel ballast, which, at the time, was frozen. It is interesting to compare some of the results obtained with the observations made on the 100-lb. rails of the Pennsylvania R. R. The depression of the rail at a point in the rail quarter, under each driver (69-in.) of an eight-wheel passenger engine weighing 115,700 lbs. and carrying 37,500 lbs. on each driver axle, was .140 in. It was found, however, that by redriving the spikes before making the test at a quarter point on another rail the depression under each driver was reduced to .085 in. The tensile stress in the rail flange at a point on the rail quarter midway between ties spaced 24 ins. centers, was 6870 lbs. and 9160 lbs. per sq. in., under the front and rear drivers, respectively. The tensile stress under the front truck wheel in this test was high, being 6100 lbs. per sq. in. In seven tests made at various points on a rail, including the rail joint, quarter and center, the maximum tensile stress was found to be 11,450 lbs. per sq. in., under the rear driver, at a point on the rail quarter. In observations on track in frozen ballast it is doubtful if any finely drawn conclusions are of any value, since the conditions of tie support depend so largely upon the manner of the heaving of the ground; and then the depth to which the roadbed is frozen, underneath the ballast, would make all the difference imaginable, since if only the ballast was frozen the support for the track would be only partially affected.

In this account of track depression and stresses in the rails the space devoted to the subject has permitted only a general consideration, making use of typical examples. The reader who wishes to go into the subject in detail is referred to the government reports on "Tests of Metals and Other Materials," at the Watertown Arsenal, Mass., for the years 1894 and 1895.

In the track deflection experiments considered hitherto the observations of depression and strain were taken with the locomotive at rest, so that the behavior noted of the rails and track was with statically applied or quiescent loads. During subsequent years means have been devised and used for measuring track depression and rail strains under trains at speed These experiments are of course more interesting, as then the track is put to test under more severe, but nevertheless working, conditions. Such experiments in this country, confined to the measurement of strains in the rail flange, have been conducted by Mr. P. H. Dudley, with an instrument of his invention known as the "stremmatograph." This instrument consists of a micrometer clamped to the under side of the rail flange, over a length of about 5 ins., and provided with a scriber point which moves in unison with the elongation or compression of the metal. The record is taken on a strip of polished copper, which is moved at right angles to the rail and across the direction of movement of the scriber point, while an engine or train is passing over the rail. In using the instrument the scriber point is set for recording, and when the train is within a rail's length the metallic strip is started and moved continuously while the wheels are passing. The fluctuating movement of the scriber point, due to the stretch and compression of the rail fibers, traces upon the moving metallic strip a curve whose ordinates, measured to a reference line drawn before starting, denote the strains in the metal for the various wheel loads. From these strains the unit fiber stresses of the metal are computed.

By means of this instrument Mr. Dudley has obtained a great deal of information on rail stresses under moving trains which has enabled comparisons to be made showing the effect of speed. Thus, for instance, in comparing data obtained with the same engine, moving at speeds of 2 and 10 miles per hour, it was ascertained, from an average of the tensile and compressive stresses in the rail under and between all of the wheels, that at the higher speed the stresses in the rail were increased 14.3 per cent over the stresses which took place in the rail at the slower speed. A record taken on the New York Central & Hudson River R. R. at West Albany, N. Y., on a 5-in., 80-lb. rail laid on ties spaced 25 ins. centers, in gravel ballast, while an 8-wheel engine weighing 118,950 lbs., with 40,000 lbs., 41,950 lbs. and 37,000 lbs., on truck, main axle and rear axle, respectively, hauling five Wagner palace cars passed at a speed of 40 miles per hour, showed the following stresses per square inch on the under side of the rail flange: Compression in front of truck wheel, 1417 lbs.; tension under front truck wheel, 13,070 lbs.; tension under rear truck wheel, 12,579 lbs.; tension under front driver, 31,415 lbs.; tension under rear driver, 26,456 lbs.; average tension under car wheels, 12,720 lbs.; maximum tension under car wheels, 16,534 lbs.; minimum tension under car wheels, 9448 lbs.; maximum compression between engine wheels (rear truck wheel and front driver), 5433 lbs.; average compression between engine wheels, 3247 lbs.; average compression between tender wheels, 1810 lbs.; average compression between car wheels, 2057 lbs. The maximum compressive stress per square inch found between car wheels was 4960 lbs.—between the rear wheel of the fourth car and the front wheel of the fifth car. All the compressive stresses between the trucks of different cars were in excess of the average compressive stresses between wheels of the same car. The weight of the cars was in the neighborhood of 100,000 lbs. each.

In view of the above data it is interesting to contemplate the severity of the service imposed upon a rail, even at that moderate speed, due to the rapid reversal of the stresses. At a speed of 40 miles per hour a train runs 58 ft. 8 ins. per second—a distance which extends over the entire wheel base of the engine and tender and past the first wheel of the car following, or past nine wheels. That is to say, nine wheels pass over any given point in the rail per second, each causing a reversal of stress amounting to thousands of pounds per square inch, as indicated.

Comparing records obtained from an 80-lb. rail in gravel-ballasted track, with records obtained from a 100-lb. rail in stone-ballasted track, a 63-ton engine moving at a speed of 20 miles per hour developed tensile stresses of 11,574 lbs., 12,046 lbs. and 14,172 lbs. per sq. in., under front truck wheel, front and rear drivers respectively, on the 80-lb. rail; as against stresses of 10,865 lbs., 4960 lbs. and 9448 lbs. per sq. in., for front truck wheel, front and rear drivers respectively, on the 100-lb. rail, from an engine of the same weight and class running at a speed of 19 miles per hour. In all of the experiments on 100-lb. rails in stone-ballasted track, so far as reported, the strains produced by one or the other of the truck wheels (the front wheel in every case but one) exceeded the strains produced by either of the drivers; whereas on 80-lb. rails in gravel-ballasted track the strains produced by the drivers were the larger. With switching engines having no truck the maximum stress was found under the front driver. A comparison of the stresses produced by such an engine on 65-lb. and 100-lb. rails is especially interesting. The engine was six-coupled, carrying the entire weight of 125,000 lbs. upon the drivers. The speed of the engine and kind of ballast are not stated, but tie plates were in use. With the instrument between ties spaced at 30 ins. centers the stresses in the 65-lb. rail were 51,694 lbs., 22,445 lbs. and 23,856 lbs. per sq. in., for the front, middle and rear drivers respectively, while in the 100-lb. rail the stresses were 8031 lbs., 6849 lbs. and 6142 lbs. per sq. in. for the drivers in the same order.

The records from the stremmatograph show that the dynamic effects from the wheels increase with the speed of the train and with roughness of the rails and treads of the wheels. The record above presented for the speed of 40 miles per hour shows that the stresses were about double the static effects from the same wheel loads, or about double what they were found to be when the engine was just moving over the track without exerting much tractive force. With 8-wheel engines using steam in accelerating the train it appears that much the largest stress takes place under the front driver, which is undoubtedly due in some degree to the vertical component from the thrust and pull of the main rod, as explained in connection with the subject of excessive counterbalance. With engines having more than two pairs of drivers the stresses under the middle driver were usually less than those under the other two drivers. When engines were working hard the stresses were also increased under all the wheels, compared with their average values for the engine running at the same speed but exerting only a small tractive force. With engines running at high speed the position of the counterbalance at the instant the wheel passed the stremmatograph (as shown by instantaneous photographs) had an important effect, as indicated by the strains measured. The tests further showed that the stresses per ton of loading were less for engines having more than two pairs of driving wheels than was the case with the 8-wheel type of engine. The deformation of the roadbed was decidedly less for 10-wheel and consolidation types of engines than was the case with the 8-wheel type. As a general thing, the closer the wheel spacing of the engine the less the fiber stresses per ton of load.

On the whole, it appears that maintenance-of-way engineers in Europe have given more attention to track experiments than have the engineers of this country, and as a rule they have gone into the subject with greater elaboration. On this point it will suffice to describe briefly a series of interesting experiments performed on the Warsaw-Vienna Ry., by Mr. Alexander Wasiutynski, permanent way engineer. In order to eliminate as far as possible the effect of ground depression and vibration on the apparatus four brick piers 5 ft. 3 ins. square at the bottom and 3 ft. 3⅜ ins. square at the top, with layers of felt at every fifth course of bricks, were built in timber-lined pits 7 ft. square and 24 ft. 3 ins. deep, spaced 13 ft. 1½ ins. apart, c. to c., in line, parallel with the rail, and 14 ft. distant from it. The brick piers were isolated from the lining of the pits and on top of the same were laid two lines of rails 46 ft. long, on which to slide the observing apparatus parallel to the track. This arrangement permitted observations to be taken on a stretch of track of the same length, or past both joints on a rail 39 ft. 4 ins. in length. In these experiments the deflections were recorded photographically on diagrams, thus dispensing with mechanical connection with the track. The apparatus consisted of a camera arranged at the end of a telescope tube, 11 ft. 4 ins. clear of the track. The exposure was made through a narrow vertical slit upon a sensitized film, about 4¼ ins. wide and 26. ft. long, unrolled by clockwork from a cylinder at a speed of 2 to 8 ins. per second. By means of electrical connections the film was started and stopped automatically by the wheels of the train. The point of observation in each case was a spherical mirror of polished steel ⅛ in. in diameter, attached to the rail or tie, upon which was thrown a strong light from an electric arc lamp, which was reflected as an intensely bright spot, or strong enough to make an instantaneous exposure. In this manner a wavy line was photographed upon the moving film, representing the movement of the point of observation under the weight of passing wheels. Two instruments, electrically connected, were used simultaneously at a known distance apart, and by means of time-interval exposures upon the film through a small aperture above the vertical slit, it was easy to calculate the speed of the train and the distance of a wheel at any instant from the point under observation.

The track at this point was on tangent, on an embankment 5 ft. high, and on a grade of about one tenth of 1 per cent. This embankment had been built 37 years and consisted of clayey soil mixed with some sand. From borings it was found that the soil underneath the embankment consisted of fine sand with a slight mixture of silt for a depth of 33 ft. below rail level, with a layer of coarse sand mixed with pebbles and clay at a depth of 21 ft. Water was found at a depth of 24 ft., or at the foundation of the piers. The traffic at the time the observations were taken amounted to 32 passenger trains and 24 freight trains daily. The ballast consisted of gravel intermixed with coarse sand, with some earth, the depth of the ballast being 10 ins. below the ties.

In experiments to ascertain the amount of compression of the roadbed at different depths, 4-in. holes were bored at depths of 20, 39 and 59 ins., respectively, and cased with iron pipe. Pieces of pipe of smaller diameter were then placed within the casing, extending to a point within 16 ins. from the top, and the diagrams of depression were taken of the movement of marks fixed to the upper end of the inner pipe. The diagrams showed clearly a depression of the roadbed under each wheel of the locomotive at various depths, the maximum depressions being .05 in. at a depth of 20 ins. below the rail, .03125 in. at a depth of 39 ins. below the rail and .025 in. at a depth of 59 ins. below the rail. At a depth of 21 ins. below the bottoms of the ties the depression was found to amount to only one fourth to one third of the depression of the ties. Notwithstanding all the precautions taken there was found to be a slight vibration in the piers, the amount of which was ascertained by observations with the recording instruments during the passage of trains, the film being unrolled first horizontally and then vertically, to get the vertical and horizontal oscillations respectively. From careful observations it was found that the oscillation of each pier was within .003 in. vertically and .002 in. horizontally, showing that at a depth of 24 ft. below the rail and at a lateral distance of 16½ ft. from the center of the track there was sensible elastic depression of the ground.

In the experiments to determine the bending curve of 6x10-in. oak ties a six-coupled switch engine was used at a speed of about 6 miles per hour. The ties selected were the two at the middle of a 76-lb. rail 39 ft. 4 ins. long, and observations were taken on a point at the middle of the tie, at the outside of the rail seat, and at the end of the tie. In order to prevent the compression of the wood fiber from affecting the record of the depression of the tie a hole was bored through the tie and a bolt of smaller diameter carrying the point of observation was passed through the tie and made fast at the bottom. It was found that with the middle driver of the locomotive midway between tie supports the deflection of the rail extended over three ties in either direction; and with distances between the axles of the locomotive equal to two to three times the tie spacing, the maximum rail load amounted to 39 to 44 per cent of the wheel load. With ties 8 ft. long the deflections at the middle of the tie, at the rail seat, and at the end of the tie, respectively, stood in the ratio of 69 to 100 to 124, showing that the end of the tie was deflected most and the middle of the tie least. Observations on ties 8 ft. 10 ins. long showed that the deflections for the middle of the tie, rail seat and end of tie, respectively, stood in the ratio of 75 to 100 to 68, showing that on ties of this length the deflections were greatest at the rail seat and least at the end. Under 63-lb. rails the deflection of ties 8 ft. 10 ins. long was in the ratio of 91 to 100 to 78 for middle of tie, rail seat and end of tie respectively. These observations are interesting, as affording data for the determination of the proper length of tie, or a tie which should deflect the same everywhere along its whole length. From the results of these experiments it would appear that ties 8 ft. in length are too short and ties 8 ft. 10 ins. in length too long. A tie 8 ft. 6 ins. long (corresponding to a depth of 6 ins.) is probably not far from the theoretical length, for standard-gage (4 ft. 8½ ins.) track, such as was the track experimented upon.

Another series of observations was made to determine the depression of the ties at the rail seat, for different types of track. The experiments were repeated two or three times at each tie and an average was taken of the depressions of all the ties under each rail, for each type of track, so that the data obtained were not the results from chance observations. The locomotives running over the experimental section were of two types, one having six coupled drivers without truck, with a load of about 13 tons per axle, and the other an 8-wheel passenger locomotive with a load of 15 tons on each driving axle. One type of track experimented with was laid with 62-lb. rails 19 ft. 8 ins. long, on eight 6x10-in. oak ties 8 ft. long, spaced 19½ ins. centers at the joint, 26½ and 31½ ins. centers, respectively, for the next two ties, and 33½ ins. centers for the intermediate ties. The joint ties were provided with tie plates. The average depression of the ties in this type of track was found to be .0184 in. per ton of wheel pressure. The depression of the ties at the rail center exceeded the depression at the joints and quarters.

Another type of track was laid with 76-lb. rails 39 ft. 4 ins. long, on

16 ties spaced 19½ ins. centers at the joint, 21½ ins. centers for the two next ties and 31½ ins. centers for the intermediate ties. Tie plates were used on all ties. The average depression of the ties in this type of track was .0113 in. per ton of wheel pressure, or 40 per cent less than the average depression for the track previously mentioned. In this track also the depression of the intermediate ties exceeded those of the joint and quarter ties.

A third type of track was laid with 76-lb. rails of the same length and 8 ft. 10-in. ties, with the same tie spacings as in the second type just noted. The average depression of the ties for this type of track was found to be .0091 in. per ton of wheel pressure, or 20 per cent less than the deflection of the ties in the preceding type of track laid with the same weight of rail. In this type of track the depression of the ties was more nearly uniform throughout the length of the rail than in the other tests, but still the maximum depressions were found with intermediate ties. By changing the tie spacing so that the two joint ties touched each other, with the next two ties spaced 21½ and 25½ ins. centers, respectively, and the intermediate ties spaced 33 ins. centers, the average depression of the ties was found to be .0111 in. per ton of wheel pressure, or an increase of 22 per cent over the average depression for the type of track with ties of the same length differently spaced. In this type of track the depression of the ties throughout the length of the rail was more nearly uniform than was the case in the other experiments. It was found that accidental causes, such as unequal tamping of the ties and surface kinks in the rails, might, even on well maintained track, affect the depression of individual ties to the extent of 50 per cent. A large number of quite careful observations showed that the depression of the rail between tie supports was only slightly greater than its depression over the ties. The difference did not average more than .0118 inch or .3 millimeter for any of the tie spaces experimented with.

The report of these experiments disagrees on a very important point with reports of almost all other experiments of the same kind; namely, as to the effect of the dynamic action of the load. The speed of trains and locomotives from which these records were taken varied from 6 to 37 miles per hour, and it is claimed that the difference in the deflection of the rails per ton of wheel pressure at varying speeds was unimportant. It is suggested, however, that had the speeds reached 50 miles per hour or more the dynamic action of the load might have had a perceptible effect

In experiments to determine the efficiency of joint splices it was found that none of the patterns experimented with could effect continuity in the line of depression of the track. With no splices on the joint the rails were deflected independently of each other, as would be expected. By the use of plain angle-bar splices the depression of the joint was reduced to about half of what it was without any splice at all. The most efficient splice—that is the one which permitted the least depression of the joint—was a 6-bolt Z-bar splice, or an angle bar splice with vertically depending flanges between the joint ties, resembling very much the Churchill joint, used in this country, but without the base plate and lower bolts used with that device. The conclusion reached was that with any joint splice in service the depression of the joint can be reduced only approximately to the depression at the middle of the rail, and this only by spacing the joint ties closer together than the intermediate ties.

It should be explained that the different types of track—i. e., rails of different length and section, ties of different length and variously spaced, different patterns of splice bars, etc., for the different series of experiments—were all laid upon the same stretch of roadbed at different times. Subsequently the gravel ballast was removed and replaced with broken granite of $1\frac{5}{8}$ ins. size. One reason for making this change was to investigate the influence of the improvement of the ballast on the stiffness of the track, but, contrary to expectations, the results did not show an increase in this respect. Observations showed that the depression of roadbed under the ballast was affected by the type of the rail and by the length of the ties, but not by the change in the ballast. It was therefore concluded that the superiority of broken stone ballast depends upon other qualities than that of relative stiffness imparted to the roadbed underneath.

182. Variations from Standard Gage.—In the United States, Canada, England and in most of the countries of Europe (Russia and Spain excepted) the standard track gage is 4 ft. $8\frac{1}{2}$ ins. or 1.435 meters. In this country all car wheels are gaged with reference to this standard, or to what is generally known as the Master Car Builders' standard wheel gage. Nevertheless, aside from the practice of widening gage on curves, there is a large mileage of track laid to a gage of 4 ft. 9 ins. This is the gage of the Chesapeake & Ohio Ry., the Southern Ry. and of many other roads in the South. The Pennsylvania R. R. works to the principle of 4 ft. $8\frac{1}{2}$ ins. as the gage of its passenger tracks and 4 ft. 9 ins. as the gage of its freight tracks; that is, the single-track and double-track lines are laid to a gage of 4 ft. $8\frac{1}{2}$ ins., but on three-track and four-track lines, where one or more tracks are devoted exclusively to the freight service, the gage of the freight tracks is 4 ft. 9 ins.

Nominally, 4 ft. 9 ins. passes for standard gage, the half-inch variation being regarded as an irregularity of standard practice. The reasons given in explanation of this irregularity are various and not without interest. So far as the southern roads are concerned, 4 ft. 9 ins. has been the standard since 1886, when the gage of many thousands of miles of track was changed from 5 ft. to 4 ft. 9 ins. It is said that the reason for adopting this gage at that time was the impossibility, in many cases, of setting the gage of locomotive drivers back sufficiently to fit standard track. As it was practicable to set them back to fit a gage of 4 ft. 9 ins., and as that gage would accommodate all cars of standard gage, it was therefore generally adopted by the roads making the change. But experience with this gage has induced many to continue using it. Concerning the amount of side play in the wheels that is necessary for the proper running of the cars there are widely varying views, with various shades of opinion coming in between. The great majority of railway engineers consider that $\frac{3}{8}$ in. is sufficient, this being the side play of new wheels gaged to the M. C. B. standard and running on track gaged to 4 ft $8\frac{1}{2}$ ins. As the wheel flanges wear, the side play increases to double or even three times this amount. On the other hand, the people who prefer the 4-ft. 9-in. gage approve of $\frac{3}{4}$ in. of side play to start with, and the wheel flanges are allowed to wear to the limit of $1\frac{3}{4}$ ins. side play, which is certainly plenty. Others (but comparatively few in number) have taken the view that a compromise is obviously safe, and have accordingly split the difference and made the gage 4 ft. $8\frac{3}{4}$ ins. The Macon & Birmingham Ry. was one of the roads which adopted this gage as standard.

At one time there was a good deal of carelessness in gaging freight car wheels, and the tight running of an occasional pair of wheels too widely gaged was an argument in favor of retaining the 4-ft. 9-in. gage for the track. The general observance of the M. C. B. standard, which now prevails, has overcome the difficulties in this respect. Some claim to have ascertained by experiment that an engine can haul more freight cars on a gage of 4 ft. 9 ins. than on the standard gage of 4 ft. 8½ ins., but that passenger trains run steadier on standard gage, although requiring a small margin of excess power to propel them. This view concerning the easier running of freight cars with widening of the gage is much disputed, but with certain roads where the freight traffic predominates it is the chief consideration for retaining the 4-ft. 9-in. gage. Another consideration which finds some support is the recognized necessity for widening gage on curves. It is quite extensively the practice to widen gage as much as ½ in. on sharp curves, and some who incline to a preference for standard gage under ordinary conditions have adopted it (4 ft. 8½ ins.) for districts where the line is mostly straight and curvature light, but on parts of the line where there is a great deal of heavy curvature, the gage is made 4 ft. 9 ins. throughout, and no widening is done on the curves.

The preponderance of engineering opinion supports the view that the closer the track and wheel gages correspond the steadier the cars will run; and a considerable number make no exception even with curves, except where it is actually shown that widening of the gage is made necessary by the wheel base conditions of the locomotives. Such opinion is, of course, favorable to standard gage proper, and the principal objections to a gage of 4 ft. 9 ins. are as follows: The increased side play of the wheel flanges permits excessive side oscillations of freight cars, with the result that the track is frequently knocked out of line. The increased side play of the wider gage permits a greater degree of slewing or "cornering" of car trucks, particularly under heavily loaded cars that are down on their side bearings. The result is a corresponding increase in the obliquity of flange contact with the rails, increased train resistance and more rapid wear of wheel flanges. The wider flangeway through frogs required by the wider gage reduces the area of possible wheel-bearing surface and results in more rapid wear than with standard gage. A good paper ("Standard Car and Track Gages") which elaborates on some of these points was prepared by Mr. C. C. Dunn and presented before the Roadmasters' Association of America, in 1899.

The tendency is all the time toward standard gage. Occasionally a road which has maintained 4-ft. 9-in. gage will decide to make the change. and as the rails are renewed the gage is gradually drawn in without appreciable extra expense. The Indiana, Decatur & Western Ry., the New York, Susquehanna & Western R. R. and the Atlanta & West Point R. R. were some of the roads that were pursuing this policy in 1901. The experience of one engineer was stated as follows: "I had the gage of our road changed last year from 4 ft. 9 ins. to 4 ft. 8½ ins. I think the standard is much better than the wider gage, and I know that since the change the trains ride better. I see no need of 4-ft. 9-in. gage in any case."

183. Automatic Block Signals and Track Circuits.—Automatic block signals are generally arranged to give their indications under the control of a track circuit. The same device is also used in some systems of highway crossing alarms, and to some extent in connection with interlocking, as explained in § 83. The basis of a track circuit is a section of track in which the two lines of rails are insulated from electrical connection with each other and also from the abutting rails at the ends of the section. The circuit is completed by a battery (*B*, Fig. 525 A) connected across from rail to rail at one end of the section and by a relay (*R*) similarly connected at the other end of the section. The circuit is thus seen to be a closed one, and normally there is a current flowing through all parts of it. To insure good electrical connections throughout the circuit the rail joints are bonded around the splice bars with iron or copper wires fastened in holes drilled in the web or flange of the rails. To provide against breakage it is customary to use two bond wires at each joint, and as a means of protection they are commonly run behind the splice bars; that is, through the open space between the splice bar and web of the rail. In some locations they corrode more rapidly behind the splice bars than outside them, and when laid in this manner the larger part of the wire is hidden from inspection. For such reasons, pro and con, both methods are extensively found in practice. The insulation between the two lines of rails in the circuit is afforded by the wooden ties, and between rails which come in abuttal at the ends of the section insulated splice bars and joint filling are used.

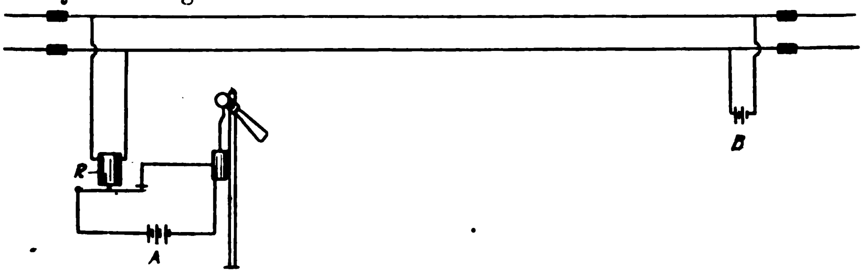

Fig. 525A—Diagram of Track Circuit.

To break the cross connection between the two lines of rails at switches, it is sometimes arranged to have the open point rail lift from the slide plates when the switch is closed. This is done by means of iron wedges spiked to the ties alongside (but not touching) the slide plates, in two or three places. When the switch is closed the open point rail rests on these wedges clear of the slide plates, but in throwing the switch to open it the open point is then moved off the wedges and let down upon the slide plates. In this position of the switch the track circuit is shunted. Another arrangement is to cut out a section of the through rail by insulating a joint each side of the switch, and then connect around the rail so cut out by means of an insulated wire run underground. By this method the track circuit is not shunted in either position of the switch. Still another arrangement is to insulate the switch rods and a joint in the lead rail. The switch-rod insulation may consist of sheet fiber placed between the clip and the point rail, with insulation bushings and washers for the bolts; or the switch rod may be cut in two in the middle, with the two pieces joined by T-ends bolted together with insulation fiber between them. At crossovers the connection is broken by insulating a joint in both lines of rails between the two tracks. At crossings with other tracks joints are insulated on either side of the crossing, on both lines of rails, and jump wires are laid underground to run around the insulated section and thus cut the crossing out of the circuit. At sidings an insulated joint is placed at or beyond the clearance point, on each side of the track, and between this and the switch there is an insulated section in the outer rail of the turnout which is electrically connected with the far rail of main line, so as to virtually form a part of the track.circuit. An engine or car on the siding within fouling distance of main line will therefore short-circuit the track relay in the same manner as would a train on main line, and hence would cause the signal governed by this track section to stand at danger. Such, in brief, describes the methods of connecting and insulating rails in simple track circuits.

In nearly all systems of automatic block signaling the track is divided into insulated sections or blocks, with a signal placed at or near the entrance to the block and a track battery at the distant end, connected as above explained. Normally there is a current flowing out of the battery into one line of rails, thence through the relay controlling the signal, and then back through the other line of rails into the other terminal of the battery. When a train arrives on the block the rails of the track circuit are connected across or shunted through the wheels and axles, and as the resistance by this path is very low compared with that through the relay, the current is short-circuited and cut off from the relay; that is to say, practically all of the current flows across through the wheels and axles and almost none through the relay. The relay then loses its magnetism and the armature drops, opening or closing a local circuit which operates or directly controls the signal and causes it to go to danger. The agency for operating the signal may be gravitation, compressed air, an electric battery (*A*, Fig. 525 A), electricity from a power circuit; or carbonic acid gas stored under pressure, in a tank at the foot of the signal post. The battery for the signal circuit is usually of higher intensity than the track battery. In any event the current in the signal circuit must be powerful enough to set in motion the mechanism which actuates the signal. In one system this mechanism is a weight and clockwork, in another it is a cylinder and piston operated by air or gas pressure through valves controlled by the signal circuit; in another it is an electric motor and in another it is an electro-magnet, either of which is usually operated by batteries in the signal circuit. After the train passes off the block (or the overlap in advance of it, in case the overlap is used) the current of the track battery again flows through its normal path, energizing the relay which controls the signal and causing the signal to be restored to its normal position. In one system the signal stands normally at clear and in another it stands normally at danger. In the "normal danger" system the signal stands at danger at all times except when cleared by a train entering the block in the rear, and this can be done only when the block in advance is clear; if it remains at danger the engineer is thereby notified that the block is occupied.

The description thus far has taken into account only one signal at the entrance to each block, and such applies to practice quite extensively. It is also common practice to use two signals at the entrance of each block: one a home signal for the block (suppose it to extend from *A* to *B*) and the other a distant signal for the next block ahead (*B* to *C*). This distant signal (at *A*) moves in harmony with the home signal (at *B*) of the block for which it gives the indications. The control of the distant signal is effected by the movement of the home signal with which it belongs, and the connection may be through a line wire or through the track circuit between them; that is, the same track circuit (*A* to *B*) controls the home signal of its block (*A* to *B*) and the distant signal for the next block ahead (*B* to *C*). The home signal (at *A*) is controlled by its track circuit and relay in the ordinary manner, but the distant signal (at *A*) is controlled by a polarized relay which is not operative except when the direction of the current through the track circuit is reversed by the action of a circuit breaker on the home signal at *B*. In automatic block signaling various types of signals are used: the disk, the banner, the banjo and the semaphore. The foregoing describes the purpose of track circuits and the manner in which certain arrangements of signals are controlled by them. It is not intended to go further into the subject of signal mechanisms, their arrangement and their operation, but as track circuits are constantly under the care of the trackmen, if not nominally in their charge, it is appropriate to consider them in some further detail.

Owing to the poor insulation of the rails from the ground it is necessary to use a track battery of low voltage. Usually it consists of two cells of the gravity type (ordinary telegraph jars) connected in the circuit in parallel, giving the same voltage as one cell but twice the current capacity. To remove the battery from the action of frost it is usually lowered into a well 5 or 6 ft. deep, consisting of a long wooden box or piece of iron pipe sunk into the ground and tightly covered. As the leakage through the ties and ballast in wet weather is usually considerable, and in proportion to the length of the circuit, it is not practicable to operate track circuits longer than 2000 ft. to a mile in length, according to the quality of the ballast. The conductivity of slag and dirt ballast are relatively high, and these materials give more trouble than other kinds. Cinder comes next, with gravel relatively low and broken stone lowest and least troublesome of all. Where the length of a block exceeds the feasible length of track circuit, two or more track circuits are used in succession, each supplied with a battery and relay. The relay of one section may be connected in to open or close the circuit next in series, or the signal wire circuit may be run through the relays of all the sections in the block.

Bearing in mind that the working principle of a track circuit is the demagnetization of the relay forming part of the same, it is obvious that a break in the circuit will accomplish the same result as the presence of a car or train on the circuit. The track circuit will therefore detect a broken rail which pulls apart, as it is very liable to do if broken in cool weather. By placing a circuit breaker in the track circuit, to be actuated by the movement of the point rails at a switch, the opening of the switch is made to do the same thing; that is, to open the track circuit and cause the signal to go to danger. The arrangement in this case is to connect the circuit breaker around an insulated joint in the track circuit, and should the insulation fail the circuit breaker would then be out of circuit and the opening of the switch might not be indicated by the signal. To provide against such danger it is usual practice to carry the signal circuit through the circuit breaker, by means of a line wire; and to make doubly sure some run both track and signal circuits through the circuit breaker at the switch. This circuit breaker opens immediately the switch rail begins to move from its closed position. As any metallic connection across from rail to rail will set the signals, the same as a train on the block, it is the practice of some roads where automatic block signals are used to insulate the cross bar of iron track gages, and the axles of hand cars from the wheels.

Insulated Joints.—The original method of insulating joints, and one that is followed extensively, is to place a fiber "end piece" or templet of the rail section in the joint opening and splice the rails with long wooden bars 3 or 4 ins. thick. To strengthen the splice as much as possible the wooden bars are sometimes reinforced with old angle bars or fish plates cut in two and separated at the middle. For insulating purposes this device is efficient, and the most reliable of any, but it possesses no strength vertically, and under heavy traffic a good deal of attention is required to keep such joints tamped to surface. The alternative type of joint splice insulation consists in lining metal splice bars with fiber sheets and using fiber bushings on the bolts. One plan is to plane off ordinary angle bars to make room for the fiber. Of the many patented devices on the market the Weber pattern is very well known and extensively used. The parts are something similar to those of the ordinary Weber joint splice (Engraving *F*, Fig. 18). There is a metal shoe angle or base plate lined with insulation fiber plate, that is used with wooden splice bars or "fillers" and fiber bolt bushings. In principle it is a wooden splice with a metal base support of L-shaped section which imparts a vertical stiffness to the joint that is much greater than that of the wooden splice bars. The Wayland insulated joint splice is similar except that the vertical leg of the angle base plate does not extend as high as the line of splice bolts, and it has in addition two bolts passing vertically through the outside wooden splice bar and the base plate. The Neafie insulated joint splice consists of a shallow steel channel for a base plate, with an insulation shim and wooden splice bars. At the ends of the base channel the vertical flanges are flattened out and punched for spikes. Each wooden splice bar is secured to the base plate by two vertical bolts. The Atlas insulated joint splice is described in §212 and illustrated by Fig. 542.

Maintenance.—The maintenance of insulated joints is a matter attended with no little trouble. Under heavy traffic the wooden fillers or splice pieces break and the insulation fiber is cut out or broken up. During wet weather the fiber becomes water soaked and rapidly deteriorates. Respecting the first difficulty, the service of the insulating material can be much prolonged by keeping the joint ties tamped up to surface. When the joint is allowed to get down or the bolts to get loose the working of the rail ends vertically breaks up the fiber and destroys the insulation. To make the insulating material impervious to water it is the practice on

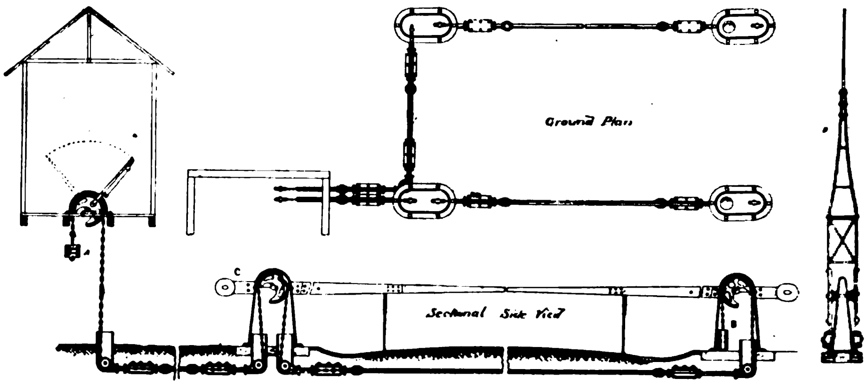

Fig. 526.—"Standard" Railway Crossing Gate.

the Chicago, Milwaukee & St. Paul Ry. to unbolt the splice occasionally, brush the parts clean of dust and oxide scale and then coat the insulating shims and liners and contact surfaces of the rail with black oil. With a view to reduce leakage from rail to rail during wet weather, as far as may be practicable, the ballast should be dressed off clear of the rails. As old rails are usually covered with oxide of iron, which is a poor conductor, the leakage of current between them through contact with the ballast is less than from new rails. It is said that the leakage through ties treated with chloride of zinc is considerably more than through untreated ties.

184. Crossing Gates.—At busy highway crossings in towns and cities, and in many other places where the view along the track is obscured by curves, buildings, trees, etc., railroad companies are frequently required to give warning of approaching trains. This is done either by a flagman stationed at the crossing, by automatic alarm bells or by railway gates. Automatic crossing alarms are usually worked by electricity, being controlled either by track circuits with batteries, like automatic block signals, described in the previous section, or by a circuit opened and closed by the motion of a treadle that is actuated by the wheels of the approaching train, or by the undulations of the rail underneath the same. Such a treadle, known as a "track instrument," consists of a lever pivoted to bring one arm at the side of the rail head and slightly above it, so that it will be depressed by passing wheels; or this arm may extend under the base of the rail and receive its motion from the undulations of the same while trains are passing.

The typical railway crossing gate consists of a light wooden arm swinging vertically on a post at the curb line. At narrow streets or roads the arm may reach entirely across the highway, but where this is not practicable a gate is placed on either side of the street and the swinging arms meet in the middle. As travel must be shut out from both sides of the railroad, this arrangement, which is quite general, requires four gates. The gate arms are sometimes as long as 55 ft., and in some cases where trolley wires would interfere with the movement of a straight arm, the latter is jointed at a suitable point and the end section folds up automatically like a jack-knife, while the arm is swinging past the wire, and extends the gate when the arm is lowered. To obstruct the sidewalk behind the gate post there is usually a short arm (Fig. 527) geared to swing in unison with the longer arm that extends across the street. The gate posts usually stand about 4 ft. high, and to minimize the force required to operate the gate the arm is counterbalanced (*C*, Fig. 526). The simplest arrangement for operating the gates of a crossing is a crank on one of the posts geared to the arm, with underground chain or wire connections with the other posts. It is preferable, however, and most extensively the practice, to have the gateman and the means for operating the gates in an elevated cabin or tower, from which a clear view may be had along the track. The means for operating the gates from a tower may be a lever, with chain or pipe line connections with the posts, or an air pump with pipes for conveying pressure to mechanisms at the posts.

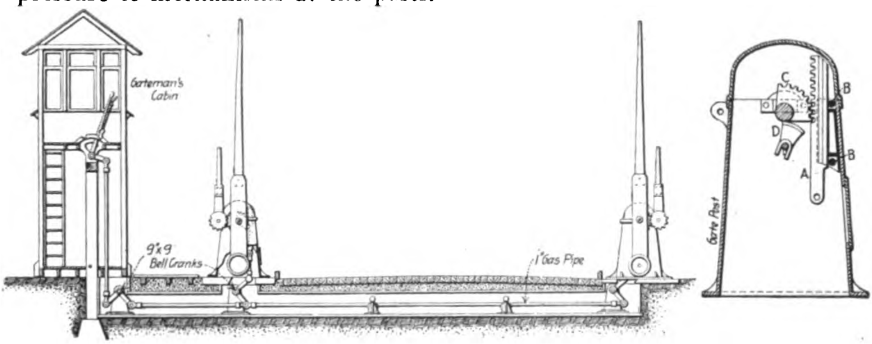

Fig. 527.—Wilson Railway Crossing Gate.

Some lever gates have a double connection or return wire between the tower and the posts, but to avoid multiplicity of parts the "Standard" gate (Fig. 526) is worked by a "single connection" or one line of wire and chain, thus saving one line of pipe for each pair of gates, and half the number of wires, chains and sheave wheels. This arrangement is accomplished by weights at the two ends of the chain, the weight *A* in the tower counterbalancing the weight *B* in the post, so that the same force is required to throw the lever in either direction. The underground wires and chains are carried in 1¼-in. pipes fitting into cast iron sheave boxes or "boot-legs" extending up inside the posts far enough to prevent surface water from finding its way into the pipe. In a four-post installation there are three lines of pipe—one between each pair of posts and one under the track. Number 4 galvanized steel wire and $^9/_{32}$-in. short-link crane chain are used. To prevent the gates from being blown down by the wind the levers are latched.

The Wilson railway gate (Fig. 527) is a lever gate with pipe-line and bell-crank connections similar to those of an interlocking plant, and of standard sizes. The pipe line from tower to gates and under the highway is supported upon the ordinary pipe carriers, and the movement of the pipe is transmitted to the arms through the rack bar *A* meshing with the segmental pinion *C*, shown in the figure. The back of the rack bar is supported by the rollers *B*, and the arm shaft is carried by the rocker bearings *D*. A 7-in. stroke of the pipe line rotates the shaft a quarter turn and raises or lowers the gates. As the levers are provided with sectors and latches the gates cannot be pushed up by persons in the street or carried down by the force of the wind.

In pneumatic gates there are two designs. Gates of the Chicago pneumatic pattern are operated by cylinders and pistons inside the posts. The Bogue & Mills pneumatic gate is operated by a rubber diaphragm in an air-tight ()-shaped chamber placed at the foot of the post and outside of it, as shown in Fig. 528. Where there is a single arm covering the entire roadway (No. 1 pattern) the gate is raised by pumping air against one side of the diaphragm and lowered by pumping against the opposite

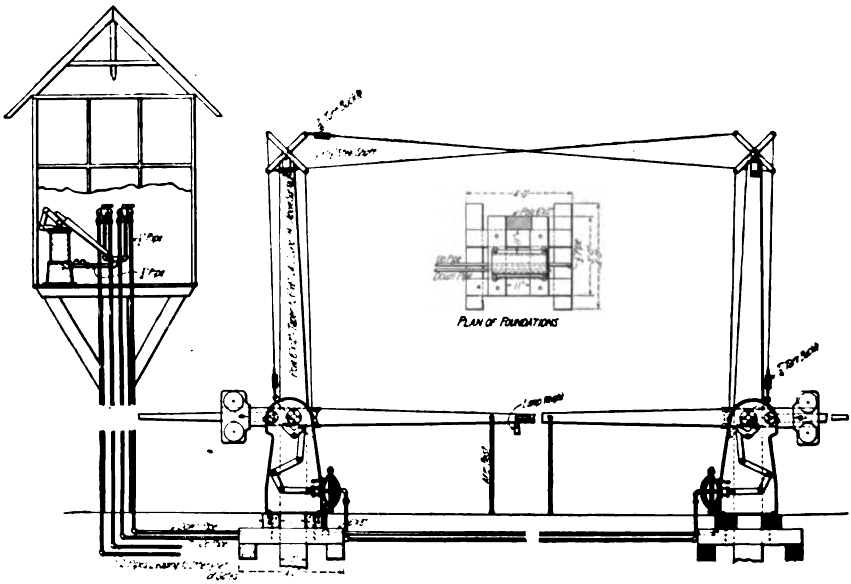

Fig. 528.—Bogue & Mills Pneumatic Railway Gate.

side. In the tower there is a cock and valves for each pair of gates which admit pressure to either side of the diaphragm and simultaneously open the other side to the outside air. In the case of the No. 2 gate, that is, where the arms protecting the roadway are double, being operated through posts from each side of the street, one of these posts has the function of lowering the arms and the other post the function of raising them. In the first instance, the air is applied on one side of the diaphragm in the down post, to lower the gates, and to raise them the air is applied to the diaphragm in the post on the opposite side of the street. The gates are worked at a pressure of 2 to 4 lbs. per sq. in., and in their down position they are locked fast. In operation it is desirable to have the two gates on opposite sides of the street move simultaneously, so as to come down together. The tendency, especially in windy weather, is for the gate nearest the tower, which receives the greater pressure, to respond more quickly than its mate, arriving at the down position while the arm on the opposite post is still at a considerable angle from the horizontal, or high enough to permit a team to pass under. To prevent this unequal action of the two arms with pneumatic gates it is necessary to have positive connection between the two. One plan is to use an underground rod connection, enclosed in a pipe with stuffing boxes at both ends to prevent the entrance of water to freeze and obstruct the operation. The installation of this arrangement necessarily requires tearing up the street, which, under a street paved with asphalt, brick or other carefully laid material, would be expensive. In order to avoid trouble of this kind the No. 5 gate of the Bogue & Mills system is designed for simultaneous operation of both arms by means of overhead wires, the operation of which is made clear in Fig. 528. Beside each gate post, there is a pole, usually 6x12 ins., tapered to 6x6 ins. at the top, the ordinary length being 24 ft., the pole standing 19 ft. above the surface; although the pole can be made of any length required to carry the tie wires above trolley or other wires. The pole is bolted to the foundation of the gate post. The overhead connection is by means of galvanized wires running from cross arms placed at the tops of the poles, with turnbuckles inserted for the purpose of adjustment. At streets of ordinary width this overhead connection is used to operate the arm on the far side of the street, the post supporting the same being "dead," so that no underground connection, requiring the pavement to be torn up, is necessary. At a wide street, however, where extremely long gate arms are required, the strain on the overhead wires is too great to operate the gate against hard winds, and in that case a "live" post is put in at the far side of the street, and pipe connections are laid, preferably between tracks, so as to avoid tearing up the pavement.

To give warning when gates are being lowered there is usually a bell on the gate arm, operated by a ratchet, and at much-traveled crossings a bell or gong is frequently placed on the tower. For use at street crossings where gates are located one or more blocks from the tower, or at one or more crossings where gates or flagmen are not required, but where it is nevertheless desirable to give a signal, the Bogue & Mills system includes a pneumatic or distant gong, which is operated by air pressure from the tower, connection being had by means of ⅜-in. pipe.

The foundation of a gate post usually consists of pieces of sawed ties halved together and buried in the ground so that the upper surface will come level with or a little lower than the sidewalk. In some cases, however, as where extra long arms are used, or where the hight at which the post must stand will not permit the foundation to be laid deep enough, an anchor tie is buried 3 or 4 ft. deep, with long bolts to secure the foundation. The principal trouble with gate operation is the freezing of the underground connections in winter. The difficulty arises from two sources —surface water and water of condensation. Surface water can be kept out by properly laying and connecting the pipes, or by substantial connections with the sewers in case the connections are run through conduits, without pipes. There is usually less trouble with pneumatic gates than with others in this respect, simply because the pipes must be made air tight or the gates will not work. The difficulty with water of condensation can be overcome by using pipes large enough to obtain a proper circulation of air. Authorities recommend nothing smaller than 1¼-in. pipe for wire or rod connections. To guard a gate post from wagon hubs where teams turn a corner, a piece of old rail may be planted for a fender, being set to lean toward the post, in position to keep the wheels at a safe distance.

It is practicable to operate all the gate arms at a crossing with a single lever or pump, but from the fact that it is frequently necessary to hold the gates open in front of a team while closing them behind to prevent other teams from coming on the crossing, the arrangement of operating the arms on each side of the track separately is preferable. With pneumatic gates there is one lever but a separate set of pipes and valves for each pair of gates. With lever gates there is a separate lever for each pair of gates. With the "Standard" gate it is arranged to lock both levers together whenever it is desired to operate all the arms simultaneously. This is done with the latch, and if independent movement is desired at any time the levers can be immediately released. To economize in expense of attendance crossing gates are sometimes operated from an interlocking tower in the vicinity, and the gates at two widely separated highway crossings are frequently operated from one position. The tower is sometimes located midway between the crossings, and sometimes at one of them. Either lever or pneumatic gates may be operated in this way, the distance from gates to tower being sometimes as far as 800 ft. Another idea in highway crossing protection that has been put in practice to some extent is the interlocking of two sets of gates, one set working across the street and the other across the railroad. Such an installation is particularly desirable where the steam railroad is crossed by a street railway, as then the protection of the crossing is in the hands of the railroad company. The gates are so interconnected that one set is always down while the other set is up, so that either the steam railroad or the street travel is blocked at all times. The prospect of being reported for tardiness in clearing the steam road for an approaching train should also be an incentive for the gateman to attend to the gates promptly. At crossings with street railways there should be derails or stop blocks in the street car tracks at a safe distance from the crossing and interlocked with the gates, for street cars have frequently been known to run into crossing gates and break them down.

It is not supposed that arm gates will absolutely stop travel over a crossing. They warn people that a train is about to pass, and this is supposed to be sufficient for the safety of the public and a reasonable fulfillment of the duty of the railroad company. Nevertheless accidents sometimes occur when the gates are down, for pedestrians are much in the habit of stooping under the arms and crossing the track in front of approaching trains. Danger of accident is greatest where there are yard tracks to cross or two or more tracks of any kind, for there are people who will thoughtlessly venture upon one of the tracks while a train is passing on another, and if a second train happens to be approaching, the sound of it is not liable to be distinctly heard. To a small extent gates are built to completely obstruct the street and sidewalks, breast high. At a number of crossings on the Long Island R. R., largely used by children going to and from school, screens are hung from ordinary gate arms to reach nearly to the ground. When the arms are raised these screens fold up out of the way. Hoisting gates on the portcullis idea are also used on a few railroads. Gates of this type on the Long Island R. R. consist of a light truss with $3\frac{1}{2}$x$4\frac{1}{2}$-in. chords (in four pieces), vertical bolts and $\frac{3}{4}$-in. iron pipe diagonals. The truss is 65 ft. 8 ins. long and 3 ft. 8 ins. high, and reaches within 12 ins. of the ground. It is carried by a braced bent (5x8-in. posts, with 3x6-in. braces) 10 ft. wide and 29 ft. high, over the sidewalk on each side of the street. At the top these bents are united by light trusses across the street and across the (two) tracks. The gate is counterbalanced and is hoisted by means of a shaft and pulley at the top of the bent, at each end. The gates on both sides of the track are operated from one crank, all the hoisting pulleys being turned by means of shafting and bevel gears.

185. High Speed.—High speed, which signifies higher speed, is a favorite topic for discussion at railway club meetings and in the daily newspapers, and of course the track comes in for its share of attention.

Properly considered, however, the question of increased speed, in a general sense, is more appropriately discussed by the financiers of railroads than by officials or employees concerned only with the operating or maintenance departments; for primarily the question of high speed is a financial one. Occasionally a writer will approach the subject with the apparent understanding that a problem is at hand the solution of which involves matters none other than the evolution of track construction and car equipment capable of accomplishing the end sought, when really the possibilities of train speeds depend a great deal more upon financial resources than upon mechanical or engineering achievements. It is no rash statement to say that as soon as people are willing to pay what it costs they can ride as fast as they please; at any rate, such will answer for the general statement of the case. In writing on this subject I lay no claims to gifts of prophecy, and there is no intention to suggest what might be the limiting speed of railway trains. It is certain that train speeds have for some years been increasing, but the increase has been gradual, and will likely continue so to be. The time is past when a speed of 60 miles per hour (while running) is considered wonderful or even noteworthy. Scheduled trains are making upwards of 50 miles per hour, average speed, including stops, over distances of several hundred miles. It is no uncommon event to attain an average speed of 80 miles per hour on a run of considerable length on some of our best roads, and higher speeds are recorded of test runs, at a spurt. For business purposes, however, it will be looking sufficiently far ahead during the early part of this century to consider schedule speed of 60 miles per hour, including stops, or a running speed of 80 miles per hour, as "high speed." Not until we actually get to carrying passengers over the country at that rate, on regular schedules, will it be timely to concern ourselves about average speeds of 80 and 100 miles per hour.

In the engineering field high speed is first of all a question of rolling stock, and secondly one of track. It would seem that a very important improvement of rolling stock would be some means to increase the effect of the brakes at high speed. A considerable increase of speed beyond present attainments in service, without a corresponding improvement of the braking equipment, would make it necessary to place signals farther from the danger point than is now required in standard practice. Improvement in braking apparatus for high speed would therefore work an economy in two ways. Another improvement in rolling stock which would conduce also to high-speed requirements would be an increase in the diameter of car wheels. Such increase, however, would set the car bodies higher, and unless the gage of the track was widened correspondingly, it would tend to make the cars top-heavy, and too responsive to rough surface in the track. Any proposition to change the gage, however, would be so revolutionary that it is not likely to be seriously considered, so that some sacrifices in other directions must be expected.

The improvements in track necessary to meet the requirements of high speed can be carried out on lines of practice already settled. In this field important conditions in any case must be smooth surface and alignment, which are merely questions of expense. Improvements which will involve change to the most extent will be the abolishment of grade crossings with highways, wherever practicable; the fencing of the right of way in more substantial manner than obtains in ordinary practice, and, in general, a more careful regard for conditions external to the track. High speed will mean the extensive installation of block signals, and interlocking apparatus at all grade crossings; the elimination of facing switches, as far as possible, and the interlocking of such switches with distant signals, where they must be retained; bridge floors should be solid and ballasted; and, drawing conclusions from the best results now attained, separate tracks for passenger and freight trains will be desirable, if not entirely essential. Still further, it is not to be overlooked that the tracks should receive close inspection at frequent intervals, which means that on at least some lines there would have to be a restoration of the track-walker. The limit of curvature for sustained high speeds will necessarily have to be small—down to 1 deg., say, for 80 miles per hour and somewhere in the neighborhood of ½ deg., and few curves at that, when we get to the point of preparing for speeds approximating 100 miles per hour. The curves will necessarily have to be elevated for the highest speed, which will require the spiraling of their ends. It will be desirable, although not entirely essential, to have unbroken rails at the turnouts, avoiding the use of frogs of the style now in ordinary service if a substitute can be found which will be safer for the main line, even though it may not answer so satisfactorily in every respect for train movements through the turnout. Some switch of the Wharton type is undoubtedly safer for main-line trains than the point switch.

During the fall of 1903 some unprecedented speeds were made on the Marienfelde-Zossen military line, in Germany, which aroused a world-wide sensation, and the particulars of the track construction and of the rolling stock are interesting in the present connection. The road was 14¼ miles long, nearly level and mostly straight, there being one curve of 52½ minutes (radius 6562 ft.) near one end. The track was laid with 84½-lb. rails, generally 39.37 ft. long, on fir ties, 18 to the rail length, with tie plates; 6-bolt angle-bar splices 31½ ins. long, with vertical flanges hanging 1½ ins. below base of rail, between joint ties, but some of the joints were of the lap type, as illustrated in Fig. 17, with a lap 9¼ ins. long. The ballast was broken stone. On 10½ miles of the line guard rails were laid inside the traffic rails, to a flangeway of 1.97 ins. These were ordinary T-rails laid on side, with the base (4⅛ ins. wide) presented for the service side of the guard, the upper edge coming 1¾ ins. above the top of the traction rail. They were supported upon cast iron chairs lag-screwed to the ties. With the exception of these guard rails on part of the line (which were found to be an unnecessary precaution), the track was, as thus to be seen, only of ordinary construction. There were two electric cars, one being used in each of the many experiments. Each car was 72 ft. long, mounted on two 6-wheel trucks, wheels 49.2 ins. diam.; wheel base of truck 16.4 ft. long; each truck equipped with two 250.-h. p. motors, on the outside axles, and air brakes, with brake shoes on both sides of all wheels; total weight of car 101½ tons. As the experiments continued the speeds were gradually increased until trips were made repeatedly at 105 to 110 miles per hour, or the whole distance each way in 8 minutes. The energy consumed in driving the car at such speeds was about 1600 horse power, and stops were made in 6560 ft. from the point where brakes were applied. On Oct. 23 one of the cars attained a speed of 128½ miles per hour, and on Oct. 28 the other car was run at the tremendous speed of 130½ miles per hour.

CHAPTER XII.

ORGANIZATION.

186.—In order to fully comprehend the relative importance of the track department in railroading it is essential that a just conception be formed of the magnitude of the railway industry in this country, the mileage of track, the cost of its construction and the annual expense of its maintenance. The total number of railroads (corporations) in the United States is between 2000 and 2100. As classified according to organization for operation, however, the total number of "operating" roads is a little upwards of 1000, of which about 800 are classed as "independent" roads and about 200 as "subsidiary" roads. The total length of railroad in the early part of 1904 was 210,000 miles, and this is being increased 3000 to 6000 miles each year. The total length of track, however, was about 289,000 miles, including, in round numbers, 17,000 miles of second, third and fourth tracks and 62,000 miles of yard tracks and side-tracks. For a proper investigation of the subject, however, it is necessary to fall back upon the latest available classified statistics, as contained in the report of the Interstate Commerce Commission for the year ending June 30, 1902. The total length of railroad on that date was 202,472 miles, and the total length of track 276,513 miles, which included 15,820 miles of second, third and fourth tracks and 58,221 miles of yard tracks and side-tracks. It is necessary to bear in mind, however, that the length of railroad covered by the reports made to the commission, and used as a basis for the statistics which follow, was 200,154 miles.

The total cost of building and equipping 187,442 miles of this railroad was 10,658 millions of dollars, of which amount the cost of road was 10,021 million dollars and the cost of equipment 637 million dollars. Complete balance-sheet statements were not obtained of all the mileage of road reported, but on the same basis the cost of the railroads in completed condition, with their equipments and other property, must have been not far from 11,500 million or 11½ billion dollars. From the official figures the cost of the road itself was $53,400 per mile of line, from which it might be inferred that the cost per mile of track was about $40,000, which includes, of course, the cost of roadbed and structures. The total operating expenses of the 200,154 miles of railroad reported for the year named was $1,116,248,000, of which amount the cost of maintaining track and structures was $248,381,000, and the cost of maintaining equipment, including all rolling stock and shops, $213,380,000. The cost of maintaining the track alone was $174,826,000; the cost of repairs and renewals of bridges and culverts, $28,888,000; the cost of repairing and renewing fences, road crossings, signs and cattle guards, $6,968,000; and the cost of repairing and renewing buildings and fixtures, $28,552,000. The total number of employees on all the railroads reported for the year named was 1,189,315, of whom 316,775 were trackmen, 35,700 being section foremen and 281,075 other trackmen; 227,442 were engaged as carpenters, machinists and other shopmen; 224,422 as trainmen; 9855 as general and other officers; 176,481 as general office clerks, station agents and other station men; and 233,360 as switchmen, flagmen, watchmen, telegraph operators and all other employees. It is thus seen that trackmen are by far the most numerous class of railway employees.

A review of the figures above quoted discloses the following facts: The cost of the track, roadbed and structures constitutes about 94 per cent of the entire cost of all railroad property. The expense of maintaining the track alone for the year 1902 was $874 per mile of line or about $644 per mile of track. Track maintenance costs about 15 per cent of all operating expenses of railways and is equaled by the maintenance expenses of but one other department—the expense of maintaining the equipment. The number of employees engaged in track maintenance constitutes 26.7 per cent, or more than one fourth, of the whole number of railway employees. The proper organization of the labor engaged in this department is therefore a matter of much consequence.

At the labor end the organization of employees for the work of the track department differs but little on the various railways throughout the country. On all roads the unit of organization is the section crew, which operates over, and looks after, a few miles of track, the responsible head being a section foreman or boss. Over each division or subdivision of 50 to 150 miles of road is placed an official generally known as "roadmaster," but in less numerous instances he is called a "supervisor." In exceptional cases the length of road in his charge may exceed or fall short of these limits. To this official all the section foremen are accountable, either directly, or indirectly through one or more assistant roadmasters or supervisors, the latter title being equivalent, on some roads, to that of assistant roadmaster on other roads. Thus far the arrangement may be considered pretty general throughout the United States. Likened to a military organization the roadmaster might be considered the lowest commissioned officer holding direct command—the captain, with his assistant roadmasters or supervisors as lieutenants. The section foreman would be a non-commissioned officer, and the crew the set of four.

It is in the arrangement of the positions above that of roadmaster that railroads differ in their organization of the track department. Logically considered, railway operation involves the maintenance of three separate and distinct lines of work, namely, that pertaining to roadbed, track and structures, or the fixed property of the company, properly termed engineering; that pertaining to rolling stock and the repair shops therefor, commonly recognized as the property in charge of the mechanical department; and that pertaining to the movement of trains and the handling of traffic, commonly understood as the work of the transportation department. The most common organization of the working forces of these three departments is what is known as the division system, the heads of the three departments reporting directly to the division superintendent, who reports to a general superintendent or general manager, so that in the distinct lines of work, as outlined, the separate departments are carried no higher than the division superintendent. This arrangement virtually makes the superintendent the general manager of his division. In this system it is usually the case that the responsibility of maintaining track and structures is divided between a roadmaster, for the track, and a master carpenter or superintendent of bridges and buildings, who has charge of structures. Quite frequently, however, the charge of both track and structures is combined with one official, who is called a supervisor of track and bridges, or is known by some other convenient title. Such doubling up of responsibility is more commonly the case on small roads or on roads where the bridge work is comparatively unimportant. On some roads where the signaling and interlocking work assumes importance there is a third division of responsibility in the maintenance-of-way department, whereby there is a signal engineer, or a foreman, supervisor or inspector of signals, reporting independently of the roadmaster or superintendent of bridges and buildings, to the division superintendent. In some cases, however, but less extensively than in former years, the maintenance of the signaling and interlocking equipments and their operation are in charge of the division roadmasters. On the Chicago & Eastern Illinois R. R. there is a foreman of signals, reporting to the superintendent of bridges and buildings.

On perhaps the majority of roads where the division system of organization is in force the name "engineering" is not associated with the maintenance of track and structures, as in that case the engineering department is usually limited, in its duties and responsibilities, to new construction of track, bridges and buildings, relocation, and work involving change of some sort, being represented on each division by an "assistant" or "division" or "resident" engineer, accountable to the division superintendent, perhaps in a nominal way, but reporting directly to the chief engineer, from whom he receives his instructions. Whatever duties he or the chief engineer may have in connection with the maintenance of the track are usually in a consulting capacity, and more frequently in relation to standard plans and specifications, surveys of the right of way, etc. The head of the mechanical department of the division is the master mechanic, but in this department, also, the responsibility is frequently divided between the master mechanic and a master car builder. The head of the transportation department of the division is the trainmaster, with his yardmaster, train dispatchers, etc.

Examples of roads on which the division system of organization is in force are so numerous that it is hardly necessary to designate, but the Chicago, Burlington & Quincy, the Atchison, Topeka & Santa Fe, the New York, New Haven & Hartford, the Erie, the Northern Pacific and the Wabash roads may be referred to. On the various roads where this system is in vogue the relative standing of the roadmaster is about the same, but the scope of his authority varies to some extent. Thus, for instance, on some roads, the roadmasters have an assistant engineer or surveyor, with a small party. On the New York, New Haven & Hartford R. R. the maintenance of track on each division is in charge of a roadmaster, the maintenance of bridges, turntables, coaling and water stations under a supervisor, and the maintenance of signals and interlocking under a signal engineer, all three of whom report to the division superintendent. The superintendent of buildings, however, who has charge of the carpenters, masons and painters, reports direct to the general manager.

Another distinct system of organization for railway operation is the department system, in which the three distinct lines of work, namely, the engineering, the work pertaining to rolling stock, and to transportation, are carried up separately to department officers reporting to the general superintendent or general manager. Thus, in the track department the division roadmaster may report to an engineer of maintenance of way, a general roadmaster or superintendent of tracks, who reports directly to the chief engineer, if the engineering department has charge of track maintenance, or to the general superintendent or general manager, where maintenance work and construction are in separate departments. Division master mechanics report to the superintendent of motive power, who reports to the general manager; and the division officer of transportation reports to the superintendent of transportation, who also reports to the general manager.

There are but comparatively few roads operated on the department system pure and simple. One of these is the Michigan Central R. R. On that road the chief engineer has full charge of both the construction the maintenance of all the fixed property, and the reports from beginning to end reach him by a direct process; that is, independently of any division officer outside of his own department. The division roadmasters report to division engineers, who report to the assistant chief engineer. Under the division roadmasters there are assistant roadmasters over sub-divisions of about 100 miles each. On each division there are masons, carpenters and painters reporting to the division foremen of buildings and water supply, who reports to the superintendent of buildings and water supply, who reports to the chief engineer. There are division foremen of bridges and assistant bridge engineers, reporting to the bridge engineer, who reports to the chief engineer. Inspectors of signals and interlocking report to the signal engineer, who reports direct to the chief engineer. The assistant chief engineer, who receives the reports of the division engineers and performs other work usually connected with that title, reports direct to the chief engineer. It is thus seen that immediately under the chief engineer there are four subordinate officers on apparently the same footing, namely, the bridge engineer, the superintendent of buildings and water supply, the signal engineer, and the assistant chief engineer, who are in direct charge of all the maintenance-of-way work and construction on the several divisions. The division superintendents have charge principally of train operation.

On the Lake Shore & Michigan Southern Ry. the engineering department has direct charge of the maintenance of way, the division roadmasters reporting to the principal assistant engineer (of the chief engineer's staff) independently of the division superintendents. Formerly the New York Central & Hudson River R. R. was another example of a road conducted on the department system, the engineering department having charge of all construction and maintenance of the fixed property. That organization, although changed, is still of interest in the present connection. On maintenance of way work on each division there was a supervisor of track, in charge of the track forces, wrecking gangs and steam shovel forces; a supervisor of bridges, in charge of iron men, masons, pile-driver crews, bridge carpenters and bridge painters; a supervisor of buildings, in charge of carpenters, painters, mechanical foremen, scale men, water supply and electrical mechanics, etc.; and a supervisor of signals, in charge of the signal maintenance forces. These officials, together with the assistant engineer, reported to the division engineer, who in turn reported through various staff officers, to the chief engineer. The heavy construction work was handled by the resident engineers on each division, reporting through the principal assistant engineers to the chief engineer. The chief engineer had on his staff certain assistant engineers who handled special work assigned to them from time to time, such as mechanical questions, bridge designs, track problems, etc. Besides the assistant chief engineer and the two principal assistant engineers there was an engineer of track, an engineer of signals, and an engineer of structures. The change which took place in 1903 was the appointment of an engineer of maintenance of way, reporting direct to the general superintendent. The duties of this office cover the execution of the standard plans and the charge of all current maintenance of track, bridges, buildings and signals, under the direction of the general superintendent. The office of engineer of track was abolished. The chief engineer prepares the standard plans and has charge of the construction work.

It has come to be quite largely the practice to place the maintenance of way work in charge of men of engineering training, with engineering titles, but in most cases the construction and maintenance branches of engineering are conducted separately and independently. Some roads whereon this is the case are organized on the division system pure and simple. Thus, on each division of the Ohio (grand) division of the Erie R. R. there is a track supervisor and a master carpenter, reporting to a division engineer, who reports to the division superintendent, who reports to the general superintendent, who reports to the general manager, who reports to the second vice-president on an equal footing with the chief engineer. The general superintendent is assisted by an "assistant chief engineer." On quite a number of roads where division engineers have immediate charge of the maintenance of way work there is nominally, at least, a maintenance of way department, under an engineer of maintenance of way, general roadmaster or superintendent of tracks, but usually the division principle of control prevails. That is, the line of authority passes through the division superintendent, in whom all the reports and business of the lower officials of the various departments are first drawn to a focus, and from whom the digest is dispersed to the various department officers above him. In other words, the reports of the division officer in each department reach the superior officer in that department second hand. In such cases the organization might be recognized as semi-departmental or as a combination of the division and department systems. On some roads the engineer of maintenance of way or general roadmaster is in authority, and receives the reports of the division superintendents respecting maintenance matters, while on other roads he acts only in an advisory capacity as an assistant to the general superintendent or the general manager. In the one case the departmental principle predominates and in the other the divisional principle. And again, some roads are organized on a compromise basis, part of the maintenance of way officers reporting to higher authority through the division superintendents and others reporting to the engineer of maintenance of way or to the chief engineer direct. The title of general roadmaster, by the way, is, on some roads, equivalent to that of chief engineer, and carries all the duties and authority of that office. Such is the case with the Florida East Coast Ry. and the Chicago & Western Indiana R. R.

On the Pennsylvania R. R. the chief engineer, who reports to the second vice-president, has general charge of the construction work, until it is completed, when it is turned over to the maintenance-of-way department, in charge of the general manager, who is assisted by the chief engineer of maintenance of way. On each division there are supervisors having charge of 25 miles of road, to whom the section foremen report. These supervisors and a master carpenter report to a division engineer, who is called an "assistant engineer," who reports to the division superintendent, who reports to the general superintendent (of the grand division), who is assisted by a "principal assistant engineer." The principal assistant engineer, on the staff of each general supt., and the chief engineer of maintenance of way, on the staff of the general manager, do not have direct personal control over the engineering forces of the road, but handle the maintenance of way department through their respective superior officers, who rely upon them to watch all the details and keep matters straight. The following extracts from the organization rules of the road show a little more in detail the duties of the heads of the two engineering departments: "The chief engineer shall, under the direction of the second vice-president, have charge of all engineering and construction work upon the railroads owned, operated or controlled by the company east of Pittsburg and Erie, and be responsible for the proper preparation of plans, specifications and estimates connected therewith; and also for the preparation of plans and specifications for all bridges and other important structures. He shall keep in his office a detailed record of the cost of all new work chargeable to construction account; prepare and certify to the correctness of the charges therefor, and forward to the proper officer for approval and payment the necessary bills and pay rolls. He shall keep an account and have charge of the distribution of steel rails for construction and renewals. He shall perform such other duties as may be assigned to him by the second vice-president, the president, or the board. . . . . The chief engineer of maintenance of way shall have general supervision of the maintenance of way department, and shall assist the general manager in all matters pertaining thereto and keep the general manager advised of the condition thereof. He shall be responsible for the preparation of maintenance of way plans, which, after approval by the general manager, shall become standard. He shall be aided by an engineer of maintenance of way. . . . The engineer of maintenance of way shall, under the direction of the chief engineer of maintenance of way and of the general manager, have direct charge and control of the maintenance of way department in so far as may be necessary to insure the efficiency of the department and adherence to the standards of the company. He shall prepare, for the approval of the chief engineer of maintenance of way and of the general manager, all maintenance of way plans. He shall furnish the principal assistant engineers with copies of all standard drawings, and shall give them such instructions as may be required to insure adherence thereto. He shall, with the approval of the chief engineer of maintenance of way, make such suggestions to the general superintendents as may promote the efficiency and economy of the service. It shall be his duty to thoroughly inspect in person all bridges and other structures, and make report thereon to the chief engineer of maintenance of way." The engineer of maintenance of way is assisted by an engineer of signals. On some of the grand divisions the principal assistant engineer is assisted by an assistant engineer; and on some of the divisions there are assistant supervisors.

The organization of the Pennsylvania Lines West of Pittsburg is similar to that of the "Lines East." The section foremen report to a supervisor, the supervisor to an "engineer of maintenance of way," the engineer of maintenance of way to the division superintendent, and the latter reports to the general superintendent of the grand division. On the staff of the general manager there is a "chief engineer of maintenance of way," who communicates with the general manager, the general superintendent and division superintendents in matters connected with the maintenance of way department. The chief engineer of maintenance of way is responsible for the preparation of maintenance of way plans and standards, subject to the approval of the general manager, and he has direct supervision of construction work on completed lines, preparing plans and estimates for the same.

On the Southern Pacific road the chief engineer, who reports to the president, has charge of construction and important changes, while on each grand division of the road, east and west of El Paso, Tex. (the Atlantic and Pacific systems), there is an engineer of maintenance of way reporting to the general manager of the Southern Pacific Co. in matters relating to standards, and to the manager of his "system" regarding other matters. The engineer of maintenance of way has charge of track, bridges, buildings, water supply, coaling stations, turntables, signals and interlocking. On the Atlantic system each superintendent has direct jurisdiction over the mechanical, maintenance of way, train and station service on divisions varying from 300 to 500 miles. He has general charge of the maintenance of his division, reporting to the engineer of maintenance of way in all matters relating to track, bridges, structures, water service and signals. He is assisted by a resident engineer, who has direct charge of these matters with the exception of signals. Each resident engineer is assisted by a number of roadmasters, depending upon the length of the division, and by a superintendent of bridges and buildings. The engineer of maintenance of way is assisted by an assistant engineer and by an assistant engineer of signals. On the Pacific system of the road the section, bridge, and building foremen report to roadmasters, who report to resident engineers, who report to division superintendents, who report to the engineer of maintenance of way regarding maintenance. The signal department is headed by a signal engineer, who reports to the engineer of maintenance of way.

With the Lehigh Valley R. R. there is on each division a supervisor (of track) and a master carpenter (or foreman of bridges and buildings), both reporting to a division engineer, who reports to the division superintendent, who in turn reports, on matters relating to maintenance, to the engineer of maintenance of way, who reports to the general superintendent. On this road the general superintendent has duties similar to those of a general manager on other roads. The chief engineer, who has charge of all construction work, bridge renewals, special heavy structural work and general engineering investigations, reports to the general superintendent. There is a bridge engineer reporting direct to the chief engineer, and a signal engineer reporting direct to the engineer of maintenance of way.

The organization of the Illinois Central R. R. is a combination of the division and department systems and is more complicated than any of the foregoing. The immediate assistants of the president are a vice-president, who has charge of the finances; a second vice-president, in charge of operation and traffic; a board of pensions, various officers constituting the legal department, and a secretary. The general manager receives the reports of the assistant general manager, general superintendent of transportation, assistant general superintendent, superintendent of telegraph, chief surgeon, chief claim agent and chief special agent. The assistant general manager receives the reports of the superintendent of machinery, chief engineer, consulting engineer and chief engineer of construction. The maintenance of way proper is in charge of the division superintendents, who receive the reports of the roadmasters, station agents, trainmasters and master mechanics, although the last named report on some matters direct to the superintendent of machinery. Road supervisors having charge of about 100 miles of track, supervisors of bridges and buildings having charge of the ordinary repairs of bridges and buildings, and waterworks foremen report to roadmasters of divisions 350 to 500 miles in length; and, as above stated, these roadmasters report to the division superintendents. North of the Ohio River the division superintendents report to the chief engineer in matters relating to construction and maintenance of way, to the superintendent of machinery on machinery matters and to the general manager in matters pertaining to transportation and other affairs; south of the Ohio river the division superintendents report to the same heads through an assistant general superintendent. It will be noticed that the position of supervisor on this road corresponds to that of roadmaster on most other roads, and the position of "roadmaster" to that of division engineer. On this road special bridge construction and renewal of bridges are in charge of the superintendent of bridges, and the special construction and renewal of large buildings in charge of a master carpenter, both of whom report to the engineer of bridges and buildings, who reports to the chief engineer. Signals and interlocking are in charge of a signal engineer, who reports direct to the chief engineer. Other officers reporting direct to the chief engineer are the architect, the general foreman of waterworks and the supervisor of scales. In some matters the master carpenter reports direct to the chief engineer instead of through the engineer of bridges and buildings.

The classification of systems of organization here presented covers practice only in a general way. The details of the various organizations in existence among the different roads are almost too numerous to admit of ready generalization. On some roads both the division and department systems are in vogue on the different grand divisions, while on others, as already seen, there is a combination of the two systems. On some roads there is a semblance of the department system where, for instance, the office of the general roadmaster is made an advisory one, the division roadmasters reporting to the division superintendents, who consult the general roadmaster regarding standard plans, methods, etc., but to whom they do not report the work and expenses of the department.

It is hardly worth while to inquire for reasons explaining the adoption of this or that system of conducting maintenance work. Probably the best explanation of the differences existing is that different men in official capacities have different views regarding ways of carrying on business. The fact that some general officers prefer to be in close touch with details, while others assume to select subordinates who are competent to shoulder such responsibility, explains a great many differences. Apparently there are good arguments for either the division or the department system, and there is evidence to show that either can be conducted economically and smoothly. There could therefore be but little profit in discussing the relative advantages or disadvantages of the various organizations in vogue. The important matter for consideration is that there shall be adequate responsibility for the safe running of the trains and for the economy of track maintenance; and that in placing this responsibility it should be equitably and consistently distributed among capable and reliable heads from the top to the bottom of the list. But such is an old song, and professedly is never departed from in making appointments; and so we arrive at the starting point. So far as track maintenance is concerned, it is my opinion that it matters but little how the higher offices are arranged or classified, so long as the man who is held responsible for each division or each hundred miles, more or less, of the road, is reliable, understands his business, and is so supported that he can carry it out—be he called roadmaster, division engineer, supervisor or what not. The ball starts rolling with the section foremen. Unless the roadmaster (or equivalent officer) be competent to select good foremen he cannot hope to succeed, and no number of wise men in the higher positions—either division superintendents or engineers—can make amends for deficiencies in the office of roadmaster. On the other hand a competent roadmaster can do good work whether the officials over him are competent in his line or not, providing he is not interfered with. If at this juncture a suggestion should follow I might venture to say that over the head of the roadmaster there should be but few officials in direct authority—one might almost say the fewer the better, because his position is one of great responsibility and his relations with the chief of his department should be as direct as may be possible, considering the size of the road. For the successful conduct of track maintenance the roadmaster must be a man who can be depended upon, but to interpose a multiplicity of routine processes between him and the source of issue is to encumber his work, discount his judgment and subordinate his position. More than upon any one else the responsibility for the physical condition of the track falls upon the roadmaster. He must judge of the fitness of men to take charge of sections of the property, to look after it and to direct the labor to be done upon it, and he must be responsible for the discipline of these forces.

187. The Roadmaster.—The roadmaster is referred to so many times in connection with various kinds of regular and emergency work and supervision that a list of all his duties in detail is hardly necessary in this place. In a general way, however, we may look at some methods for the government of his work. The greater portion of a roadmaster's time should not be spent in the office—he should be an inspector rather than a bookkeeper. While he should keep well enough posted on the important statistics relating to his track to have the run of things, the clerical force of his office should be sufficient for routine matters and so well instructed that he need give to such affairs only a general supervision. The roadmaster should manage to escape the bondage of office routine. No executive officer can exercise the best of his ability if the most of his time is consumed in clerical duties of a recurring nature. Neither should he make himself too conspicuous for his presence at the rear end of the passenger trains. The manner in which the foremen and men on some roads watch the movements of "the big boss" has become proverbial. The trackmen meeting from different sections seldom pass the time of day without referring to the time and place when the roadmaster was last seen. It is customary to either enquire or report whether he is "up the line" or "down the line;" and should he ride past without their knowledge, or fail to appear on certain days, there is then all sorts of speculation as to what is going to happen. While with the right kind of men the habits of the roadmaster in his calls should be of little or no concern, yet where there are some of the "watchful" kind it is wholesome practice for the roadmaster to make visits at any and all times, unannounced and unexpected.

On the principle above stated roadmasters should spend a large part of their time at inspection of the track and in personal contact with the section crews. Maintenance of way officials should lay stress upon daily, rather than annual, inspection of track. The roadmaster who gets nothing more than a glance at things occasionally, as he rides by on the trains, will, upon closer inspection at the end of the year, or even after but a few weeks, usually find many things which should have received his attention long before. He should have accurate knowledge of the state of affairs at all times, and this can be had only by frequent inspection. The many forms of hand and machine-propelled inspection cars make it convenient for the roadmaster to do this. It is wasteful of a good deal of time to encourage section foremen in the habit of hanging around or working near stations purposely to get a chance to talk with the roadmaster while the train is stopping. In such cases it usually happens that the foreman gets about half the information he wants by the time the train starts, and then the conversation is cut short. Information regarding the work at any point is best given or received on the ground; hence the importance to the roadmaster of traveling independently of the trains. It is also a good plan to do a good deal of walking, especially in the summer time. It is well enough to make use of the hand car and section crew, or part of the crew, when time is limited and it is desired to reach some certain point, but for a close observation of things the best opportunity is to be had by walking. It is important for roadmasters to frequently investigate the wear of material, and to discuss the same with their foremen, and this can best be done by walking over at least parts of the sections where there is occasion for making observations. The best method of inspecting a section with the foreman is to walk over the track with him alone. In this way there is time for discussing matters as they come to view, and opportunity for correcting the foreman in any mistakes or wrong methods, at a time when he will not be embarrassed by the presence of his crew. It works harm to correct a foreman within the hearing of his men. Even a slight disapproval of his work subjects him to chagrin and tends to lessen the respect which the men have for his authority. At times, when it is found that the work is not being done satisfactorily, some roadmasters will go so far as to take the work out of the foreman's hands and issue orders to the men direct. For the sake of discipline such practice should be avoided, as far as possible, for, if occasion requires, better results can usually be had by calling the foreman aside and instructing him privily.

Many railways require their roadmasters to make close inspection of their divisions at least once each month, and some roads require it oftener. The rules of the Southern Pacific Co. require the roadmasters to "pass over the entire straight portion of their districts, either on foot or on velocipede cars, at least twice every month, and over that portion in canyons and in the mountains at least three times per month." This method of getting over the work is the most thorough, and instructions can be issued to the foremen on the ground more satisfactorily than by hastily written notes ("butterflies," the trackmen call them) flung from the rear of trains. On such visits the roadmaster should be in no hurry, but spend considerable time with each crew, so that he may observe and criticise methods of work. This is an important matter, and an attempt should be made to secure uniformity of the best methods of work among all the crews. In this way the roadmaster can get acquainted with the men, and they will come to know and understand him. By keeping his office informed as to his intended movements and making himself accessible to telegraph stations as far as possible, he can spend two or three days at a time out on the road. He should get so well acquainted along the track that he will feel at home wherever night overtakes him. The interests of any railroad company may be materially advanced by the larger personal acquaintance of some of its well disposed officers with the residents along the line. By suitable preparation for the unexpected, and proper understanding at headquarters, a roadmaster, even if out on the road when emergencies occur, can almost always handle things satisfactorily. While there is a work train engaged the roadmaster should aim to get around to it two or three times per week, or perhaps oftener, if the importance of the work so demands. To observe line and surface to every advantage he should occasionally make a trip over his division on the locomotive of a fast passenger train. At wrecks his presence is generally required.

The roadmaster must handle his men with decision and firmness, yet with a kind of firmness which conveys no impression of obstinacy. He should be capable of gentleness, where such treatment answers best. He must be prepared to meet emergencies promptly and effectively and without hesitation. His relations with his men must be such that they will respect not only his intelligence and his experience, but also his disposition and his character. He should be an accurate and thorough observer, unhesitating in correcting neglect and other defects in his foremen. He must be able to look ahead and plan his work and aspire to keep abreast of his work, and not let the work do the pushing. Roadmasters should not fall into the habit of giving specific orders to foremen every time it becomes necessary to take up routine work, such as tie renewals, cutting grass and weeds, mowing, cutting brush, etc. New foremen should be instructed concerning the proper season for the various kinds of ordinary track work, but the old foremen should be given to understand that such work must be taken up at about the proper time without specific orders. The care of looking closely after all such matters throws too much work upon the roadmaster and virtually relieves the foremen of that much responsibility for the condition of things under their charge. In case it is observed that a foreman has failed to do such work as might have been expected of him, it is more conducive to discipline to require from him an explanation than to forthwith order him to do it. The section foreman's position necessarily carries with it a good deal of responsibility, and this is the main thing to be impressed upon the foreman's mind. It cannot be done, however, if the roadmaster assumes to direct the ordinary work of the section.

The office work should be in charge of a clerk who has a liking for the work and to whom all routine matters can be left. He should be something more than a bookkeeper—a sort of private secretary, say, who understands so well the plans of his chief that he can answer the bulk of the correspondence on his own responsibility, leaving for the roadmaster's approval only such matters as require executive discretion. He should acquaint himself thoroughly with the track, especially concerning the physical characteristics along each section, and he should get acquainted with the men. In order to do this he should be given opportunity to make occasional trips out over the road, preferably in company with the roadmaster. The position is no mean one, for the services of a good clerk are invaluable to a roadmaster, and some discrimination is necessary in selecting a man with the qualifications necessary to fill it. A trackman possessing at least a common school education should be sought.

A roadmaster having charge of 100 miles or more of double track will usually need one or two assistants. Such assistant, sometimes known as assistant roadmaster and sometimes as supervisor, should be a man in whom the roadmaster can place entire confidence, and whom he can entrust to act in his own capacity when sent to look after special work, or who can act for him on his (the assistant's) own judgment if present where exigency demands decisive action without delay. One of such men will usually be needed around the work train most of the time, and, on many roads the assistant to the roadmaster is given charge of the work train. As a rule it is best not to have much authority come between the section foremen and the roadmaster, except where, as is the practice on some roads, supervisors, under the roadmaster, or under the official corresponding to roadmaster, are given regular charge of portions of the division. Of course special occasions will arise when circumstances will prevent misunderstanding, and it is in such particular lines that the assistant can be most useful, rather than by trying to oversee those ordinary affairs where even slight differences in judgment between him and the roadmaster are confusing to foremen. If, however, owing to a division of too great length, the need of an assistant consists in the multitude of regular track duties, rather than in lines of special work, it is well to set off a portion of the division to the assistant and give him full control as far as direct supervision is concerned. This plan works better than that by which two men conjointly try to supervise the whole division as to details; because the ordinary duties are of such nature as not to require a division of the supervisory authority. Where part of the division is in this way put under an assistant, the roadmaster may find in it such relief that while looking after the whole, yet paying special attention to the other end, he may be able to get along with one assistant.

The qualifications for the position of roadmaster are considered at some length under the heading "The Training of Roadmasters," § 206, Supplementary Notes.

188. Section Foremen.—The section foreman is employed to look after the safety of a piece of track of certain length and, with the help of a crew, to maintain it in good condition. He should therefore be reliable, honest, competent, and intelligent. No man, however able, should be placed in a position of trust or be allowed to retain it who cannot be relied upon. Some men are unreliable out of indifference or neglect, while others are so because they are dishonest; but as far as there is any dependence there can be no choice between the two. Much property is placed in the hands of the foremen, and the condition of the track and the economy of its maintenance rest largely upon their ability and judgment, but no less important to the same ends is integrity of character. In order to be reliable a man must be willing, or he may not be strong enough to carry out his professed motives. His first duty, above others, is to at all times satisfy himself that his track is safe for the passage of trains and, in case of doubt, to use all possible means to ascertain its condition and make it safe. This implies that he must be willing to go at all hours and in all kinds of weather to threatened points on his section whenever, in his most reasonable judgment, he thinks he might be needed there.

In order to be competent the foreman must necessarily have had considerable experience as a track laborer, and to have become so skillful at it that he is able to instruct others. The criterion by which some would judge of a man's fitness to take charge of a section would be his ability to lay a turnout or "switch," as trackmen usually call it. Somehow there seems to exist with trackmen pretty generally a sort of strange fancy that, connected with "putting in a switch," there is some hidden secret or trick of the trade, so to speak, which, if once discovered or mastered, opens up to one all the supposed arts of the trackman's craft, or about all there is concerning track that is worth knowing. It is hardly necessary to comment upon ill-conceived notions of this character. Suffice it to say that while some good trackmen who have never had opportunity for doing such work might be a little slow at the first turnout attempted, yet no man could be considered anything of a trackman who could not choose a fair location for a turnout and oversee the laying of it properly. And there are, too, some railroad surveyors who will fuss around the location of a turnout for a spur track as though it must be placed with mathematical precision, instead of proceeding with a view to choose favorable ground and place the headblock or frog with such relation to the joints as will reduce rail cutting to a minimum. And they will also set stakes for the curve of the turnout between headblock and frog, when a frog table gives all the necessary measurements for locating the different parts of the turnout and for properly curving the lead rail. Competent track foremen do not waste time on such matters. It is but stating what every experienced trackman knows, to say that there are scores of instances where foremen are called upon to use more judgment than is ordinarily required when laying frogs and switches. It is needless to attempt to give, even in a general way, an enumeration of the things in track work which a foreman should have knowledge of. The entire treatment of section work in the foregoing chapters relates only to practical details which foremen should know about. A fair amount of knowledge is essential, but proper judgment, which must be used with it, can come only from experience. Knowledge alone, in the sense of mere information, is not always a safe guide, for a certain amount of that can sometimes be picked up in a short time without learning the uses to which it may be put.

As for his intelligence or education, it goes without saying that every foreman should be able to express fairly well his thoughts in writing and to be able also to perform the fundamental calculations of arithmetic; but alas, how many are the instances where foremen are unable to measure up to these simple qualifications! Some can neither write nor cipher, nor read plain language understandingly, and must consequently seek assistance from the station agent or from some of their men; while others are so poor at ciphering that many a time book goes in filled out evenly opposite all the names, or with a full mark under each date worked, purposely to avoid multiplying fractions or picking them out of the table of wages, usually placed in the back of the time book. There are many people (and not all trackmen, either) able to read, to whom tabulated information is practically as difficult as hieroglyphics. Certainly, roadmasters are to blame for appointing such men to position.

Before any man is appointed foreman he should succeed in passing a thorough oral examination covering the principal duties he is to assume and the ordinary work of the section. Stress should be laid upon ascertaining his knowledge of the use of signals, and his judgment as to just what ought to be done in certain cases of emergency, such as broken rails, slides, washouts, etc. He should also, as part of his examination, be required to make out reports and fill out and make up a time book, from a given diary or memorandum of the daily work of a section crew for a month.

The best plan to follow in selecting section foremen is to look for promising men among the most competent track hands in the different crews, giving preference always to the men oldest in point of service. By consulting the old time books or pay rolls on file at the headquarters the roadmaster can ascertain who are the oldest men in the service without making his purpose known. These men should be specially sought out by the roadmaster, who should for a time observe closely their work and movements, with a view to determine in his own judgment the ability and fitness of each, before inquiring of his foreman. It frequently happens that an old and well deserving track laborer is purposely withheld from promotion out of jealousy or prejudice on the part of his foreman, or from a desire on the part of the latter to aid certain other of his friends. And then, too, some foremen are very cautious about allowing any opportunities for apprenticeship under them or of imparting information to their men, while other foremen have not the ability so to do. The roadmaster should, therefore, investigate for his own benefit and to his own satisfaction, and endeavor to fill vacancies by drawing from the rank and file in preference to hiring outsiders or men from another division.

A good way for the roadmaster to ascertain the qualifications of men as foremen is to have an apprentice crew work as a floating gang, under an expert foreman who is known to be a good and impartial judge of men, and whose disposition and characteristics are worthy of imitation. Such a floating gang is usually needed on most roads and the variety of work to which it is assigned furnishes an excellent school for prospective foremen. The aim of the foreman of this gang should be to hold up to the men a high standard of duty. He should constantly impress upon their minds the importance of economizing time and material and the necessity for thorough work and careful inspection. They should be required to familiarize themselves with the rules of the track department and the various adopted standards for roadbed sections, ditches, frog and switch construction, switch layouts, curve elevation, etc.; and they should, of course, acquire readiness in construction and repair work about switches and frogs. Wherever opportunity arises for comparison of different methods or standards of work the foreman should discuss with the men the advantages and the defects observable. When surfacing or lining track the men should be allowed to take their turn at sighting the rail, and they should have instruction and practice in making reports. This can be arranged by permitting each man to attend to the foreman's reports a month at a time. In time, therefore, good opportunity is afforded to observe the disposition and willingness of the individual men to learn to work for the company's interests. Into this crew the roadmaster may call those men whom he considers suitable candidates or those old hands who desire to make application. After working some time a man's fitness will show itself and, as new foremen are needed, men can be drawn from this crew in turn and given examination with a view to advancement, but some may have to be rejected without examination.

In order to test a candidate's ability for handling men he can be sent to take the place of some regular foreman who is absent on account of sickness or other cause, or he can be put in charge of a gang to do some special work, if necessity arises. In such ways as this there is opportunity to work the man in gradually and ascertain his qualifications. This plan places the roadmaster on an independent footing, for whenever it becomes necessary to make a change for the good of the service or when vacancies occur he has satisfactory men to put in charge. If the situation is otherwise he may often hesitate to make needed changes, out of fear that available substitutes may not do any better, or in cases of emergency he may be obliged to appoint men of doubtful qualifications. Incompetency that is not discovered until after a permanent appointment has been made often results in costly mistakes, and such failures have a demoralizing effect upon the service.

The system of recruiting foremen from among the section laborers stimulates the ambitious young men and puts a premium on faithful and efficient service. Inducement is then held out to those progressively inclined, and the company is able to retain a better class of labor than otherwise, so that the system is productive of good results in more ways than that of securing a desirable class of men for foremen. The system of training foremen in apprentice gangs is in force on a number of roads, and the results are generally satisfactory. For sake of example reference may be made to the Oregon Short Line R. R. On this road there is a training gang on each roadmaster's division, most of them being located at division terminals. The men for each of these gangs are employed by the roadmaster of the division, who selects young men seeking to make track work their occupation. A foreman of more than ordinary ability and intelligence is selected for the gang and the men are paid ordinary track laborer's wages. The roadmaster puts in a good deal of his spare time with these men. They are instructed in track surfacing and lining, laying switches and turnouts and in general track repairs. They are also taken out to assist at wrecks, washouts, etc., and in this way get a good general knowledge of all kinds of track work. A high official of this road has stated that some of the best foremen in the service have been trained in this way.

Another plan that is followed a good deal is to pick out the best man in each section crew and make him track-walker, and then when a foreman is needed promote him from the grade of track-walker. There is reason to doubt whether this plan is as satisfactory as that of the training gang, for the position of track-walker removes the man from active participation in track work, and he remains all the time on the "same old section." In the training gang the man has opportunity to see more kinds of work done than he is liable to find on any one section, and he sees the same kind of work done under a variety of conditions. He also comes in contact with a good many trackmen and gets in touch with their ideas, and the tendencies of such an experience are broadening. It is also to be remarked that there are many men well qualified in every way for track-walkers who have no capacity for handling a crew of laborers.

The importance of selecting good foremen cannot be overestimated. Aside from the roadmaster's own fitness it is the keynote of his success. The test of executive talent in any official is his ability to secure and retain the services of capable and willing men as his subordinates. This for the simple reason that good subordinates, when properly organized, can keep things moving. Many can doubtless call to mind what excellent reputations some men have built up for themselves on the skill and brains of other men, simply by dint of their executive ability, and nothing else; whereas other men of far greater resources and abilities, without competent subordinates, or by distrusting their subordinates, have tried to accomplish too much by their own efforts and have failed. In order to secure men of judgment for his subordinates an official, particularly when taking a new position, must sometimes resort to the weeding-out process. And then, again, any one is liable to be mistaken, at times, in judging of men, and some have not the moral courage to afterwards right the matter even though they see the mistake. It is an unpleasant duty to have to discharge a man for incompetency alone, especially if one is dealing with a man of character or with an old acquaintance; yet such must be done, at times, if an official is to do right by his position. The man least troubled in this respect is undoubtedly he who makes it an unvarying rule not to appoint intimate personal friends to position. Relevant to the same subject is another matter which should not escape attention, and that is the influence of race prejudice in the appointment of men to responsible positions. The policy which makes nationality the basis of eligibility in filling positions, particularly in a country like this, is short-sighted and weak. It is destructive of good feeling and it is bound to lower the standard of fitness for position. It is detrimental to discipline and gives to the favored class a certain conceit of themselves which is not promotive of industry. About the least one can say of any man who follows such a policy is that he is too narrow-minded to properly discharge the duties of roadmaster.

Foremen should be given authority to hire and discharge men. No man should be discharged, however, except for cause, or when forces have to be reduced. In the latter case it is customary, of course, to retain the oldest employees. A roadmaster should not be too willing to investigate every complaint coming from discharged men, still it is but fair that he should give earnest attention to those complaints when coming from old employees. A foreman should always be sure of his position when discharging an old employee for any cause, and if so, any fair-minded roadmaster will stand by him, and he need not fear investigation. A roadmaster cannot very well afford to override the authority of the foreman in such matters, or compel him to retain men in his employ whom he does not like: it is easier to discharge the foreman, when it comes to that. Another way out of a difficulty of this kind, if the roadmaster is satisfied with the merits of the "distasteful" employee's case, is to find opportunity to promote him.

In order to get along well with employees it is necessary to make careful discrimination in the selection of them. One discontented, refractory man will often spoil the discipline of a whole gang. The only thing to do with such men is to promptly discharge them. As soon as a foreman finds that a man is incompetent, unwilling or disposed to stir up mischief he is compromising matters by retaining him longer in service. If a man has worked in the same place a long while it is presumable that he is a worthy employee, and the foreman who discharges him necessarily places himself on the defensive. A foreman should not be upheld in discharging men because they refuse to board with him or because of any wrangling springing out of that or any other personal matter. Complaints of this nature will sometimes bear close investigation. It is certainly to a company's interest to know whether the chief business of any of its foremen is that of running the section or running a boarding house. In the same connection, foremen should not be permitted to use the services of their men as wood choppers, berry pickers, gardeners, or at other personal work, on the company's time. Neither should foremen be expected to present the roadmaster with turkeys each Thanksgiving or Christmas, or with a mess of fish occasionally. It is usually the case that such "offerings" are fully compensated for in one way or another, and by accepting such things the roadmaster places himself in a compromising attitude toward a strict enforcement of discipline.

The rules of most companies require that the foremen shall "engage in the work, personally," but it is well understood that they cannot always do this and at the same time properly oversee the work of their men. The question is sometimes raised, therefore, as to whether or not foremen generally should be expected to do manual labor with their men. This depends largely upon the amount of oversight necessary; upon the size of the crew, to some extent; upon the skill of the laborers; and upon the character of the work. In a large crew the presence of an overseer is always necessary. Human nature is so constituted that men gathered together in large bodies, for any purpose, lose more or less their sense of individual responsibility. Under these circumstances it is expedient that employees should have continually before them visible evidence that this weakness in humanity is known to the employer. The business of the foreman, then, while not actually engaged in giving directions, should be to stand around where he can see and be seen. But in small crews this is not so, necessarily, and a foreman should, in order to be profitable to his company, make it a rule to keep himself employed at something most of the time when not directing others. He need not necessarily be expected to fill the place of a laborer, at all times, but to at least do something which helps along the work in some way. There is always a certain amount of tinkering or work at odd ends to be done in order that all the men be kept at work with reasonable steadiness. In a small crew such things should usually be looked after by the foreman. One might inquire as to what number of men would in this connection, be considered a large crew, and what number a small one. This is one of those questions where it is difficult to draw a line, and one can hope only to offer suggestions; for very certainly no strict rule can be laid down. In a general way, a crew of less than six, besides the foreman, might be considered small, and one of more than eight, a large one. Between these two limits, it might be left for the foreman to debate in his own mind as to whether he should exert himself little or much. The rules of some roads require that foremen having fewer than five or six men must engage in work personally. It often happens that in work where men engage in pairs, such as tamping, spiking, tie renewals, and much other section work, the foreman can pair himself with the odd man, in case there be such, to good advantage. In many cases, therefore, roadmasters make it an aim, when reducing the forces, or when assigning the number of men allowed to each section, where the crews are small, to make the number exclusive of the foreman an odd number, like three or five, so as to give the foreman this opportunity of employing himself.

As is elsewhere stated in several connections, one of the most important duties of a section foreman is inspection, and this includes bridges and trestles as well as roadbed, or track on terra firma. He should carefully observe the surface and alignment of track on bridge floors, and the condition of the track fastenings in such places; the condition of bank sills and other end construction, the action of water around foundations; and, in fact, every condition which affects the safety of trains or the smoothness of riding thereof. To this end he should be required to ride over the track on the engine of a passenger train once in about every three months, going over several sections, so as to be able to compare his own section with the others. This gives a good opportunity to observe the condition of the curves with respect to elevation, and sometimes there are "soft places" under the track in such short stretches that the track springs back to surface as soon as it is relieved of pressure from the traffic. These are known as "blind sags," and the yielding character of the material is not apparent except while a train is passing. The engine will find all such places, if they exist, and when the foreman is aboard he should take note of the vicinity of each and afterward make it a point to be there while trains are passing, so as to discover the exact location. One remedy for a case of this kind is to raise the track up out of surface sufficiently to allow for the excess amount of yielding at the place. But if the cause is not plainly in view it is well to dig down and find it. In some instances a "hard place," like a log lying in a fill, just under sub-grade and diagonally to the center line, or a rock under one side of the track, has been found to be the cause of disturbance, without any sign of uneven surface in the rails when trains were not passing the spot.

Foremen should be encouraged in taking a lively interest in their work and in making an economical showing in the expense of keeping up their sections. They need, however, in some cases, to be taught the ill economy of temporarily keeping down expense by ordering insufficient amounts of material for repairs; allowing tools to go too long without repairing; failure to provide proper watchmen, on needed occasions; and possibly in some other short-sighted plans. Foremen should cultivate watchfulness, and the habit of observing things closely. In order to keep up with the times they should be regular readers of periodical railroad literature. There is no responsible position on railroads wherein the occupant is not better fitted for his duties by study and thinking. And then the better educated a man is, so much the better ought to be his control over the men working under his charge.

In the way of educational advancement a few roadmasters have adopted the commendable practice of calling their foremen together at regular intervals, once each year, or oftener, usually in the winter time, when work is not pressing, for a general discussion on track questions. The meetings are conducted in a manner somewhat similar to the procedure of the annual meetings of some of the railway associations. For example, the roadmaster acts as the presiding officer, and some weeks before the meeting he selects certain questions for discussion and sends a request to each foreman to be prepared to attend the meeting and discuss these questions.

At the meeting the foremen are permitted to conduct the proceedings pretty much in their own way, being free to give their experience and to criticise the methods of work and other matters brought out in course of the discussion. The results accomplished where such meetings are held regularly are said to be decidedly beneficial. In the exchange of ideas the foremen learn of new methods in practice and the meetings seem to stimulate a friendly rivalry which raises the importance of the work in the estimation of the foremen. It also conduces toward a uniformity in methods of work on the different sections represented. A supervisor on one of the large railway systems of the country, who introduced the practice of calling yearly meetings of his section foremen, has stated that such meetings were greatly enjoyed by himself and were found to be extremely interesting. He relates that the discussions were entered into with spirit and that progressive tendencies were readily traceable. He claims to have been much benefited on his own part, for in listening to the proceedings he was enabled to pick up many advanced ideas on the work of track maintenance. Mr. I. O. Walker, while roadmaster with the Paducah, Tennessee & Alabama R. R. (now part of the Nashville, Chattanooga & St. Louis Ry.), followed the practice of calling his foremen together four times each year. Other roads have various arrangements for the same purpose.

On the Chicago & Council Bluffs division (in Illinois) of the Chicago, Milwaukee & St. Paul Ry. there is a section foremen's debating society, organized in 1893 by Mr. Edward Laas, while roadmaster of that division. All the foremen of the division, to the number of 34, are members of the society, which has a constitution and by-laws, with officers elected yearly. The object is to meet and discuss questions pertaining to track and track work. All of the affairs of the society are conducted in a business-like manner. The meetings are held on Sunday, every two months, at Elgin, Ill., in a rented hall, in the business part of the city. Each meeting consists of two sessions, held during the forenoon and the afternoon. The meetings are conducted in parliamentary form. The proceedings usually consist in the reading of papers on methods and devices pertaining to track work, and in the reception and discussion of committee reports. Preparatory to these meetings the roadmaster usually suggests a subject or subjects to be taken up for discussion. The roadmaster is usually present, and occasionally takes part in the meetings, but the foremen are supposed to feel free to express their opinions and judgment on all questions brought before the meeting.

One of the results of these meetings is that the foremen are stimulated to think and study their work, and from such experience they are enabled to discuss track questions in an intelligent manner. Another important result has been that diversified methods of doing certain kinds of work have given way to standards adopted after careful and thorough investigations. On the other hand, by taking account of the conditions existing on different parts of the division, explanations are found for variations of practice in certain cases, where, without looking into the matter thoroughly, the various methods might not seem to accord with the best practice for the case. The fact that section foremen are at all times upon the ground and thus able to observe conditions and results in minute detail should make them authorities on a great many track questions. The periodical meetings of the society afford them the opportunity of analyzing the results and forming conclusions on methods of work and the efficiency of devices, which, without doubt, are valuable suggestions to the roadmaster and the purchasing agent.

The division superintendents of the Philadelphia & Reading Ry.

have in practice what are called "schools of instruction on the book of rules." In 1900 a committee composed of superintendents, division engineers and supervisors prepared a set of rules for the maintenance-of-way department. In connection with these rules there are illustrations, showing standards, and instructions concerning the use of material in work covered by the illustrations. After the rules had been published in book form the company inaugurated meetings on each division, at which section foremen and one or two of the more intelligent men from each section are required to be in attendance. Instruction is given by the supervisors and other competent instructors. At these meetings it is the endeavor to ascertain how each individual understands certain rules taken up for consideration, and his practice in connection with the same, the idea being, of course, to have all come to a uniform understanding of the rules and to hold discussion on all matters about which there can be any question. In this way the officers give the foremen such instructions as their talk would indicate to be necessary, and explain to them effectively any points that may come up in the meeting. These meetings are held at occasional intervals, and the discussions cover not only the rules laid down in the book but methods of doing work in general, the aim being to illustrate or exemplify the principles underlying the practice followed. The meetings have resulted in more uniform practice and a more strict adherence to standards.

Having been a section foreman, myself, I cannot resist the temptation to criticise certain defects and odious practices that are more or less widely tolerated or winked at by higher authority. It is my observation that some foremen are better qualified for the management of a large crew than a small one, for with the small crew they quite overdo the matter of overseeing. A small crew engaged at ordinary section work, especially if it be made up of experienced hands, ought not to call for the continual exercise of the foreman's vocal powers. Nevertheless there are many foremen, often well disposed men, too, who seem to take it for granted that every workman needs a certain amount of instruction each day, notwithstanding that the man may be quite familiar with what he is doing. And so instead of leaving competent men alone, and trying to make themselves of some use by their own efforts, as they should, they stand around fretting and actually hindering the work. Manual labor is not nearly so tiresome to endure as is the habitual fault-finding, irritating lingo of some peevish foreman; for when a man's mind gets tired he feels tired all over. Men working under such oversight will, in time, grow hesitant, lose interest in the work, and strive to do nothing more than to in some way meet the fancy of the "boss," or else to relieve their minds occasionally by provoking him all they dare. It is only telling the plain truth to say that hard taskmasters are not exceptional among track foremen. There are men in charge of English-speaking track crews in this country who fall a long way short of being gentlemen. Some foremen in giving directions to their men make habitual use of profane and violent language, repeating their tirades occasionally for the sake of emphasis. Judging from the language used, some track foremen seem to act on the proposition that the men are mules and themselves the drivers. Reference is not here intended to words occasionally spoken in anger, but to the every-day abuse which some foremen heap upon laboring men, who, under certain circumstances, perhaps, must endure it. Of course, such treatment of men can be regarded only as an indication of shameful ignorance combined with a little authority. Out of lack of confidence in themselves such foremen usually stand in continual dread of losing their positions, and they feel like keeping every one around them in the same stress of mind.

Although such demeanor cannot be charged as typical of track foremen as a class, it is nevertheless too largely followed in practice to be overlooked in any general treatment of track labor. It is hardly necessary to add that roadmasters ought not to allow such things to go on. No men working under such foremanship can take a lively interest in the work, and the result is damaging to the company from a dollars-and-cents point of view, even if there be no concern for the inhumanity.

189. Section Labor.—It is a commonly accepted notion that track work is essentially and necessarily the most ordinary type of labor—and such, indeed, some of it is. It is a great mistake, however, to regard all, or even the larger part, of track work, especially section work, as mere "puddling in dirt." The prevalence of the notion referred to may no doubt be explained on the fact that the occupation of the trackman is too frequently thought of in connection with the class of men who may chance to be following it in some certain locality, or class of localities, as in and around the large cities, for example. Taking the whole country into consideration, it is to be admitted that track labor is not up to the standard it maintained years ago. By this it is intended to say that throughout the country there are to-day fewer expert trackmen in proportion to railway mileage than there were, say, twenty years ago. One reason for this state of affairs is that of late years the country has been overcrowded with an ignorant, unskilled foreign element eager to work for a lower rate of wages than English-speaking laborers and their families could well subsist upon. As the result the low rate of wages paid has bid for nothing better than common labor, and but few who could get any other employment would seek labor at track maintenance or remain at it; and hence almost any man possessing an abundance of "main strength and awkwardness" has too frequently been acceptable.

Such is certainly a wrong state of affairs, for, notwithstanding that it seems to be the policy of railway companies to pay track labor no more than the lowest rate that is paid for labor anywhere, there is nevertheless in the occupation of the trackman as much scope for the exercise of skill and intelligent manipulation as will be found in that of the ordinary mechanic. An expert trackman is a skilled laborer, a tradesman—fully as much so as is a carpenter, a smith or a mason. Men cannot become expert at all kinds of track labor in a few months. A good, bright man would do well if he gained the necessary experience in two years. In order to acquire a good knowledge of things in that length of time he would have to have more than an ordinary opportunity, and at all times be prompt and willing to learn. As a rule young men do best at track labor, but unfortunately for the railway companies they do not offer enough inducement to always hold those who are most capable. In manufacturing districts, where better wages are usually paid for other labor, but few take pride in the work, and most of those who remain at it do so from force of circumstances, not being able to do, or not caring to do, more than to in some manner hold a job. In short, it seems that railway companies have failed to raise track labor, generally, up to the average efficiency which is certainly possible for it, if indeed such labor has not, as above declared, actually deteriorated.

The same aptitude for the work and the same qualities of character as were recommended in the case of the section foreman are of course desirable in the section laborer, although it could not be expected that their application would obtain so largely in practice, for in many instances it is a question of getting men of any kind or none. Nevertheless, as far as may be practicable, men should be sought who have a fair amount of intelligence, who are reliable, willing to learn and to do, and, of course, men who are physically able. Foremen should attempt to teach men all they can when the men first begin. Men are always more willing to learn at that time, and, besides, it should early be ascertained whether or not the man is going to make a success. It is a mistake to permit a man to work long without ascertaining what he can or will do. Special stress should be laid upon the proper use of tools; the way to handle the various tools; and the posture of the body which enables a free and easy use of any particular tool. Foremen should endeavor to explain the reason why such and such things are thus and so, and the object to be aimed at in any given kind of work, thus appealing to the man's intelligence.

But willing men cannot always make good trackmen. A man must have some aptitude for the work. If I was to name any one qualification which, above all others, is essential to skillful workmanship in this line I would call it *genius for matters of adjustment*; that is, the ability to see just what relation the different parts of any structure hold to one another, so that one may know just where and how to go to work on one part in order to put the whole into proper order or condition. I can refer to some examples which may set forth, more clearly, perhaps, just what I mean. Take, as an instance, the matter of lip at a stub switch. Now some men would see right away whether the lip was caused by a wrong setting of the stand, or by lost motion; and whether that lost motion was between head rod and rail, or between head rod and connecting rod, or between connecting rod and crank pin, or, whether it might not be due to loose or worn parts in the stand itself; or whether the gage of the moving rails corresponded to that of the lead rails; or whether the cause might not be due to a combination of two or more of such defects. But some men would never in all their lives be able to locate the trouble, and would therefore not know where to put in a key or what to change in order to right the difficulty. As other illustrations to the same point, take the lining of curved track; the proper point at which to place the lifting power in raising a low rail; how to pull spikes with a claw bar; how to most easily and rapidly put on a splice; how to secure the proper hold in lifting with a pinch bar, etc.

Good men cannot be retained on the section unless they can have steady employment. This means that, although it is usually necessary or advisable to reduce the section forces for the winter below the allowance for the summer, when most kinds of track work can be done to best advantage, it does not pay to lay off the entire crew, even if but temporarily, or to put all of the men retained on part time. There should always be retained a nucleus of from two to four men working steadily the year round. It is certainly to be doubted whether in the end anything is gained by laying off the entire section force during the winter season. Good men will not remain at employment where they are much needed during the hot weather only to be laid off or put on half time during the winter. The result of the prevalent system of working track employees is that the oldest (in service) and most capable men are constantly drifting into other kinds of employment, so that every spring the foremen must break in new men, whose work in general will not compare either in quality or quantity with the work of experienced track laborers. One of the drawbacks in securing and holding skilled labor on track is the uncertainty of steady employment. In an address before the Eastern Maintenance of Way Association, in 1900 (on "Skill in Track Maintenance"), I made the following comment on this phase of the situation:

"It is largely the practice, as winter comes on, each season, to either discharge trackmen or lay them off, or put them on short time, to reduce expenses. This practice causes the men to thoughtfully 'reflect on their summer's earnings', and the most industrious among them will look elsewhere for steady employment. The higher officials give their orders to have the men laid off and when spring comes the roadmasters and section foremen must procure and hold their labor the best way they can. In many cases a much better arrangement would be possible, even where retrenchment becomes necessary. For instance, roadmasters might be permitted to distribute the labor among the seasons in their own way, with a view to furnish steady employment to a goodly number of the oldest and most skillful section laborers. In very many cases this could be done, without sacrificing anything in economy, by postponing certain kinds of work until the winter season. The subject is worth a good deal of study, and in any case an improvement of the situation will call for some readjustment of the usual plans of doing work."

Water Boys.—In hot weather men should have plenty of good water to drink, if it can be had. Ice water is poor stuff for men who are not used to it, having a nauseating effect on those who are working and sweating; besides it does not quench thirst as well as does cool spring or well water. To protect laboring men against ill effects from drinking too freely of water while perspiring it is quite generally the practice to mix oatmeal or rolled oats with the water. When this is done the water vessel should be emptied and thoroughly cleansed each evening, as the oatmeal will sour over night. The drinking cup should also be scalded or scoured out, for obvious reasons. Where the supply of water along the section is not plentiful it is usually necessary to take a half or a full day's supply on the hand car. By carrying quite a large quantity in a keg or large jug wrapped in a wet blanket or covering it may be kept cool several hours. But where good water is in sight men always want it, and ought to have it. Where there are as many as six men in the crew it requires a good part of one man's time to supply the rest with water, if it must be carried some distance, and in such case it pays to employ a water boy with each crew, during the summer time or during hot weather. Such boys are usually paid about two thirds of a man's wages. When not occupied busily enough at carrying water he can be useful at running errands, looking after tools, and many kinds of light work, to keep him out of mischief.

190. Watchmen.—Track watchmen comprise track-walkers, crossing flagmen and gatemen, and special watchmen detailed to watch portions of the track liable to be endangered by slides, falling rocks, washouts, forest fires, etc. These men usually report to the section foremen. Track-walkers are regular watchmen employed to patrol the track, and on some of the busiest roads such watchmen are constantly in service both day and night. The usual practice is to walk over the track, following the freight trains in time to clear the track as far as possible ahead of the passenger trains. Thus a passenger riding from New York to Buffalo, say, on a through train, may quite likely be preceded all the way by watchmen on foot, each getting over his beat a few moments before the train arrives.

An ordinary day's work for a track-walker is to walk from 16 to 20 miles, making two round trips over a 4 or 5-mile section or beat. To do the walking alone usually requires altogether about six or seven hours, depending somewhat upon the way the track is filled in. He is required, however, to be out on the track, or near by it, a full day of ten hours, but not necessarily busy the whole time. The day track-walker is supposed to carry at least one tool of some kind. Part of the time it may be a light steel wrench, for tightening loose bolts; or a light hammer, referred to in the chapter on tools, for replacing broken spikes or driving down spikes which have worked up, or, with the pick end of the same, to clean out dirt or ice packed into the flangeways at highway crossings and behind guard rails. Sometimes he may carry a shovel, to drain puddles of water in the ditches. During snow storms he should carry a broom to sweep snow from point switches and spring-rail frogs. The day track-walker fills and cleans the switch lamps along his beat, except in yards where they may be too numerous. In winter time he lights the lamps and puts them up before dark, and takes them down after daylight in the morning. In the summer time, however, it is the duty of the night track-walker to put up and take down the lamps. Ashes dumped at water tanks on main line are usually cleared away promptly by both the day and the night track-walkers.

The track-walker should keep his eyes more or less on the rails ahead of him, and watch for spread spikes on curves. Spikes are most liable to spread in wet weather, when the ties are softened, and in winter when the ground is frozen and the ties are held rigidly in their beds. It is at such times that the curves are most liable to give trouble. In winter time he should watch the shims closely, replacing any which have worked out of place. He should take special notice of each frog, guard rail, switch, switch stand and connection therewith, and try the switch lock, to see if it is fast. In hot weather it is important to watch closely the moving rails of stub switches and report them when they run tight. The replacing of broken frog bolts and light repairs of this character may be attended to by the track-walkers. When telegraph wires are found down the track-walker should try to get at least one wire connected through; if not, he should call upon the nearest assistance he can get, after which he should report the break to a telegraph office or to his foreman, giving an account of the condition of the wires, poles, etc. He must see that cars left on side-tracks are fully clear of the main track; that derailing switches in side-tracks are properly set and locked; that doors of loaded box cars are locked or sealed, if not in charge of an attendant; that farm gates or other private openings upon the right of way are kept closed, and stock kept off the right of way; and put out fires which may get started on or near the right of way. Wooden bridges and trestles should be closely inspected for fire. When going off duty in the morning the night watchman should notify the foreman of delayed trains which have not passed.

The principal duty of a track-walker is, of course, to inspect the track. He is given only such other small duties as cannot well be attended to by the section crew, and is not supposed to do general track work, such as cutting grass, raising joints, etc. Indeed the man who walks 20 miles has plenty to do at that alone. Where there are numerous minor duties, 20 miles is too much, and the beat should be shortened. In any case the track-walker should not be burdened with duties too numerous to distract his attention from the real object of his position—that of carefully inspecting the track. If his time is too largely occupied with various other matters he is compelled to hurry over the track in order to make the end of his beat on time, and cannot therefore be expected to observe everything carefully. The night watchman is not supposed to carry track tools except, as above pointed out, a broom, during snow storms. A tubular kerosene lantern gives better light on still nights than a railroad lantern, but not on windy nights; neither is it so safe against blowing out. Some place a guard, consisting of a band of leather, around the lantern covering the open space at the top of the globe. This will keep it from being blown out in the wind, still in a heavy wind it will flicker badly and show poor light. It is therefore better to carry a railroad lantern on windy nights. The best way to light a lantern or switch lamp in windy weather, without means to shield it from the wind, is through the top, if the top can be taken off or swung back. For this purpose a piece of soft copper wire of small size, 6 or 8 ins. long, is a very convenient device for holding the match, if the opening is not large enough to admit the hand. It may be twined around the lantern frame or doubled up and carried in the pocket, and to hold the match the wire is wrapped around it a few turns.

Both day and night track-walkers should carry a watch, train schedule, red flag and torpedoes. A pocket rule or tape line should also be carried to measure the length of rail in case one is found broken. In lieu of such the rail may be measured as so many lengths of a stick of any convenient length. If the track-walker patrols past a telegraph office he should keep himself informed on the running of the trains, so that in case of any irregularity in the same he may arrange his trips according to the time they will arrive on or pass over his beat. After a watchman on single track has gone over his beat it is, under ordinary circumstances, useless for him to start back until a train has passed over it after him, and he should therefore wait. It is necessary, then, to have a cabin or shanty at each end of the beat, furnished with a stove, for a man cannot be expected to stand out of doors and wait during all kinds of weather. The same protection should be (and usually is) afforded watchmen at slides, or wherever the man is compelled to remain in one place for a considerable length of time.

On double track, track-walkers travel as much as possible facing the trains. They should make it an unvarying rule never to walk or stand on one track while a train is passing on the other track or is moving near by. Unless they are as prompt as clockwork about this they are liable to forget, some time, and meet with an accident. A track-walker should always observe closely every train which passes, the signals carried on the engine, and whether or not it is on time and, if not, how much late. Whenever he discovers a train parted, a car or truck derailed, or a dragging brake beam, he should by some means try to draw the attention of those in the caboose and signal them to stop. He can sometimes make himself very useful in this way.

Being under the section foreman's orders the track-walker is considered part of the section crew. His position is considered a promotion above that of section laborer and, as he usually works Sundays, he makes better pay. On account of the greater responsibility attached to his work he ought to be paid 10 per cent., or some such amount, more per day than the common track laborer. A track-walker should be a man who can be trusted. He ought to be a good trackman, temperate, and thoroughly reliable in every way. Without a knowledge of track and track work he may not, under some circumstances be able to properly judge of the safety of the track. He should be thoroughly acquainted with train signals—hand, flag, lantern, torpedo, and whistle signals. It is usual to keep the same man or the same two men steadily at watching, but sometimes a foreman will allow the section hands oldest in service to take it by periods in turn. It is a good plan to have the day and night track-walkers change about every month. Track-walkers find it easier on the feet to wear shoes having very thick soles.

Before sending out a watchman or track-walker the foreman should satisfy himself that the man will be competent to act properly in case anything is found wrong with the track. There are cases on record where watchmen, upon finding danger, have become so excited as to run several miles to get the foreman, taking no thought about holding the trains. When finding a dangerous place in the track, which he cannot repair, a watchman should stand by and see that no trains run onto it unawares. It is the duty of the trainmen to stop and call out the foreman if they are going that way. Of course it might happen that on double track the watchman could reach the foreman by going against the trains which use the track on which the danger lies. There have been instances where a watchman on single track, when trains were late, has found danger at such a time as not to know from which direction or how soon the first train would come. In such a contingency it might not always be possible to avoid trouble, especially if the danger be found on a curve, in a cut, and a heavy wind be blowing at the time. It would be unwise to attempt to get torpedoes out very far in either direction, and one might make a mistake in trying to get them out at all. Under such a consideration about the only thing to do would be to stand at the danger point until some indication of an approaching train is perceived, and then to get out in that direction as fast and as far as possible. One could quite likely get far enough to stop a passenger train in time. In a contingency of this kind at night a fusee would come handy. On single track it is never sure protection to put signals out in only one direction. Of course the first thing to do is to put out the stop torpedo signal the proper distance toward the first train due. A good rule to follow is to then run back to the danger point and, leaving a red flag (if by day) or red lantern (if at night) in the track get a stop torpedo signal out in the other direction a safe distance. Then run back to the danger point and go a little distance out toward the first train due, but not out of sight of the danger point after a train is due. As soon as a train is known to be coming near, get out toward it as far as possible.

With a good system of track inspection the chances are mostly in favor of the discovery of slides, washouts, burnt bridges, broken rails and other dangers in time to stop the trains. Nevertheless railway companies have been gradually falling away from the practice of employing regular track-walkers. One reason for this is that the length of road subject to trouble from slides, water or fire is comparatively short, and danger is most threatening when the weather conditions are unusual, at which times special watchmen are detailed to look after the track. Another reason is that broken rails are not so common as was the case 25 years ago. When iron rails were in use it was not an uncommon occurrence for a section foreman to find as many as three or four broken rails in the same day during very cold weather, and in those days it was the practice on some roads to give an extra day's pay for each broken rail found, to the trackman who first discovered it. Since stronger and better rails have come into use the tendency has been to dispense with regular track-walkers, except where conditions are unusual or during the coldest weather.

Another consideration is the cost. The expense of employing regular watchmen, or men to patrol the track constantly, is very considerable, amounting to about $90 per mile per year for one watchman during the 24 hours—that is, for either a day watchman or a night watchman—figured on the basis of a five-mile beat and wages at $1.25 per day. On most roads where the traffic is light it is simply out of the question to incur this expense except at places where, or at times when, danger is threatening. It must, of course, be understood that the number of trains running is one of the factors which have to do with the condition of the track respecting safety, for there are many ways in which a dangerous condition in the track may develop under traffic from a defect which is small at the beginning. Against trouble which arises in this manner an occasional trip over the track on some roads would afford the same measure of protection as regular trips at more frequent intervals over the track on a road carrying a correspondingly larger number of trains. As the amount of traffic under consideration in this connection increases it may be a matter of some difficulty to decide as to just when the need of regular track-walkers justifies the expense. It is one of those cases where a certain course is always known to be the safer, yet where the probability of accident due to not taking the precaution seems to be exceedingly small. There is no such thing as absolute safety at any expenditure. On roads where the traffic is light, and the rails of good weight and quality it may not be necessary to get over the track every day during summer, when the weather is fair; and if the section crews are small it is certainly not convenient to do so. It would seem, however, that all track should be inspected at least two or three times per week, at all seasons of the year. If obstruction or danger is liable to arise from conditions exterior to the track, such as sliding earth or rocks, fire or flood, that is, of course, a different matter.

Where regular track-walkers are not employed it is commonly the case that the section foreman or one of his trusty men is required to walk over the section, or ride over it on the hand car, at least once each day. In order to economize time it is sometimes arranged to have this man return by train and work the remainder of the day with the crew. On some of the long sections in the West the watchman is sent over the track on a velocipede, especially where he has to follow the trains and watch wooden bridges. On the Boston & Albany R. R. the foreman or one of his competent men is required to walk over the section in both directions every day in summer, and in both directions twice every day in winter. There are no night track-walkers except in stormy or rainy weather, when, as a rule, at least two men patrol each section at all times day and night. On the New York Central & Hudson River R. R. regular day track-walkers are in service throughout the year, the length of beat varying from two to five miles, according to the number of tracks. On sections where the conditions are unusual, such as track having a large percentage of curvature, track in dangerous rock cuts, tunnels etc., special watchmen are employed both day and night, their beats being usually limited to one half mile or one mile. They are required to patrol the track at stated intervals, usually just ahead of the schedule time of fast passenger trains. In some instances registering clocks are placed at each end of the beats, particularly for checking up night watchmen. On the main lines of the Pennsylvania road both day and night track-walkers are employed. On the Nashville, Chattanooga & St. Louis Ry. day track-walkers are employed during all seasons. The sections are from 6 to 12 miles in length, and the usual duties of the track-walker are to get over half of the section each day, tightening all loose bolts, carefully inspecting the track and taking note of all places that need attention. And so on it will be found that some railway companies follow the old practice of employing men to patrol the track regularly both day and night at all seasons, while others have cut this service down to that performed by day track-walkers only; others employ regular watchmen only during the winter season; while on the large majority of roads only such watchmen are employed as may be necessary to cover once each day that part of the section which has not been seen by the foreman. On some roads, even where regular watchmen are employed, the foremen are required to get over their sections at least once or twice each week.

Careful inspection of the track should be the principal duty impressed upon the mind of the section foreman. Nevertheless, it is often the tendency, during certain portions of the year, to reduce the amount of time devoted to inspection to the lowest possible limit which appears to be consistent with safety. Thus it sometimes happens that when hard pressed with important work, such as tie renewing or reballasting the track, a section foreman is inclined, during good weather, to keep his force at work as steadily as possible, sometimes sending a man to patrol the track each day, but quite frequently not. And so it comes to pass that, unknown to the foreman, the bolts in some frog may be breaking, one by one, while at some other point on his section cattle or other stock may be making a pasture field of the company's right of way, with now and then an animal killed. As a general proposition it is desirable that the section foreman should personally inspect his whole section each day or send a trusty man to do it. Under ordinary circumstances the results of careful track inspection do not always show plainly, since, as a rule, it is only when inspection is neglected for a considerable time that the results of such negligence are seen. For instance, the spreading of rails on curves usually takes place slowly, and if attended to when the spikes first begin to spread the difficulty is remedied before matters reach the danger point. The foreman who neglects inspection for a considerable length of time will frequently find conditions which could hardly obtain under a more frequent inspection, when tendency to disarrangement of parts is nipped in the bud, so to speak.

During very stormy or windy weather or at times of sudden thaws, especially at night time, when the track is liable to be flooded or washed out, or during extremely cold weather, the force of track-walkers is customarily doubled. During excessively hot days it is also necessary to watch the track carefully, particularly on very sharp curves, as trouble not unfrequently arises from the expansion of the rails. At dangerous cuts or sliding banks, and at streams which threaten to undermine the track, watchmen should be stationed to remain at one point or in the same vicinity. On sections where the switches are widely scattered it requires a considerable portion of a day's work for one man to walk over the track and light the switch lamps in the evening. On some roads where the track-walker makes only one trip each day he goes in the afternoon, in time to clean and light any switch lamps that may be distant from the foreman's headquarters. Men who attend to this work are frequently permitted to use a velocipede or light hand car. On double track it is safer to run such cars in opposition to the direction of the trains, as then the rider does not sit with his back to the danger (except where it is the practice to move some of the trains against the current of the traffic).

The necessity for night track-walkers depends, of course, upon the number of night trains running, particularly the number of fast trains; and so far as concerns the same measure of protection to trains the need of night track-walkers is more urgent than for day track-walkers, because in daytime the section men pass over some portion of the track; and then there is the greater probability that obstructions or defects in the track can be seen by the engineer in time to prevent trouble. In warm weather cattle, hogs and other stock are liable to break into the right of way for feed or to escape insects in the bushes, and sometimes they are found lying down or asleep on road crossings—in which event they are almost sure to derail a train if struck. In some cases where only one track-walker can be afforded during the 24 hours it would conduce better to safety to dispense with day track-walkers and have the track patrolled at night, while in other cases the arrival of the fastest trains on certain sections might make it advisable to have the track-walker employ half his time during the day and the other half during the night, arranging his trips to best protect the fastest trains.

Crossing Watchmen and Switchmen.—Crossing flagmen and gatemen and switch tenders are required to learn the schedule of the trains, the code of signals and the instructions in the book of rules and regulations regarding their position. On some roads they are examined every three years for hearing, strength of vision and for perception of color. Gatemen and flagmen are provided with red and white flags and lanterns, torpedoes and a train schedule. They use the white signals to prevent persons and teams from crossing when trains are approaching. The red signals are intended for use only when it is necessary to stop trains. Flagmen and gatemen are required to know the exact time when each regular train is due at the point where they are stationed, take particular notice of signals carried by the trains and be on the alert for irregular trains. They must prevent cattle and other stock from loitering near the crossing and prevent people from walking or driving over the track when a train is approaching, taking the same precautions for the passage of hand cars and gasoline cars as for trains. At crossings where the view along the track is obstructed the man on duty should be warned of approaching trains by automatic signal.

Some judgment is necessary in the time allowed for closing the gates or clearing the crossing while trains are approaching. Gatemen must be careful not to lower the gates upon persons or teams passing under, particular attention in this being required at night and while crowds are passing. The proper station for a flagman while trains are approaching and passing is in the middle of the street, at the side of the track, where he can be effective in stopping people who may attempt to drive across. Gatemen are required to keep the gates closed until the entire train has passed the crossing, and in case of double track they must not open them until they are sure that no other train is approaching from the opposite direction. After the passage of vehicles the crossing should be carefully observed, to see that the rails are not obstructed. In case the crossing becomes obstructed by a fallen horse, a broken wagon, a street car or by any other object not quickly removable, danger signals must be promptly displayed at a safe distance. At crossings where the street travel is slack during parts of the day the flagman or gateman is required to keep the flangeways clear. Defective crossing plank should be reported to the section foreman without delay.

On some roads the switchmen or switch tenders report to the roadmaster, and on others to the superintendent, but in yards it is usual for them to report to the yardmaster. It is the duty of switchmen to operate the switches under their charge, for the trains, and be responsible for their safe working. This requires careful inspection of the parts and frequent observation of the switch while trains are passing. In winter time they must keep the switches under their charge clear of snow, and at all times promptly report defects which they cannot repair. They have signals to display by day and by night, and as soon as the switch has been used, each time, they must set it for main line and see that the switch signal gives the proper indication. Where both day and night switchmen or watchmen are employed at the same point one is not permitted to leave the post until relieved by the other man. None but a total abstainer from liquor should be employed as a switchman or a crossing watchman, and these men should not be permitted to entertain loafers and other unauthorized persons in the watch house or vicinity thereof.

Bridge Watchmen.—Watchmen stationed at wooden bridges are required to walk over the structure immediately before each train is due, and in time to stop the train should anything be found wrong. On such trips they must always have danger signals ready for use in case of necessity. They are usually required to observe carefully the condition of the rails and fastenings and to pass several hundred feet beyond the ends of the bridge, to examine the track for broken rails and other defects. They must see that the water barrels are kept filled and that the means for handling water in putting out fires are maintained in good condition and always ready for use. After the passage of a train or engine the watchman is supposed to walk over the bridge and make careful examination of the floor and timbers for fires started, or to quench live sparks. In some cases they are required to carry a pail of water. The rules of some roads also require them to observe the ash-pan dampers of engines and report them when they are left open.

191. Length of Section.—The proper length of section on any road is a matter of importance and requires some study. On single-track roads the length varies from 4 to 10 miles, and on double-track, three-track and four-track roads from 2½ to 5 miles, being 2½ miles on most of the four-track roads. The proper length depends upon many conditions. The volume of traffic, the weight of rail, the quality of the ties, the kind of ballast, the number of switches; the condition in which the track is expected to be maintained; the condition of the track with respect to local elements of danger, such as slides, falling rocks, troublesome streams, and the clearing of land adjoining the right of way—all these have to do with the proper length of section. From a labor standpoint 3 miles of double track is considered the equivalent of about 5 miles of single track, conditions being the same in either case, and 5 miles of double track to about 8 miles of single track.

An all-the-year average of one man per mile of single main track or 1½ men per mile of double track, that is working force, exclusive of foremen and watchmen, is a general allowance supposed to be sufficient to keep in good condition a well-used track in gravel or equivalent ballast. The actual force allowed, however, is often regulated to correspond rudely to the earnings of the road, and in perhaps the majority of cases the general excellence of the track is determined upon that basis. A number of busy roads get along with ¾ man per mile, and some manage to reduce the allowance even further. Under ordinary conditions it is not profitable to keep the force constant in number at all seasons of the year, but to reduce it somewhat during the winter and increase it during the summer, when tie renewals, weeds, grass and low joints all seem to need attention at the same time. Five men for eight months of the year and two or three men for the other four months, exclusive of the foreman, is an ordinary allowance for 5-mile sections on single track.

It is not always a simple matter to compare the section labor of one road with that of another, even where the natural conditions appear to be the same, because some roads spend large sums of money to put the roadbed, track and right of way up to a high standard, after which it should be expected that maintenance expense can be reduced to a low figure. To illustrate difference of expense in relation to conditions of maintenance, consider that A., B. & C. Ry. is laid with heavy rails, tie plates, ties of long life, ballast of good quality and of good depth; that the roadbed has everywhere been constructed to a standard section, with wide shoulders on embankments and wide ditches through cuts, with surface ditches above the cuts; that the right of way has been completely fenced, snow fences constructed, etc. Now suppose that X., Y. & Z. Ry. is carrying traffic of equal volume and of the same class, and is required to be maintained in the same condition respecting surface and alignment, but is laid with lighter rails, on ties of shorter life, without tie plates; the ballast is dirty or of inferior quality, and insufficient in quantity; the roadbed is narrow on embankments and the cuts have never been widened to permit sufficient ditch room, and each season the section crews must put in several weeks extending the right of way fences. It is easy to see that the work of maintenance on this road is an entirely different proposition from that of the A., B. & C. Ry.

The number of men required for a section also depends a good deal upon the assistance which the section crew is supposed to render station agents, telegraph linemen, bridge and building foremen, tie inspectors, car repair men, surveying parties, fence crews, landscape gardeners and other of the company's servants; on many roads the men in charge of these various kinds of work are supposed to look to the section crews for help. The labor is, of course, charged up to the proper account, but, for a usual thing, it all comes out of what is generally supposed to be the allowance for the track. Again, some roads get along with small section crews because the heavy work, such as relaying rails, constructing turnouts and side-tracks, reballasting, raising sags, extensive ditching, handling material, fence construction, and frequently tie renewals, is all done by extra gangs. Some treatment of this plan of work is contained in the next section (§ 192).

According to the reports of the Interstate Commerce Commission the average number of section foremen per 100 miles of line has remained almost constant at 17 since the year 1890; and in 1902 each 100 miles of line represented, on the average, about 136½ miles of track, including second, third and fourth tracks and side-tracks. The number of trackmen per 100 miles of line, exclusive of foremen, averaged 105 during the same period (1890 to 1902 inc.), the largest being 140, in 1902, and the smallest 85, in 1894, since which time there has been a gradual increase. These figures do not, however, give a close estimate of the average length of section and the men employed thereon, because the number of foremen and laborers employed on yard tracks is not stated.

On poor roads, where the expenditure on the track must be reduced to the smallest possible figure, the sections are lengthened out in order that the force allowed may be collected into larger and more effective crews, instead of being scattered along in crews of two or three men in a place. The number of foremen needed is thus reduced and more than a proportionate number of laborers can be added by the saving so made. Up to 8 miles the advisability of this plan is certainly good, where the conditions demand it; and where the track does not, for various reasons, need an extra amount of watching, the length may even be made 10 miles; and such it is on numerous roads. The length of section ought not to exceed 10 miles where the regular daily trains exceed four in number, for that distance is about all one man can make a round trip over in a day on foot. But it is difficult and perhaps useless to lay down rules in such cases; for a road which can hardly keep running must do the best it can, for the time being, anything more than ordinary safety and convenience being necessarily secondary matters, seeming good policy to the contrary notwithstanding. Expediency rather than precept must be followed. On prosperous roads handling a fair amount of traffic, 5 miles is perhaps the most satisfactory length for single-track sections, and 4 miles for double-track sections, not taking switches or side-tracks into account. It is quite generally considered that the care and labor of attending to 12 or 15 switches is equivalent to that of attending to a mile of single track. On this point the Eastern Maintenance of Way Association has recommended that 15 switches and frogs (15 turnouts) should call for an extra man in the section force. Stub switches give the most trouble in summer and point switches during snow storms. The distribution of the switches makes a considerable difference in the work of keeping them in good condition and attending to the switch lights, as a number of switches near together are more easily looked after than the same number scattered over the whole length of the section. Two miles of important side-track or three miles of side-track but little used are considered equivalent to one mile of single main track.

The location of the section house or the foreman's residence is a consideration of some importance. So far as the duty of inspection is concerned it is not as convenient, and in some cases not as economical, to have headquarters at an intermediate point of the section as it is at one end. This for the reason that in sending one man to inspect the section he must first double back on part of the track before he can get over all of it. Where headquarters is at one end of the section, the foreman, in going to work with his hand car and crew in the morning, can, if desirable, first run to the end of the section and then on the way back stop at the points where work is to be done. If the crew is small this plan is about as economical as any. If he has a large crew he would most likely stop where the work is to be done and send a trusty man to walk over the rest of the track. In either case it is not necessary to lose time walking over track that has been covered by the foreman and the crew. Where he starts out each morning from the middle of the section or from some intermediate point, the usual plan is to send one of the men in the opposite direction, and then if the crew stops short of the end of the section to work it is necessary to send another man to inspect the remainder of the distance on that end. This man doubles that part of the section, the hand car or crew in course of the day doubles the part between the tool house and the point where the work was done, and the first man sent out doubles the part of the section in one direction from the tool house; and then, in order to reach the crew, to work the remainder of the day, he must walk over the part inspected by the foreman. The whole section is therefore inspected twice and part of it three times during the day. The plan of locating the section house and tool house at one end of the section therefore requires less walking in order that the inspection may cover the section daily than is the case where headquarters is at some intermediate point. If regular track-walkers are employed, however, the difference in the two arrangements is inconsiderable.

On the other hand, the foreman located at the middle of his section is the easiest found in the majority of cases of emergency. On sections where slides are to be frequently expected it might be advisable to locate the section house within convenient distance of the seat of trouble, and if this is as liable to happen on one part of the section as another, then the middle of the section will be the most convenient in the long run. Where sections are very long it is not desirable to locate the section houses at the opposite ends of any two of the adjoining sections, as that arrangement would bring a long stretch of track between the headquarters of section forces; on 10-mile sections the distance between section houses would be 20 miles. Of course, in some sections of the country the local conditions may be such that an arrangement of this kind cannot well be avoided, but in general cases the rule can be observed. Another important consideration, and in the majority of cases, perhaps, the most important consideration, is to have the section headquarters near a telegraph station, and a night telegraph station if possible. In thickly settled country it is usually feasible to do this. This arrangement puts the roadmaster in quick control of his track forces, and in times of emergency, as when wrecks and washouts occur, he can, as a general thing, mobilize them promptly. From the standpoint of hiring and retaining labor for the section crews, the plan of locating the foremen in the towns and villages, or at least in settled districts, generally gives best satisfaction.

192. Floating Gangs. On roads where there are a good many turnouts to lay, take up or change, or where there is enough of any kind of special work on the division to keep a considerable number of men busy, and still not of a kind that can be profitably done by the work train crew, it is customary to have one or more floating crews going from place to place to do such work. Such an arrangement relieves the section crews of extra work, thus enabling them to attend more carefully to the regular affairs of the section than would be the case if this work was to fall to them. On many roads it is the policy to keep the section crews employed strictly at the routine work of the section, such work as reballasting, laying new steel, extensive ditching, removing slides, repairs at washouts, widening banks, grading for side-tracks, laying new turnouts and side-tracks, etc., being attended to by extra crews or floating gangs. In times of emergency, as, for instance, when wrecks or washouts occur, the floating gang is generally in demand and can be used to good advantage, because the men are together and can be brought quickly to the scene of the trouble as a reinforcement. There is also more or less night work or work of a special character about the yards which this crew can perform to better advantage than the regular crews. Moreover, it is the practice on some roads to send the floating gang to help out section foremen who are behind with their tie renewals, or who have an unusual amount of such or other work on hand. The use of floating gangs to do common section work under ordinary circumstances, however, is not recommended as good practice, for it tends to relieve the section foremen of some responsibility, while foremen of special gangs are not usually disposed to assume any more responsibility in such things than the rules compel them to.

Just where to draw the line in the division of work between floating gangs and the section crews is something of an unsettled question, but many difficulties in this respect can be reconciled on the fact that the necessity for floating gangs on different roads does not always arise under the same combination of circumstances. Local construction work for which the regular section crew is not a sufficient force to complete it in the time required, or which comes during the season when the regular crew cannot spare the time, would seem to be one case about which there could be no question. Heavy repair work, like relaying rails or reballasting, which cannot be done economically by small crews, would seem to be another case of the same kind, but not many are in favor of taking ordinary repairs, such as recur every year, out of the hands of the regular section foremen. It frequently happens, however, that there is a scarcity of laborers in localities, and the section crews cannot be filled up to their regular allowance. In that event they must have help in order to get the regular work done in season. The point on which objection is most frequently raised is in regard to the poor quality of the work sometimes done by special gangs. As to this, much depends, of course, upon the reliability of the foreman and the kind of men he has to do the work; and right here it is well to point out the distinction between special gangs as they are differently organized.

An "extra" gang, as commonly understood, is a party of men organized for temporary service, usually for some special work during the busy season, and is then disbanded. It is usually got together quickly by hiring any available laborers, with little or no regard to skill, for skilled trackmen are seldom available for temporary employment. In the West such gangs are frequently composed of the migratory or "hobo" class of laborers, the most of whom are not in the habit of working in one place longer than until the first pay day. In other cases the gang is composed of aliens of the Dago or Polack nationality, who possess little or no skill and work in a leisurely and indifferent sort of way. Floating gangs are supposed to be organized for permanent service, like the section crews, and should be composed of a better class of labor than extra gangs. Ordinarily this gang is reduced when winter comes on, but the skilled trackmen are kept at work and the organization is maintained. There is usually enough work around the yards and terminals, such as shoveling snow, handling material, odd jobs about the switches and crossings, or occasional trips over the road with snow plows and flangers, assisting the wrecking crew, etc., to furnish steady employment. On some roads the gang is employed during winter time in stone quarries, getting out rock for ballast or for building purposes, while frequently there is track work enough to occupy their time the year round. These men, from their diversified experience, are supposed to be skillful at all kinds of track work, and even more ready to grasp new situations and adapt themselves to special conditions than ordinary section men. As for track work of a special character the chances are that the floating gang will do it more expeditiously and more economically than the regular section crews. When it comes to the point of temporarily increasing the size of a section crew by hiring a number of new men, in order to do some special work, there could hardly be any doubt about the advisability of sending the floating gang. Wherever the work of the floating gang will show distinctly for itself there is no reason to suppose that responsibility would be shirked. It would seem, therefore, that to this extent there need be no hesitancy about employing floating gangs.

In view of the aforementioned advantages derivable from floating gangs properly organized and supervised, they should be composed of capable, active and willing men. Unless they are willing workers they may take offense once in awhile when a "hurry-up" job is on hand or when, as sometimes happens, it becomes necessary to strain a point in order to complete the work in time to get off on a train. The floating gang as an apprentice school for foremen is elsewhere discussed (§ 188).

Men in floating crews, including the foreman, are usually paid a slightly higher rate of wages than ordinary section men—at least enough higher to cover the increased cost of living while traveling around. Such crews usually make headquarters at the division points. When the distance between headquarters and the work is too great to be covered in reasonable time by train, morning and evening, the crew arranges to board temporarily as near to the work as accommodations for transients can be had, going home usually on Saturday evenings. On many of the western roads floating crews are furnished with boarding cars, which are set out on the side-track nearest to the work, and go to and fro on hand cars. Floating crews are supplied with a full set of section tools and a hand car. When going to and from work by train, the work at the point being only of short duration, the tools carried along are divided between the men, who assist in loading them into the baggage car at the starting point and in unloading them at the stopping point. Each man being accountable for certain tools, is expected to see that they are all put into and taken out of the baggage car. If the work of the crew is to continue in one place for some time the whole outfit of tools, with a box to keep them in, and the hand car, should be shipped by freight.

The Ohio River R. R., before it passed under the control of the Baltimore & Ohio R. R., adopted for one of its divisions a system of track maintenance in which all the heavy work of the sections was performed by floating crews with districts regularly assigned. Under the previous system the sections were 7 miles long and were worked by a foreman and 6 men. Under the new system the sections were made 8 miles in length and were put in charge of a foreman and 3 men. In addition to this the division of 120 miles was divided into 30-mile sections, and each was worked by a floating gang consisting of a foreman, 20 men and a cook. Each of these gangs was provided with a boarding train consisting of four box cars and a flat car. One of these cars was divided and used as a kitchen and a living room for the cook; another was divided and used as a dining room, and a sleeping apartment for the foreman; and the other two box cars were used as sleeping apartments for the men. The flat car was used for supplies and materials.

The duties assigned to the section forces were to look after the small repairs, including the raising and tamping of low joints, or the light surfacing, and to inspect the condition of the track, keep the right of way fences in repair, maintain the grounds around the depots in a state of neatness, and such other work as the supervisor found it advisable and most economical to have this force do. The position of track-walker was abolished and the whole section force was required to go over its section every day with the hand car, inspecting the track, tightening loose bolts, driving spikes, etc.; thus in general doing all light work and seeing that the track was in safe condition. The larger forces, covering the 30-mile sections, performed all the heavier work of repair and renewals, such as placing ballast, renewing ties and rails, widening banks, ditching and such other work as the supervisor thought could be done more economically by this force than by the smaller section crews. The object of this organization was to secure better inspection for the track and to economize in the general work of track repairs. As the foreman was required to pass over the track daily, and was held responsible for the prompt repairing of defects, he could not divide his responsibility with a track-walker. The heavier work over each section of 30 miles being done by the same force, in charge of the same foreman, it was thought that more uniformity in the work was secured; that the forces were more nearly the size required to make such repairs economically; and that in case of wreck, in most instances, the force required could be more quickly and easily assembled. As the section foremen were still held accountable for the safety of the track in its minor, but not least important, repairs their responsibility was not lessened in any great degree. During the winter the floating gangs were cut down to 10 or 12 men and these worked only such time as was profitable. The men who worked in these gangs were young and single, as a rule, and as the quarters were made comfortable and board was furnished practically at cost, the most of them preferred to stay at the camp during the slack season. The company thus had at all times a large force for service in case of emergency. The management reported that the working of the system proved to be very satisfactory.

Fence Crews.—A man is sometimes employed to take charge of fence construction and repairs. When new fence is to be built he is given a small crew, with tools and facilities for transporting material, as described under the subject of fence (§ 151). When there is no new fence to be built he looks after fence repairs, where such are needed to any considerable extent. This arrangement is commendable, for the reason that he can see to getting the material to place better than any one else, thus avoiding delay. If he has no crew he is generally allowed to draw a man or two from the foreman on whose section the work is to be done. In the busy season it greatly facilitates matters to relieve the foremen of this work. Slight repairs should be kept up at all times by the section crews, but fire or flood will sometimes give them more fence work than they can find time to do.

193. Discipline.—In order to carry on the work of track maintenance to best advantage there must be conformity to well established business principles. The crew should report at the tool house promptly at the time set for starting out in the morning, which, by universal custom, is 7 o'clock. Section men should not be expected to run the hand car to and from work on their own time, because there is seldom or never a permanently established place where the work is done, from day to day, and also because one use for the hand car is to carry tools. It is customary, therefore, to run the hand car on the company's time. Some railways allow 5 minutes per mile going to and coming from work with the hand car. The foreman and all who habitually ride should help pump the car, and each should be expected to do a fair share of the work, too. Any foreman who is too lazy to work his passage sets a poor example for his men.

The foreman should see that each man does his work thoroughly, as well as that he does the proper amount of it. Indeed, at some kinds of work it were as well not to do it at all if it be not well done. The quality of the work is first in importance, the quantity second. Ordinarily a man should be expected to do a fair day's work, no less, no more. Very truly, the meaning of a "fair day's work" is something rather indefinite, but the term is generally understood to mean an amount of work performed at such a rate that an average man can keep it up steadily all day long without feeling tired out when night comes. The judgment of men on this point is quite liable to vary according to their physical endurance; that is, a very strong, active man might naturally expect more than would a man of ordinary strength. Now a good deal of worry and complaint on the part of foremen often arises over the fact that some men are physically able to do far above the average, and a foreman lacking in good judgment will expect that every man in the crew shall keep up with his "favorite." Surely this is not fair and it is very unreasonable. It is highly important that a foreman should know what an average day's work is. If he has been an observing man he should, from his previous experience, have learned how much of the different kinds of work ordinary men can do, and, consequently, know what to expect. The best results are turned out by a crew where the men are, as nearly as may be, on a physical equality, provided they do not fall below the average; for men do not usually like to be outdone by others in the crew, and those less able are liable unconsciously to slight their work in order to keep pace with the best. This is liable to occur in tamping, and it leads to bad results.

Having been a track laborer myself, for many years, I will venture a few observations. Some men do better at one kind of work than at another; as, for instance, some are not "built" for grubbing weeds with a shovel, but do well at other kinds of work. And again, some men are naturally a little quicker in their movements than are others. One cannot, therefore, expect to always get men to work alike. As long as a man is doing fairly well he is doing well enough, notwithstanding that some other man may be doing a trifle more than he. A fair-minded foreman can tell when men are making honest effort, and when each succeeds fairly well the foreman should not try to point out inequalities. Under ordinary circumstances I do not favor the practice of purposely placing men so that their work must show in competition. Such practice in working men is regarded by some foremen as a smart trick by which the men may be made to feel as though they ought to outdo one another. In some cases of the kind which have come under my observation, however, the aspect of things seemed to indicate that the foreman himself was a little in doubt as to just what he should expect of his men. Under such circumstances the foreman is quite likely to select as a criterion the pace set by some man who is trying to curry his favor. While temporary results may be accomplished by resort to such tactics nothing worth while is gained in the end. The men soon "catch on" and come to feel that they are distrusted and taken advantage of. In order to gain speed or make a showing they will slight the quality of the work, and when they engage in work where each man's part does not show for itself they are quite likely to take advantage of the foreman by doing as little as possible without being detected. Thus it goes "nip and tuck" between the foreman and his crew. Unless employees are encouraged to perform their work in the proper spirit the results are likely to be defective in some respect. But the foreman who understands his business can get the proper amount of work out of his men without setting up a contest among them. A man who cannot keep up a fair rate of work without hurry and worry is not a good man to retain in the service, and neither is he who is continually jumping into the work purposely to show off to disadvantage the work of some other man who is doing enough. Men of the latter class will not always keep up such activity when working alone, for in over-exerting themselves they usually have some particular end in view.

Foremen should endeavor to carry on the work methodically. One respect in which this principle may be furthered is to get men into the habit of so distributing themselves about the work that they will keep out of one another's way, as much as possible. Some men are quite clever at prearranging things so that they get a chance to move about often, or perchance to so block matters that they will have to stand idle while others work. An instance: Suppose that a rail has been raised and the ties are to be tamped. If two sets of tampers begin at the ends of the rail and work toward each other they get into each other's way near the middle, so that one or the other set must tamp the last three or four ties while the other set stands to look on, thus wasting time. Now if one set had begun at one end of the rail and the other set at the middle of it, and both had worked in the same direction, the work would have been properly divided and there would have been no interference. Men should be taught the importance of making every stroke count. Some men fly around and make a good deal of fuss without accomplishing much. The foreman should impress upon them the importance of doing the work with as few movements as possible. It is easy sometimes to mistake exertion for achievement. In very hot weather men cannot be expected to do quite as much as when it is cooler.

It sometimes becomes necessary on railroad track to do work on Sunday. It is not a good plan, however, to make a practice of looking for work to do on this day. Men are always able to work more cheerfully and energetically where they have one day out of the week for rest. In cases of emergency trackmen should expect to respond to call for duty, whether it comes at night, on Sundays, or at other times, but when the work on hand is that of mere expediency, foremen or laborers having scruples against Sunday work should be excused from such service without prejudice to their regular employment. Men should not be obliged to work on legal holidays unless the work is very pressing.

On most roads section men are forbidden to trail the hand car behind the caboose of freight trains, as such practice frequently results in a broken hand car and injury to some of the men. Such damage or injury usually occurs by the sudden stopping or slackening in speed of the train, when the hand car will dart under the caboose platform, breaking the lever and squeezing the men at the head end of the car. If proper precaution is taken there is no danger, as the men may ride on the caboose and the car can be drawn by a stout rope and prevented from running into the caboose by a pole planted against the gallows frame. On mountain roads, where the speed of freight trains up grade is slow, the section men are much tempted to hook on behind, for it saves a good deal of time, but unless the practice is forbidden or regulated in some manner the men are liable to take risks and get into trouble. Foremen should see that hand cars and trucks are clear of the track in good season for the regular trains, and they should not permit the men to throw switches when trains are about due. On double track velocipedes should be run opposite the running direction of the trains. When visiting his foremen the roadmaster or supervisor should habitually compare watches, to see that correct time is carried on the work. Foremen should see that the men get clear of the track well in advance of approaching trains. Carelessness in this respect causes no little uneasiness with the enginemen. And when standing out of the way of trains men should neither be required nor permitted to rush into the track to work immediately the rear coach passes. Such movements look bad and ought to be noted by the roadmaster with some degree of suspicion, for men are seldom as eager to work as all that—if they were they might sometimes forget themselves and leap into danger, as in the case of a break-in-two.

Foremen should be very careful how they use their switch keys and very solicitous concerning the use of the same when entrusted to their men. It should be an unvarying rule not to unlock switches for letting hand and push cars through, unless they are loaded so heavily that they cannot be easily lifted over, near the switch. When using a switch for this purpose the man who unlocks it should remain by the stand to throw it back to place and lock it for main track after the car passes. Switches must sometimes be thrown while working at them, and on such occasions men are more liable to forget themselves than in any other way. There is a rule which, if followed, will save foremen much anxiety, many times; and that is to always run the hand car over the switch, on main line, after work has been done on it, before leaving. In stopping the hand car for a little while to do a piece of work at a switch, the car should always be stopped short of the switch, so that when leaving the place the crew cannot go off and forget to close the switch.

The Brown System.—In the operation of railways occasion frequently arises for disciplining men for mistakes, neglect of duty or other shortcomings not thought to be sufficiently serious to require the employee's discharge. A method commonly followed in such cases is to reprimand for slight offenses and to suspend the employee from duty, with loss of pay, for such other offenses as are not thought to be deserving of dismissal or discharge. The punishment of employees for offense of any kind is always an unpleasant duty, and the best course to take in general cases is a large and somewhat perplexing question. During late years this question has been much discussed among railway officials of all grades, and the tendency of the times seems to be toward the adoption of what is known as the Brown system of railway discipline or "discipline without suspension," first applied to railway management by Mr. Geo. R. Brown, while general superintendent of the Fall Brook R. R. In the operation of this system the employee at fault is disciplined by record, and, as already intimated, without suspension. As conducted by Mr. Brown, himself, a record book was kept in which was written down a brief statement of every irregularity for which a man was responsible, this record taking the place of the usual "lay off." When a man began to "make a record" he was called in and reminded that if the same became too long he would have to be considered a failure for the service, but would be given another chance. If the admonition had the desired effect, as shown by the man's future conduct, he was retained in the service, but if, on the contrary, he reasoned that the record was an easy way out of the trouble, made light of it and was frequently called on to explain irregularities, he was dismissed from the service.

This original system has been modified in many ways, but the same essential principle is retained. A very common arrangement is one in which a system of merit and demerit marks or a nominal suspension of a certain number of days is substituted for the usual punishment feature, so that the standing of the employee is at all times determined by the record of merit and demerit marks or nominal suspensions entered on his account. For each offense requiring disciplinary action the employee is charged with a certain number of demerit marks, after the manner employed by old-time school teachers; and for acts of special merit he is credited with merit marks, which may cancel a like number of demerit marks. Employees having a clear record for some given length of time, like six months or a year, are entitled to a certain number of merit marks, but a bad record is followed with dismissal.

Another feature of the system, which also was originally put in practice by Mr. Brown, is a bulletin board on which are posted at stated periods brief accounts of mishaps, irregular conduct and other occurrences, pointing out errors and consequences, with criticisms thereon, but omitting, however, the names of individuals or any hint at their identification. This bulletin is intended to make accidents and other matters a lesson to all the trainmen, and in cases attempts to show how the errors might have been avoided. In usual practice meritorious conduct worthy of special remark is also bulletined and commented upon.

The Brown system of discipline, or modified forms of it, is now in force on more than one third of the railway mileage of North America. Some of the advantages of the system, as applicable to the track department of a railway, are well set forth in a paper by Mr. H. W. Church, while roadmaster with the Lake Shore & Michigan Southern Ry., read before the annual convention of the Roadmasters' Association of America, in 1898, here quoted, in part, as follows:

"In the event of a suspension it is necessary to put a substitute in charge, who, as a rule, is less skillful, lacks knowledge of the locality and conditions, and where the suspension is for a considerable length of time the company would suffer because of this lack of skill and knowledge. The suspended employee would not only lose his time, with the consequent hardship entailed upon his family, but would form a secret dislike for his superior and the company he serves. With the Brown system, instead of the employee losing his time and his family being inconvenienced, if not immediately suffering by reason of his enforced idleness, a given number of demerit marks would be entered against his record. The company would be the gainer by his retention in the service, not having to educate a new man, with the possibility ever present of his making a still greater mistake. The retained employee would feel his error more keenly and would, I think, be less likely to err in the future, and so far as the others are concerned the lesson would be equally as good. . . . . Be content, therefore, with moderate measures and moderate results; advancement is made only by slow degrees, and not in one jump. Have your men feel that you are their friend rather than their natural enemy; that your interests are mutual, and that their acts reflect credit or discredit upon you. Above all, bear in mind the truth that 'The aim of discipline should be to produce a self-governing being; not to produce a being to be governed by others.'"

Mr. Brown, himself, has said: "It often occurs that the disgrace and injury occasioned by a strict enforcement of a sentence does more to ruin the guilty than anything else, and a wise provision has been made allowing courts to use their judgment as to carrying out punishments; this is known as 'suspending sentence.' If the sometime offender does better, and is not guilty of the same or other offenses, the judge conveniently forgets the indictment hanging over him, but should he go on committing one misdemeanor after another, his 'record' rises up to condemn him. I believe in the practice of 'suspending sentence' with railroad employees.

"With this system the good men are retained, developed, benefited and encouraged, and the culls are got rid of to the betterment of the service all around. . . . . Every wreck, every accident, every mistake, every loss has taught its lesson, and these are of no less value to the railroads and to railroad men than the successes. I practice making every mishap a lesson to every man on the road. It often happens that an accident, or a 'close shave' for one, is the best kind of a lesson to the man who could be blamed; and if he is retained in the service, he is a more valuable man than he would otherwise be or one who could be hired to take his place."

In dealing with employees the essential thing for the official in authority to know is whether the employee whose conduct has been called in question is competent for the duties with which he is charged, is trustworthy and who enters into the work of his employer with the proper spirit. There is hope of any employee who fulfills these requirements, notwithstanding a fault may be chargeable against him for some occasion or other, and in the minds of many or most progressive railroad men there is hardly any doubt but that with such men the Brown system of discipline will accomplish the most satisfactory results. On the other hand, the man who fails to measure up to these qualifications should be dismissed from the service as soon as his employer or foreman is satisfied that his character has been correctly estimated. It should be borne in mind that all systems or methods of dealing with men have their limitations; and the benefits of any scheme of retrievement like the Brown system should not be extended to any man unless he is earnest, competent, straightforward and really capable of improvement. Neither the Brown nor any other system can make a lazy man industrious, or an interested workman out of a man whose chief concern is "sundown and pay day"; neither can it make a careless man careful, or a drinking man temperate or change his character in any material respect. The man's character and habits constitute the basis to work upon, and if it is seen that these are incompatible with his responsibility his dismissal should not await the announcement of a formal record of errors.

Discipline should never be so irrationally stringent as to discount the manhood of the employees. Instances have been known where subordinate employees or officials would secretly criticise some certain rule, pet notion, device or method of a superior officer, which was working trouble or ill economy, but with evident solicitude about their views being known at headquarters. Men in authority should let it be known that criticism of existing rules, methods or other matters, from employees of any rank, if presented in reasonable form, will be appreciated. If intentions to this effect were generally made known in the printed books of rules and instructions for railways it is just possible that some companies might profit thereby.

In connection with the duties of section foremen (§ 188) mention is made of certain difficulties which sometimes arise purely from the personal relations between a foreman and his men. The rules and instructions of a number of roads suggest others of similar character. Not a few railway companies find it necessary to forbid such transactions as the borrowing or lending of money between an employee and his foreman; the contribution of money for the purchase of testimonials to superior officers or the giving or receiving of presents of any kind; or the asking or receiving of money or other consideration for employment given. There are also rules forbidding any officer or foreman to prescribe to subordinates where their personal purchases shall be made. Such rules are undoubtedly justifiable, and it is possible to extend their scope still farther. In my own experience I have witnessed many a "hot time" in gangs of trackmen stirred up over gambling during the noon hour or in the boarding cars at night. Foremen should be forbidden to engage in such practice or to permit it among their employees, about the work or in company buildings or cars. When the gambling fever strikes a crew it seems that card playing then becomes the chief occupation of some of the men for days and nights at a time, and sooner or later matters terminate in a row.

Some of the worst infractions of discipline result from a too frequent use of intoxicating liquors. Most railway companies have rules prohibiting the use of intoxicating drinks *while on duty*. It is well known, however, that this rule comes far short of accomplishing its object, for it does not literally meet the case of the man who "fills up" *just previous to coming on duty*, or who carouses around at hours when he ought to be asleep. An employer has a right to expect that his employees shall have clear heads at all times while on duty, and this cannot be expected of men who will go on their little sprees Saturday nights, or on pay-day night, or "of a Sunday," or of men who drink with any degree of regularity, no matter how little. And then, in the foreman's case, his working hours may occasionally come at any time during the twenty-four, and he should therefore keep himself always in fit condition to be called out at any time. It is, perhaps, not in keeping with democratic theory to attempt any restriction upon an employee's drinking while off duty, and it is certainly futile to so attempt. But there can be nothing "unconstitutional" in the practice of choosing foremen from among men who do not drink at all, and it is the wisest plan to follow. Then any man found to be in the habit of drinking, after having represented himself otherwise, has shown cause for dismissal; for clearly he has either misrepresented or else he has degenerated.

194. Reports and Correspondence.—It is perhaps unnecessary to say that accurate reports, embodying all work done and all changing of materials on each section, and by each working crew, should be made out on systematically arranged blank forms and sent to headquarters at regular intervals. The most common reports regularly made are: Monthly time sheet, distribution of work (monthly), weekly report of work, monthly report of materials, monthly tool report, daily and monthly work-train report. Besides these regular reports there are a number of special reports in common usage, such as report of new side-track laid, report of side-track taken up, report of stock killed or injured, report of casualties, fire report, report on rail failures, report on new buildings or other structures adjacent to the track.

The exact wording of blank forms, as well as the matter of detail reported, differs with different companies, owing to conditions and circumstances local or peculiar to each, and to the different ways in which different officials choose to look at statistics—which usually amount to matters of taste only. The reports should be simple and consistent and full instructions should be noted on each blank, so that foremen may fully understand how it is to be filled out. Trifling matters should not be made subjects for special report (as is sometimes the case)—the aim should be to report as many matters on the same blank as may be practicable. On some roads all work performed on main track is reported on a single form, and likewise all materials accounted for are reported on a single form. Wherever such practice is possible without too great inconvenience it is a commendable one to follow. The making of numerous reports "is a weariness to the flesh," and waste of energy thereon begets the habit of attending to such matters thoughtlessly. The adoption of a "set of standards," a code of rules and a multiplicity of report forms does not necessarily make for system in track work.

Time Reports.—As most railroad companies pay their employees monthly, the time book or time sheet is made out and forwarded at the end of the company month, which, with some companies, by the way, does not correspond with the end of the calendar month. It is, of course, important that all records should be made in ink, or with indelible pencil. The foreman should make out his time book daily, as this is the most businesslike method and one the least liable to incur mistakes. A blank for a time sheet or page of a time book is shown as Form 1, and for the purpose of explaining some points connected with the transferring of time to the distribution sheet, it is filled out. All time worked should be entered in the time book, and whenever a time card is issued, note should be made of the same in the column for "Remarks." Bad weather, which interferes with the work of the section, should always be noted in the time book. Some roads require section foremen to make note of the weather daily.

Owing to the roving habit of railroad men in some parts of the country there would be great difficulty in retaining employees in service if there was not some security provided for their board bills; for but few traveling men of that class have means to pay in advance. It is customary on railroads to deduct board bills from the pay of employees when such bills are presented at the pay car or sent in along with the man's time. Hospital bills or dues are also deducted on many roads. On some roads regular hospital dues of about a half dollar per month are collected from all employees without the formality of asking consent. In case of accident or sickness of any kind the employee is then entitled to care and medical treatment free of charge. Strange as it may seem, whiskey or drink bills have

ter or other agent the bill should appear and be properly receipted. In some cases a page of the time book is headed and ruled for explanations of deductions, the column headings reading thus: Name—Board—To Whom Payable—Address—Amount—Hospital—Total—Remarks. In other cases the time sheet itself or each page of the time book is ruled and headed to insert the deductions from each man's pay, if there are any. This arrangement is shown on Form 1.

The time of monthly men not working a full month is usually computed by multiplying the rate per month by the number of days worked (including Sundays and holidays) and dividing this product by the total number of days in the month.

Men discharged before the end of the month are usually given a "time card" by the foreman. The customary routine is to send this time card to the headquarters, or to the paymaster, and a check or the cash is forwarded to the nearest company agent with orders to pay it. If the man discharged is not known to the agent, or at the headquarters, in case he wishes to present the time card there, he is required to put his signature to an identification card which the foreman sends to the roadmaster's or paymaster's office as soon as the time card has been issued. If payment is made through one of the station agents this identification card is enclosed with the check in the letter sent by the paymaster to the agent, who is thus able to identify the man by his signature. If the man cannot write, it is, of course necessary for the foreman or some other responsible party to identify him in person. Forms 3 and 4 (face and back) show the usual blanks for a time card, and Form 5 shows an identification card. On some roads blank time cards are not issued to the foremen until an application has been made for the exact number needed. This precaution is intended to prevent forgery. In giving a time card to a man who has not received pay for work done in the previous month it is usual to wire a request to the paymaster to forward the whole amount due the discharged employee to the agent nearest the section.

Form 3.—Time Card (Face).

Instructions to Foremen.

Whenever you discharge a man before the end of the month you must, in case he desires his pay at the time, fill out this time card and either give it to him or send it to this office. Have him sign his name to an identification card, which you will send immediately to this office, yourself. If the man is not discharged give the reason why he quit. Men who quit of their own accord will not be paid before the regular pay day, unless removing to a distance or because of some other extraordinary circumstance. When application is made for a time card you must, therefore, use judgment accordingly.

Deduction for board will not be made unless an itemized bill from the landlord is sent through the foreman.

....

Roadmaster.

Form 4.—Time Card (Back).

If special blank forms are not furnished for it, two or three pages of the time book should be headed for a description of new work, wherein should be noted all such work as grading and the laying of new track, or side-track, fully described as to location, nature of the work, etc. A convenient arrangement is to have the time book and report on distribution of work under one cover. The two are then together, which subserves the convenience of both the person who makes out the reports and the one who checks them over.

Distribution of Work.—The monthly report on "distribution of work" or "division of labor" shows the amount of labor chargeable to each kind of work performed, in hours, each day, and the amount of work accomplished. The total time worked, as shown by this report, must of course check with the time sheet for the same period. Form 2 shows the ordinary arrangement of this report. One arrangement where the time book and report on distribution of work are combined in the same report is to devote a separate page of the time book to each laborer, headed horizontally as a time sheet, with a list of the various kinds of track work in the left-hand vertical column. In entering the time worked the number of hours

Form 5.—Identification Card (Face and Back).

devoted by the man to each kind of work during each day is marked opposite the kind of work appearing in the left-hand column, and at the bottom of the sheet the total figure for the day corresponds to the number of hours worked that day. The vertical column of totals at the right-hand side of the sheet shows the amount of time for each labor account at the end of the month, and as footed at the bottom it checks with the total time worked by the man during the month. As above stated some roads have separate reports for many kinds of work, such as laying rails, ballasting, building fence, etc., instead of, or in addition to, the inclusion of such items in the report on distribution of work. This plan, of course, multiplies reports, in some cases unnecessarily, and the extra reports should be dispensed with as much as possible. Below is a list of items or line headings commonly used in reports on distribution of work. All of these items would not likely be found in the report of any one road, but the list shows what items are used on some roads. It is usual to leave at the end of the list a number of blank lines for the entry of time worked on odd jobs of work for which no headings are printed.

1. General Repairs.
2. Watchmen.
3. Line and Surface.
4. Ballasting Old Track.
5. Cutt'g Grass Rt. of W'y.
6. Cutting Grass in Track.
7. Cutting Brush.
8. Putting in Ties.
9. Replacing Rails.
10. Ditching.
11. Laying Tile.
12. Repairing Frogs and Switches.
13. Repairs to Bridges.
14. Repairs to Culverts.
15. Repairs to Tools.
16. Repairs to Side-Tracks.
17. Repairs to Fence.
18. Repairs to Telegraph.
19. Repairs to Snow Fence.
20. Highway Crossings.
21. Cattle Guards.
22. Policing.
23. Building Fence
24 Building Snow Fence.
25 Work on Sign Boards.
26. Removing Snow and Ice.
27. Removing Slides.
28. High Water and Wash-outs.
29. Handling Materials.
30. Tightening Bolts.
31. Shimming.
32. Handling Freight.
33. Handling Fuel.
34. Loading Ballast.
35. Loading Ties.
36. Loading Rails and Scrap.
37. Grading for New Track.
38. Laying New Track.
39. Ballasting New Track.
40. Construction New Side-Track.
41. Filling in Bridges.
42. Widening Embankments.
43. Riprapping Banks.
44. Wrecking.
45. Taking up Track.
46. Cleaning Culverts.
47. Removing Stumps.
48. Cutting Down Trees.
49. Disposing of Killed or Injured Stock.
50. Work at Water Tanks.

Many roads require a weekly report of work, which corresponds, as to items, with the monthly report on distribution of work. As the month is a considerable portion of time this gives the office opportunity to keep in closer touch with the work which is being done, and, moreover, it serves to some extent, as a check upon the foreman's punctuality. For instance, a foreman, if he chose, could fill out the daily record of distribution of work for a whole month, by guesswork, at the end of the month, and yet the office might not be able to detect anything wrong. With weekly reports, however, he could not neglect this longer than a week, at farthest. In form this report is usually a summary of the work only, omitting the daily record of hours performed on each piece of work. Following are the usual column headings: Kind of Work—Amount of Work Done (The "No. of," "Cu. Yds.," "No. of Pieces," "No. Lin. ft.," etc., is indicated in writing)—No. of Hours—Cost of Work—Location of the Work—Remarks. I rather favor making this report every 10 days instead of every week. The weekly reports in the aggregate for each month must tally with the monthly report for the same month; that is, the monthly report must cover four "weekly" reports, the last of which, in each month (except February), sometimes covers 9 days and sometimes 10 days, thus making the fourth report in each month cover a considerably longer period than each of the other three, and with these inequalities it is not an easy mental operation to quickly compare the data of the four reports. Reports made on the evenings of the 10th, 20th, and last day of the month would cover periods more nearly equal in length. Weekly reports are usually made on the 7th, 14th, 21st and last day of the month.

In filling out the report for distribution of work there often arises a good deal of confusion and frequent mistakes over the matter of distributing the cost of the foreman's time among the various kinds of work performed. The clearest way of handling this matter is as follows: The foreman is paid by the month, with no allowance for overtime and no deduction made for time lost on account of bad weather, etc. Opposite his name in the time book (Form 1), in the column "Amount," will then appear the amount of his monthly pay, regardless of the time worked. Nevertheless, the actual time he spends with his men should go down on the time book, and he should make a correct distribution of his own time to the several labor accounts in the same manner as that of the laborers under his charge. In the item total hours for the month there will then be included the number of hours worked by the foreman. The item "total amount," less the foreman's pay, must then check with the product of two quantities, one of which is the total number of hours less the time actually worked by the foreman, and the other is the price per hour paid the common labor. In the distribution of work, whether the foreman engages personally in the work or not, his time spent with each kind of work should be charged to that item. Compute the cost for each item, according to the time recorded and at the rate per hour paid the common labor. Then to the item "General Repairs," or "Miscellaneous Work," add the difference between the foreman's monthly pay and the pay he would receive if he was paid for his actual time at the price per hour for common labor. In the case of a weekly report, use instead of the monthly pay one-fourth of it. This throws all the extra cost (over and above the price of common labor) of the part taken by the foreman in each piece of work into general repairs, and thus avoids the necessity of increasing the cost of each separate item pro rata for the time the foreman spent with it. This is really proper, because the additional amount which the foreman is paid above common labor is not necessarily because every piece of work he engages in actually requires his oversight, but on account of his general supervision of the section and for his responsibility. He also draws pay for Sundays whether any work is done or not. This additional amount therefore belongs properly to general repairs.

The time sheet and distribution sheet (Forms 1 and 2) have been filled out purposely to show this arrangement. It will be seen that on the time sheet the foreman is credited with 245 hours for the month. Subtracting this from 2218, the total number of hours, we get 1973 hours, which, at 12 cents per hour, gives us \$236.76; and this checks with \$286.76, the total amount, less the foreman's pay of \$50. This is clear and straightforward. Now on the distribution sheet the cost opposite each item is computed for the given number of hours at 12 cents per hour, the same as though no higher wages had been paid the foreman. The item "General Repairs" is 26 hours at 12 cents per hour, or \$3.12. Adding to this \$20.60, which is the difference between the foreman's pay of \$50 and his actual time of 245 hours at 12c. per hour, the total at the foot of the cost column (\$286.76) checks with the total at the foot of the time sheet. If the watchmen were paid a different rate from that of common labor, their time would have to be considered separately. Some divide the total amount by the total hours worked, to get a general average, which is the rate at which each item in the distribution of work is then charged. But evidently the time and pay of watchmen, flagmen, etc., should not be included in this average;

besides, there is with this method a good deal of cent splitting to be done, and the totals will not check exactly; and after all it does not seem as fair as the method above pointed out.

Some roads seek to get around this difficulty by instructing the foremen not to enter their time on the report of work distribution, leaving this to be done pro rata in the roadmaster's office at the end of the month. By this arrangement the time book and distribution report will check by leaving the foreman's pay out of consideration, and matters are simplified for the foremen, but the method of charging up the foreman's time to the various items does not seem to afford an equitable distribution. On some roads the foremen are relieved of all such "difficulties" by not being permitted to do any computing in the time books and other monthly reports. This is done by clerks at headquarters, so as to avoid errors which foremen "slow at figures" are liable to make. This plan is, of course, something of a reflection upon the foremen.

Some roads require that the time books and blanks for the distribution of time must be used for original entry; that is, that time and the distribution thereof must not be kept in a separate book or memorandum and copied into the regular book at intervals. Some roads also require foremen to carry these report books or blanks out on the work with them, so that they may be inspected by the roadmaster at any time. The purpose of rules of this kind is to prevent "doctoring" reports.

Tool Report.—The foreman's monthly report of tools is usually headed to show the number of tools of each kind on hand at the date of last report, the number received since that date, the number worn out or broken and returned during the same period, and the number on hand at the date of the report. Headings worded to correspond with such information are arranged horizontally across the sheet, as shown in Form 6, while the names of the various tools appear in the left-hand vertical column; or, as the list is a long one, the report is usually arranged in the form of a double-column sheet. The list includes every kind of tool in common use on track, and blank lines are left for writing in the names of special tools. A list of the tools in common use on railway track is given in Chap. IX, § 116. On some roads the monthly reports for tools and materials are combined on the same blank, one side of a long sheet being used for the tools and the other side for the materials. The following instructions are found on the tool and material reports of various roads:

Section and other foremen will be held personally responsible for all tools and materials in their charge, and will be required to make this report in full, and send to their division roadmaster, with the time sheet, at the end of each month.

All worn-out tools to be sent in for renewal must be plainly marked, giving the number of articles and the section to which they belong. Notice of number and kind of tools sent for renewal should be sent by letter at the same time.

Broken tools must be sent to the storekeeper.

The quantities reported must be ascertained by actual count and not estimated. Keep an accurate copy of each report.

When a foreman leaves the service of the company the roadmaster must

see that all tools and other company property charged against him are properly accounted for, and must examine his time books to see that all accounts are correct. When such is not feasible settlement for pay due him should be deferred until after the new foreman sent to take charge has checked over the old foreman's final reports on tools and material and forwarded the same to headquarters.

When a foreman takes charge of a gang he must receipt for all company property delivered to him by his predecessor.

Material Reports.—The usual column headings for the foreman's monthly report of material are as follows: Material—(In the next column to the right the "No. ft.," "No. Pairs," "Lbs.," "Lin. ft.," "Ft., B. M.," "Cu. Yds.," etc., or whatever term is necessary to designate unit of quantity is put down in writing)—On Hand First of Month—Taken Out of Track during Month—Received during Month—Where Received From—Used during Month (with the sub-headings "In Main Line Repairs," "In Side-Track Repairs," "In New Construction")—Shipped during Month—Where Shipped to—On Hand End of Month—Remarks. Under the heading "Material," in the left-hand column of the report, appear the names of the standard materials, or materials commonly used on the road, with blank spaces for writing in odd material not shown on the printed form. Form 7 is a sample head for a report of material. It is usual to classify steel rails according to length and the condition with respect to wear; iron rails, being now used only in side-tracks, are classified as "Of Use" and "Scrap." The following is an ordinary form of classification for steel rails, together with a list of instructions that is frequently printed at the bottom of the report of materials:

Classification of Rails.

First Class.—Whole rails that have never been in track.

Second Class.—Rails not too badly worn for main-track use, which have been taken out to make room for laying new steel continuously; also new or worn pieces of rail 14 ft. long or longer, fit for main-track repairs.

Third Class.—Rails fit only for use in side-tracks, if 3 ft. long or longer, and better rails in pieces from 3 to 14 ft. long.

Scrap.—Rails too badly worn for side-track use and all pieces less than 3 ft. long.

General Instructions.

All material reported above is supposed to be on hand and not in use.

All ties and timber reported as taken out of the track during the month, if decayed too badly for use again, should not be accounted for as on hand at the end of the month; but all other material taken out during the month, and not shipped, if not appearing on hand at the end of the month, should be accounted for in the "Remarks" column; for instance, broken splices, when thrown into the scrap pile, should be so accounted for.

This report must be made up by actual count of the quantity of material, and not by estimation.

As with the report on distribution of work, so with the report of materials, some companies require their foremen to fill out additional separate reports for special kinds of material received and used during the month, such as rails, ties, lumber, etc.

The foregoing remarks cover the reports usually sent in monthly or at other regular intervals. Besides these there are a number of forms or blanks in common use for reporting construction work, accidents and other occurrences, which are made out and forwarded as occasion requires.

Report on Rail Failures.—It is quite usual to take careful records of broken rails, or rails which fail irregularly in other ways, and the report form on rail failures on some roads calls for a great deal of detail information. Following are column or line headings that are used on the report blanks of various roads: No. of Rails—Length of Rail—Weight per Yard—Square or Miter End—Brand and Marks—Date Marked on Rail—Length of Time in Use—Cause for Removal—Nearest Mile Post (with the subheadings No., Direction and Distance)—Kind of Joint Fastening—Kind of Ballast—Which Track, North-bound, South-bound or Single—On East or West (North or South) Side of Track—Date of Breakage—At What Hour Discovered—By Whom—Broken on or off Tie—Was there any Sign of Flaw—If Broken, Give Length of Pieces—Which End was Broken, Receiving or Leaving—Approximate Temperature at Time Break Occurred—When had Track been last Patrolled—What do You Think was the Cause of Break—Was it on Curve or Straight Line—Condition of Track Surface 100 ft. Each Way from where Break Occurred—When Repaired—In What Way Repaired—What was Done with Rail Taken out—Label Number of Stored Pieces—Marks or Brand on Rail Put in to Replace Rail Taken out—Remarks. The blank for record of broken rails on the Burlington, Cedar Rapids & Northern Ry. has the following list of questions on the back:

Cause of Breakage.

Was break in cut?
Was cut well ditched?
Was track in good surface?
Were ties good?
What was the distance from center to center of ties at the break?
Were all the ties of same thickness?
Was track heaved by frost?
Was rail full spiked?
Was it a cut rail?
Was rail shimmed?
Had any of the shims worked out?
Do you think break caused by flat wheel?
What was the number and speed of train when seen?
What was track ballasted with? (Loam, Sand, Gravel or Rock.)
Was break on straight track or curve?
Was break on bridge or cattle guard?
Was break at fish plate hole?
Was train ditched?
What damage done?

The following instructions are commonly found at the bottom of reports on broken or damaged rails:

Instructions.

Section foremen will send this report to the roadmaster as soon as may be practicable after steel rails have been removed from track, and careful investigation has been made.

Be careful to report brand and marks correctly, and see that all information called for in this report is given for each and every rail taken up.

When two or more rails of the same length are taken up, on the same day (except in the case of rails damaged by wrecks or broken wheels) for the same cause, of same marks and brand, and whose histories are alike in every particular, they may be reported together by stating the number of such rails in column headed "No. of Rails," but when there is any difference whatever in the marks, brands or record, each rail must be reported by itself, on a separate line of the report.

A piece of rail about 12 ins. in length should be cut from the pieces each side of the fracture in broken rails. These pieces should be labeled and numbered so that they may be readily identified when it is desired to inspect the fracture at some future time.

This is a special report required for the purpose of identifying failures in guaranteed rails. The monthly report of materials must be made out just the same as though this report had not been made.

Report on Broken Splices.—The Lehigh Valley R. R. supplies its foremen with blanks for a monthly report of broken splices in main tracks. Following are the column headings of this report: No. of

Splices Taken out—Between What Mile Posts—Date When Put in Use—Inside or outside Splice—On Curves; High or Low Rail—On Straight Line—Open or Close Joint—Surface of Joint—Kind of Ballast—Weight of Rails per Yard—No. of Iron Splices—No. of Steel Splices (with the sub-headings "4 holes" and "6 holes")—East or West-Bound Track—Description of Break—Cause of Failure.

Report on Side-Track Construction.—Form 8 shows an ordinary blank for reporting labor and material in new side-track construction. The same form would also answer for new track construction of any kind.

Form 8.—Report of New Side-Track Constructed.

Report on Structures.—With a view to keep informed on what is being built along the line of the road adjacent to the track, as well as to obtain a record of all structures built on the right of way, it is usual to have a report blank to cover the information desired. Form 9 is a sample of such a report.

............R. R. Company.
..................................Division.

REPORT ON STRUCTURES ADJACENT TO TRACK.

TO SECTION FOREMEN:

No structure shall be erected upon the company's property without the written consent of the superintendent. You must report to the roadmaster any violation of this order.

In all cases of New Buildings, Fences, Platforms or any structure whatever, commenced on your section within———— feet of the center of the main track, you are hereby required to furnish the information, as noted below. Fill up one of these blanks and forward it at once to the Roadmaster.

1. **Name of party building,**
2. **What is he building?**
3. **Distance from Center of Main track or Side-track; say which, or give both.**
4. **On which side of Track.**
5. **Name of nearest Station.**
6. **Distance East or West of said Station.**
7. **No. of Lot (if in a town).**
8. **Who gave Right of Way to R. R. Co.?**
9. **Any other general information.**

.................................., **Foreman.**
Section No.........

Form 9.—Report on Structures Adjacent to the Track.

Report of Stock Killed or Injured.—Reports of stock killed or injured are made by the conductor and engineer of the train which strikes the animals, and also by the foreman of the section where the accident takes place. On some roads, however, the report blank for this purpose is filled out by the station agent, from the verbal report of the foreman. The agent is supposed to repeat the questions printed on the blank and then write down the replies of the foreman. Both the agent and the foreman then sign the report. When stock cannot be buried at the point where it is killed it sometimes costs a good deal to remove the carcass to another point. One cheap way to dispose of killed stock, if the material is at hand, is to pile old ties or other waste wood on the carcass and burn it. On some roads such work is attended to by the track-walkers. Form 10 is a report blank with the questions used by various railways regarding the particulars of accidents to stock struck by the trains, followed by the usual instructions to section foremen.

Instructions to Section Foreman.

You are required on the same day you learn that any stock has been killed or crippled on your section, to fill this blank with the information required, and deliver the same to the Station Agent, to be forwarded by first train to your Division Superintendent. Be particular to answer the questions correctly. Make no statements that can be truthfully contradicted.

When stock has been injured on your section, if possible, notify owner, and request him to take charge. Assist him in removing crippled stock if he requests it. When stock is struck on a public crossing or on station grounds you should first notify the owner to take care of his property, as the company is not liable for stock struck at such places, but in case he refuses the animal should not be skinned, but buried with hide on. When cattle are killed and the owner cannot be found, or will not take possession of the animals, sell the meat to the best advantage and give the cash proceeds to the agent or remit with letter of explanation. Salt all hides immediately and thoroughly as soon as removed from stock.

When animals are injured by having their legs broken, or otherwise wounded so as to be past recovery, they should be slaughtered and sold to the best advantage for the company, and proceeds of sale handed to agent.

Keep a correct record of the brands and marks.

When a number of animals belonging to different persons are struck at the same time and place, make separate reports relative to the property of each owner.

In case the animal or animals are removed before you are informed of the accident, you must report all the information you can obtain in reference thereto, as required within, giving names of informants.

You are expected to acquaint yourself with the value of different kinds of stock, so that your estimate of damage will be correct. Guard against placing values too high or too low.

You are requested not to state to the owner your opinion as to what proportion of the value of stock will be allowed by the Company, or to admit any liability under any circumstances.

Inform owners of stock killed that to insure a prompt adjustment of their claims, they must communicate direct with the general claim agent at..........

......................, Superintendent.

Form 10.—Report of Stock Killed or Injured.

Fire Reports.—Section foremen are expected to make a report of all fires that start along their sections, when property is destroyed, whether in their opinion the company is liable or not. Careful investigation should be made concerning the origin of such fires and the progress of the same, and, particularly, whether reasonable effort was made to put the fire out or stop its progress. Form 11 is the usual blank for reports on losses by fire.

...........RAILROAD COMPANY.

SECTION FOREMAN'S REPORT OF FIRE LOSSES.

Immediately after a fire, the Foreman of the Section where it occurred must notify the Division Superintendent, by telegraph, of the fact, and then fill out this blank and send it to him by FIRST TRAIN. If several pieces of property are burned, make a separate report for each owner.

To....................................

Division Superintendent,

at ....

A Fire started on Section No.......on the......day of................190....

Questions to be Answered by Section Foreman.

Name and residence of owner of the property destroyed ....

Name of tenant, if rented ....

About how far from the property burned did the fire originate?..................

Was the property located upon land owned by the Railroad Company?............

Give name of the nearest station............Post office address of owner..........

Was it north, south, east or west of this station?......How far from station?......

EXACT time of day or night fire started...

Origin of fire..

Distance from center of track to place where fire started............feet..........

Width of right of way........................

Did the fire start on the right of way?..........Which side of the track?..........

Condition of right of way (What combustible material)..........................

Had right of way been mowed, burned or cleaned off?.......If so, when.........

If not, why?...

What was the extent of the fire?...

Distance from center of track to property destroyed...........................

What had owner done to protect his property from fire?.........................

Did owner assist or furnish assistance in putting out the fire?................

Was wind blowing high or low?..........From what direction?................
Were there other fires in the same neighborhood at the same time?...............
If so, give the origin of these fires...
Did other parties lose by the same fire? If so, give their names. (Important.)
....
Who was first at the fire?...
Was fire caused by section hands?...
What was exact time last train passed?..........What was No. of train?..........
Was it a passenger or freight?...................... If you know the fire was set by an engine, give the number and state the facts leading you to believe that it was set by such engine ....
....
How soon after the fire started did you get to it?...................................
Did you or your men assist to put out fire?...

Description of Property.

....
....
What is your estimate of loss? $..... If fence, how many boards or rails high?.... No. of panels burned..........No. of posts..........If meadow or pasture, number of acres..............Kind of grass............If standing grass, give number of acres............Hight of grass..............Kind of grass..................
If trees, give number........kind..........age..........approximate hight...... and whether burned all around or on one side, and on which side..........
If hay, number of tons. (Give length, breadth, number and approximate hight of stacks)........Price per ton at nearest market at time of fire, $......(Important). If straw, what kind..........Length, breadth, number and approximate hight of stacks) ....If grain what kind...........Number of stacks................ Dimensions of stacks..............Number of shocks..........Number of bushels (threshers' measure)..........Price per bushel at nearest market on day of fire, $..........Had there been any recent rains, or was it dry? .... Give the names and addresses of all witnesses of the fire...............................
....
How much is the owner's claim for damage?..
If the building belonged to the Company, what kind? ....
Used for what purpose?...
Dimensions...

Date..................190....

Form 11.—Report on Fire Losses.

Casualty Reports.—Section foremen are expected to report to the roadmaster, by wire, every case of derailment to engines and cars on their sections, and injury of any kind to persons, no matter how trivial, as the result of such derailment, or injury happening to any person on the track in any manner. This includes people injured at road crossings, and employees hurt on hand cars and in other ways. In case of injury to persons the name of the person is given and the nature of the injury. As soon thereafter as he is able to do so the foreman must write out the full particulars and forward the report promptly. The reports of derailments should be filled out as fully as the information can be obtained, and these should be retained by the roadmaster in convenient shape for future reference, in case he is called upon to defend the track against the reports of the train men. Form 12 is a sample of a casualty report blank.

Form 15.—Work Train Report.

It is also well to observe that in the work train foreman's daily report (or conductor's report, if he acts as foreman) it is usual to require a report of each car and what was done with it. Following are the usual column headings: Car No.—Whose—Loaded (when taken)—Empty (when taken)—Where Loaded—With What Loaded—No. of Cu. Yds. or Pieces—Weight—Amount—Where unloaded—Where Left (with the subheadings "Loaded" and "Empty"). The "Remarks" column is headed as follows: "Work-train foremen will make a brief statement in the space below, noting all delays and explaining the cause, with any other remarks of a special character." At the bottom the blank is ruled and headed for a summarization of the work performed, as follows:

Engine No ....Engineer ....Conductor..............

the supervisor or roadmaster, who passes upon it, scrutinizing the items carefully for unnecessary requests. In cases he may find it advisable to make alterations, or he may withhold it from issue pending an explanation from the foreman concerning the need of certain articles ordered. He then forwards it to the storekeeper or to higher authority for approval. Foremen are usually instructed to send in their requisitions on the first of the month, or at appointed times. This order is not, of course, supposed to cover supplies needed in haste. In such cases the foremen frequently order from the roadmaster by wire, requesting immediate shipment. For such sudden calls the roadmaster usually keeps at headquarters, independently of the storekeeper, a small stock of the different patterns of frogs, switches, etc., quantities of fastenings and other commonly needed supplies, neatly arranged on skids or platforms conveniently located for loading into baggage cars when the urgency of the situation requires such things to be forwarded by passenger train. Where considerable quantities of supplies are needed, as in new construction, it saves a good deal of labor and unnecessary handling to have them shipped from the manufacturer direct to the point of use.

Foremen should read carefully the instructions on all reports with which they have to do, and try to get a clear understanding as to how it is desired they should be filled out; and try to answer in a direct and clear manner all questions asked. Information relating to the matter of any

report, which is not provided for by a headed line, or by a place for "remarks" or otherwise, should, if the foreman thinks it of importance, be written on a separate slip of paper and pinned to the report, the foreman signing his name thereto. It is a good plan for foremen to retain duplicates of such reports sent in as include the heading "On Hand at Last Report." It is usual to furnish each foreman with two copies of time rolls, tool reports and material reports, so that he may retain a copy of each report sent in. Another plan is to send the foremen their blanks for the succeeding month in time to copy off such data as will be necessary to start the new report, before the report of the present month is sent in. It might also be arranged to supply the foremen with sheets or blanks for duplication of pen writing. In still other cases the roadmaster's office, in sending out the new blanks each month, fills in the column calling for the quantity on hand at last report. It is also convenient for the foreman to retain duplicate copies of requisitions sent in, and on some roads the requisition blanks are arranged for duplicating by the insertion of a carbon sheet. Blank books of pocket size with pages ruled for distribution of work should also be furnished the foreman for convenience of taking note out on the road when the work is performed. He can then copy from this to the regular reports sent in and be able to give the information with greater accuracy than otherwise; for duties will so press a foreman day and night, at times, that he cannot afterwards recall just how all the work was divided. This book he may retain for his own reference, and very convenient he will often find it, too. Changes of foremen or transfers from one section to another, except, of course, in emergencies, should be made at the beginning of a month, so that the man in the new place may start his reports even with the month; otherwise there is a splitting of reports.

The reports required of roadmasters by the higher officials usually call for summarized accounts of the items embodied in the reports of distribution of work from all the section crews, yard gangs, floating gangs, and work-train foremen, together with work performed at wrecking, his office and store-room expenses, tool repairs, etc.; also a report giving the sum total of the tools and track materials received, used, and accounted for at the end of the month, for his division. In other words he makes up an office record giving the total expenditure under each account for the division, for each month of the year, with the average annual cost per mile for each account. Such reports are made to the superintendent, engineer of maintenance of way, or chief engineer, according to the organization of the maintenance of way department. The roadmaster may also be called upon to fill out special blanks specifying all changes in the physical condition of the road and right of way during the month, such as new track built or track taken up, new rail laid, new ballasting, new fence built, etc., and the location of each piece of work; all of which may be gathered from the reports of his foremen. Labor and materials chargeable to maintenance and new construction are of course kept separate. Forms for such reports are similar to those used by the foremen.

Another system that comes highly recommended is one whereby all labor and material reports are digested and summarized in the office of the general roadmaster or engineer of maintenance of way. At appointed intervals, usually every month, the track foremen make their reports to the roadmaster or supervisor, who carefully examines them, giving his approval, if correct, and then passes them on to the general officer of the track department. Before forwarding these reports, however, he makes up an office record of all material on his division and of the total expenditure of labor and material under each account; this to be retained in his office for reference. In the office of the engineer of maintenance of way or general roadmaster the force of clerks consolidate the different section reports for each division into one summarized statement for the division. One of the advantages claimed for this system is that it reduces the clerical work of the roadmaster's office to a minimum, giving him more time to devote to the field than would otherwise be the case.

On some roads the engineering department requires yearly a permanent record of the right of way and all property and structures thereon. The blanks are made to be filled out by the section foremen, and are headed to show the "Number, Length or Amount at Last Report"—"Added Since Previous Report"—"Removed Since Previous Report"—"Remaining at this Report"—Remarks. The left-hand column is worded to show the amount of all kinds of railway property, such as the number of miles of main, single and double track, the number and total length of sidetracks, measured between frogs; the length and kind of fence, number of railway and highway crossings, the number and kind of frogs, switches, cattle guards, culverts, stock pens, number and kind of dwellings, tool houses, sign boards, mile posts, water stations etc.

Correspondence.—Correspondence between railway officials and their agents or employees, known as "railway mail," is carried in the baggage service. Such matter is usually marked "R. R. B." (Railroad Business) or "R. R. S." (Railroad Service) and is supposed to relate strictly to the business affairs of the company, private correspondence being forbidden by the regulations of the postoffice department. Foremen should keep well posted as to the wishes of the roadmaster regarding all matters between them, and when doubt arises they should write and find out, and not delay a week or more waiting for the roadmaster to come around, or try to catch him for a moment on some train while stopping at a station, when, as usual, there will be a number of matters to engage his attention all at the same time. In cases of emergency they, of course, communicate by telegraph. When questions are asked by letter it is a good plan to write the answer on the reverse side thereof, or on a separate piece pinned to the question, so that the question may be returned with the answer. This saves stating the question over again in the answer and may make the answer more understandable; for where scores of notes are sent out every day from the office it cannot be expected that all can be remembered, and it is too much trouble to take copies of the least important ones. Foremen should be prompt in answering all correspondence with the headquarters and in forwarding their reports. If practicable they should be sent by the first train after the time arrives for the reports to be closed. The same promptness should be observed at the headquarters in corresponding with the employees.

The practice of using the telegraph service for transmitting information between the employees and the heads of the various departments is quite commonly abused to such an extent that the wires are overburdened with work, and delay in the transmission of messages of importance is the result. It frequently happens that a message filed after 4 p. m., which would not ordinarily receive attention or be answered before the next morning, can be sent by train mail and reach the destination early enough during the night or early enough the next morning to secure the desired result, if special attention be given to such messages by the employees handling the railway mail. To relieve the telegraph wires of messages of this description a number of roads have adopted the use of the so-called "pink

envelope" or "traingram." This scheme simply provides an envelope which by its color plainly indicates the character of the message enclosed, so as to insure special attention at the hands of the baggage men and other employees concerned in the prompt delivery of such mail. Form 19 is a reproduction from one of these envelopes.

195. Track Inspection.—This subject brings us to the dress parade part of railroading. The kind of inspection that is considered on previous pages refers principally to observation of the condition of the track with respect to its safety for the passage of trains, whereas the object at present in view is to consider methods and means for examining track more especially for the purpose of comparing its condition and the surroundings with established standards or with ideals. Track may be inspected for such a purpose in two ways—by observation and by mechanical devices or recording instruments. The most thorough manner of inspecting track by observation is to walk over it and look closely into all the details which affect its condition; but such is necessarily a slow process, and such thoroughness is not desired for all the purposes for which track inspections are made. For most purposes it answers well enough to note the condition of things as they appear from a moving train, the smoothness of the track being judged by the riding of the cars. On many of the railways of the country, especially on some of the large systems, the track is inspected annually by the chief officers of the road, in company with the maintenance-of-way officials. Such inspections are nearly always made by observation from trains, for the purpose of comparing the general condition of the track and company property with that of other years, or to award prizes to the various grades of petty officials whose track is found in the best condition. On such occasions it is customary to appoint committees to carefully observe and mark the several details or features which determine the standing of each section of track. To be worthy the name of an "inspection of track" the trip must be systematically conducted—something more than a mere pleasure excursion, where the inspection party occupies the rear end of a finely upholstered observation car to gaze out upon the track through a haze of cigar smoke, at occasional intervals between stories.

The usual arrangement for conducting an annual inspection of track is to seat the marking committees at the open end of an observation car having the seats arranged in tiers, sloping back from the end of the car. In some instances an outfit is improvised by placing seats in a box car with an end knocked out, while some companies have a coach with a glass front or end, permanently fitted up for the purpose. The observation car is sometimes placed at the rear of the inspection train and at other times, and preferably, it is the practice to push it at the head of the train, giving a better opportunity for close observation of things. Such inspections are usually made during the fall of the year, after the winding up of the renewals and other important work of the season. The marking committees are supposed to take note of those conditions of the track which stand in relation to the labor performed upon it and the supervision thereof, such as line and surface, gage, level, elevation of curves, tightness of bolts and the general condition of the joints; the dressing of the ballast and shoulders, spacing and alignment of ties, the working condition and alignment of frogs and switches; the general condition of side-tracks and fences; the neatness of the track and right of way respecting the cutting of grass and weeds, and all such matters as come under the head of policing; the neatness of station grounds, section houses and yards, and tool houses; drainage conditions, which involve the condition of ditches and culvert ends; the condition of highway crossings. Where the awarding of prizes is involved in the inspection it is also customary to take account of the expense of maintenance, and on some roads also the number of failures of signal lights reported, accidents on account of defective track, including side-tracks; obedience to orders, general attention to duty, and accuracy in making reports.

In the practice of some roads each member of the inspection committee is supposed to take note of all features on which ratings are desired, and mark accordingly, but more usually the work of the committee is systematized, so that one man, or sometimes two men, are appointed a sub-committee to mark for each feature, being supposed to confine the attention to the single feature or detail. Thus, in the inspection of track for alignment, it is usual for the sub-committee on that feature to take a position directly over one or both rails, each member confining his attention solely to one rail. In the inspection of track for surface the inspector takes a position as far to one side of the car and as low down as he can get, so as to be able to catch the surface outline of the opposite rail to best advantage. He then devotes his attention entirely to that rail. Switches are inspected by stopping and making careful examination of the parts and their adjustment and of the alignment of the main track and turnout lead. For testing the gage of the track the engineer is signaled at random to stop, and this is sometimes done several times on each section. The level of tangents is tested by a level indicator on the car or by leveling across the rails when stopping. Stops are also made at curves to test for gage and for curve elevation.

The usual speed of an inspection train is 12 to 20 miles per hour—more frequently the latter speed. In some cases it is the practice to first run the inspection train over the track at high speed, in order to find the irregularities in line and surface to best advantage, and on the return trip to run at slow speed and take close observation of the condition of the ballast, ditches, culverts, switches, policing, etc. On the Pennsylvania R. R., where the managing officials have always laid stress upon an annual inspection of track, the inspection of the main line between New York and Pittsburg is a somewhat elaborate affair. The general manager, all the general superintendents, the general superintendent of transportation, general superintendent of motive power, superintendent of telegraph, principal asst. engineers, superintendents of motive power, general agents, division superintendents, chief engineer of maintenance of way and assistant engineers take a train in New York in the morning, run through at the rate of about 40 miles per hour, arriving at Pittsburg in the evening. The next morning the party, which now takes in the supervisors and assistant supervisors, is split up into four or five train-loads, which start back toward the east inspecting matters in detail, a whole day being devoted to each of the four superintendent's divisions between Pittsburg and New York. The marking committees are five in number, as follows: Committee No. 1, on line and surface; committee No. 2, on freight tracks and sidings, frogs and switches; committee No. 3, on ballast, joints and tie spacing; committee No. 4, on ditches, road crossings, station grounds and policing; committee No. 5, on telegraph lines and fixed signals. The whole party, which numbers about 200 men, is divided among the five committees, each class of officers being represented on each committee. On branch lines and on the Lines West of Pittsburg the general inspection does not take place every year.

On the Louisville & Nashville R. R. the duty of inspection is divided between five committees of one member each, and in addition a "revisory" committee composed of two members, all of whom are appointed by the chief engineer. The "five committees" are seated in the rear row of seats of the observation car at the rear of the train, positioned from left to right as they would appear to one standing in the car and looking toward the rear, as follows: Committee No. 1, on line and surface; committee No. 3, on spiking, switches and sidings; committee No. 5, on station grounds and policing; committee No. 4, on ditches and banks; committee No. 2, on joints and spacing of ties. The two members of the revisory committee sit in the middle of the next row of seats. The office of the revisory committee is "To interpret the instructions and specifications governing the annual inspection; to give a general supervision to the inspection, watching the work of all the inspectors as far as possible, and from time to time to check the markings of the different committees. If both members of the revisory committee agree that any committeeman is marking too high or too low, they shall instruct such committeeman to correct his marking accordingly, and their instructions shall be obeyed. An appeal may be made to the revisory committee from the markings of a committeeman." The car has a glass end extending over the rear platform, with seats arranged in tiers, so that those sitting on the back seats can see over the heads of those in front of them. In front of each member of the inspection committee there is a series of electric push buttons connected with a number board near the top of the car, the numbers on the board corresponding to those on the buttons at the service of the inspectors. The number boards are plainly visible to all sitting in the car, so that the rating of each committeeman on each mile can be seen by all present. The committees are composed of roadmasters and superintendents who have been roadmasters, with exception of committee No. 5, who is usually a superintendent. The revisory committees are selected from roadmasters or superintendents who have been roadmasters, and who are considered to be the most experienced men available.

On this road the committee on line and surface occupies a position directly over one rail and inspects that rail for line and the opposite rail for surface. Perfect surface requires that the tops of rails be level transversely on tangents, except at the entrance to curves, uniform elevation of outer rail on regular curves and elevation varying with curvature on spirals. Short sags, within a space of ten rail lengths, are counted as irregularities. When repairs to bridges or trestles, or other work requiring trains to run at a less speed than ten miles per hour, are being made, such piece of track is not considered in the marking. In the inspection of joints points are counted off for the following irregularities: missing bolts, missing spikes, joint out of line, joint out of surface, joint ties not properly spaced, improper allowance for expansion in the rails. Spikes must be driven straight and have a proper bearing against the flange of the rail. In the rating for spiking marks are counted off for spikes missing, spikes not driven down, and for improper position of spikes. In the rating for switches and sidings marks are counted off for headblock not properly banked, point rail not fitting snugly against stock rail, rattling of frog or switch, stock rail badly worn or bent, lead of switch not symmetrical, guard rail not in accordance with standard plans, siding not to proper grade, bad line and surface, space between tracks not filled level with tops of ties, targets of switch stands not parallel with and at right angles to the track or for colors not bright. In the rating of ditches and banks points are marked off for roadway less than standard width, imperfect slope of embankment or cut, edge of ditch or fill not parallel with the rail, embankment supported by old ties or timber, imperfect drainage on embankments or in cuts, imperfect berm at foot of fill, lack of surface ditches, imperfect sod line, bad surface of roadbed. In the rating on policing points are marked off for failure to cut right of way, old ties scattered around, rubbish not burned, unsightly holes dug in the right of way, water standing in borrow pits where drainage is practicable, earth not leveled off on tops of cuts, scattered ballast, stumps on the right of way, sign and other posts not erect or in good condition, imperfect road crossings.

In rating divisions or sections as to expense it is customary to deduct from the total expense for the year the cost for new construction and all other extra work. The sections are also credited with the number of ties renewed, the amount of ditching done, and the amount of new rail laid, a certain rate being allowed for each unit of such work performed. Where there are different kinds of ballast, such, for instance, as stone and gravel, a higher credit is allowed for the ties renewed in the stone ballast. After deducting these credits the division or section showing the least balance is awarded the highest standing in the matter of expense, and the other sections accordingly. On roads where the rails on the different sections are of different ages or of different weights per yard it is sometimes customary to give some credit to the sections laid with old rails or with rails badly worn, marking them one or more points higher, arbitrarily, after the ratings for joints and surface have been made. The principle of such practice is proper, because it may rightfully be assumed that old rails are splice worn at the joints, as well as that the splices are worn, which conditions increase the difficulty of maintaining the joints in surface. Rails which have been in service less than one year are in such cases considered as new rails. For obvious reasons credit should be given the sections laid with the lighter rails.

On various roads the ratings are marked by the roadmasters, supervisors, the assistants of these officers, assistant engineers, division engineers, and in some cases by the division superintendents, no officer who is eligible to a prize or for special mention marking for his own division. On sound principles, however, no officer who is liable to benefit by the results should be permitted to mark at all, for one disposed to be unfair could put relatively low marks on some of the best divisions, which would certainly inure to his own advantage in the general average. On the Boston & Albany R. R. the chief engineer and the division roadmasters compose the marking committee. On a fewer number of roads, however, it has been the practice to compose the marking committees of section foremen, each foreman marking every section except his own. The idea in this arrangement is to educate the foremen in critical methods, the supposition being that such a training ought to make them better judges of their own work, and at all events develop their faculties for observation. On some roads where the prize system is in force all of the section foremen are taken over the road together, after the prizes have been awarded, so as to give them the opportunity to see for themselves the appearance of the prize section and compare their own sections with others.

On the Union Pacific R. R. the official inspections of track are made by the officers and section foremen together. The section foremen are supposed to critically examine the track and are required to vote their opinions on the section in best condition. There has been no prize system on this road, but inspection trips of this kind are made over each division twice each year, during the spring and fall. The car used on these occasions is illustrated in Fig 529. The platform of the car is mounted on easy riding trucks and the seats extend crosswise the car in tiers, amphitheater fashion, giving those in the rear an unobstructed view over the heads of persons sitting in front. The car has a canopy roof stretched over the tops of well-braced iron posts and side stakes. The seats do not extend entirely across the car. On the side opposite that which shows in the view there is an aisle or passageway the length of the car. At the front of the car there is a cowcatcher and platform, with a swinging door leading from the platform to

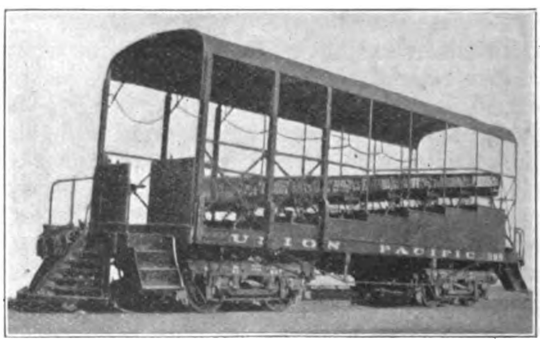

Fig. 529.—Track Inspection Car, Union Pacific R. R.

the first row of seats. At the front of the car, at the right side, there is a seat for the conductor, with an air-brake valve, an air whistle and an air signal for communicating with the engineer. When the car is in inspection service it is pushed ahead of a locomotive, where the best opportunity is afforded for viewing the roadbed and surroundings, and all discomfort and inconvenience arising from smoke and cinders is avoided.

On the Pennsylvania, the Boston & Albany and the Cincinnati, New Orleans & Texas Pacific roads a track indicator car forms part of the train on annual inspections. On the two roads first named the records of this car are not taken into account in determining the standing of the divisions and sections for the awarding of prizes. On the Cincinnati, New Orleans & Texas Pacific Ry. (Queen & Crescent Route) two sets of premiums are awarded, one of which consists of a gold medal, for the best roadmaster's division; and money for the best supervisor's division, best, second best, and third best sections, and best yard on the road. These prizes are awarded according to the usual system of markings based upon observation. The other set consists of money prizes awarded upon the line and surface records of the indicator car, to the foremen in charge of the best, second best and third best sections on the road and to the supervisor whose track has undergone the greatest improvement during the year. In looking over all the awards for one of the years it is interesting to note that in no case did any award as determined by the records of the indicator car correspond with any one of the awards made upon the basis of markings from observation; which is as much as to say that if the registrations of the indicator car were reliable, then none of the divisions or sections awarded premiums upon the usual basis of visual observations were found to be best in line and surface. On this road cards containing the averages of the inspection markings on each section are issued by the superintendents to the foremen, so that they may know in what respect their sections are not up to standard, and try by another year to make improvement in those particulars in which the inspection shows their work to be deficient.

In striving to arrive at the fairest estimate of the condition of a piece of track the relative value or weight of the different subjects marked upon is of great importance. On this matter an experienced trackman would be impressed that the officials who have arranged the details of the markings in the track inspection of many roads about the country have a poor appreciation of the relative value of the various conditions of excellence in track, for in many instances each of the whole list of subjects on which markings are made is given the same importance as line and surface, which, as every maintenance of way man ought to know, is the highest criterion of good track. By all odds line and surface should be given a high count in averaging the markings of the various subjects, because the condition of the track respecting line and surface is the condition which has most, if not all, to do with the riding of cars and the wear and tear to rolling stock. Moreover, to have good line and surface it is essential to have the ties properly spaced (which, by the way, does not imply an even spacing, if the ties be of different sizes in width of face), the bolts tight on the splices and good drainage. As a general proposition it may without serious error be assumed that the foreman who maintains his track in good line and surface attends to numerous other details, such as proper spiking, drainage, tie spacing, tightening bolts, leveling, etc., which frequently receive the same consideration in an average of markings as does the very result toward which the work involved in these items is devoted. It does not follow, however, that good surface will always be found where the ties are properly spaced and aligned, spikes properly driven, bolts tightened, and the drainage conditions good—indeed such conditions might be perfect and still the track surface very poor. Under ordinary conditions the work of maintaining track in good surface is the most laborious matter with which trackmen have to contend, and its cost is the most expensive part of track work. Laying aside the question of safety, line and surface are the most important conditions affecting track. The labor and expense of maintaining track in alignment are, however, comparatively small, so that, as between the two, track surface should receive the greater consideration. In my way of thinking, no basis for determining the standing of trackmen as to the condition of the track under their charge can be rational which does not count line and surface on a scale at least as high as 50 per cent. On the basis of 100 marks for the whole list of subjects considered my idea of an equitable arrangement would find expression about as follows: Surface, 40; line, 10; drainage and banks 12; switches, frogs and side-tracks, 12; expense 20; dividing the remaining 6 marks between policing and such other matters as one might think should be included, in any particular case.

This principle is recognized in the system of marking in force on the Southern Pacific road, where perfection in alignment, surface, and drainage each receive 12 marks; switches and frogs, 10; houses and grounds, 10; spiking, 7; alignment and spacing of ties, 7; ballast, 7; sidings, 5; material, 5; grass and weeds, 5; road-crossings, 3; fence, 3; and policing, 2. On the

Louisville & Nashville R. R. also this matter seems to have been studied more closely than is usually the case, for line and surface (considered together) have the relative value of 25 per cent; ditches and banks (considered together), 25 per cent; policing, 10 per cent; spiking, 10 per cent; switches and sidings (considered together), 10 per cent; joints, 10 per cent; spacing of ties, 8 per cent; and station grounds, 2 per cent. In marking, a half point is allowed, such as 9½ for a nearly perfect condition, on 10 as a basis. On some roads only full points are used in marking for track inspection. On the Illinois Central R. R. the following ratios of relative importance are assumed in computing averages of markings for track inspection: Line and surface, 25; joints and spacing of ties, 15; drainage, ditches and banks, 20; station grounds and policing, 15; spiking, 10; switches and sidings, 15.

The force of the application of this principle of marking is illustrated in a rating of sections published by one of the roads best known for its system of yearly inspections and premiums to track foremen and supervisors. Among the sections of one of the divisions that which took the first prize was poorest in line, poorest in surface, not the highest in switches, not the highest in drainage, not the highest in "general condition," one of the two highest in the rating for expense and the highest in the marking for sidings, the difference between this section and the next best in the last respect being so large as to make the average rating of this section foot up the highest. In line and surface this section was, compared with all the others, remarkably poor, and had these subjects received their proper relative value, or such value as is given to them by the Southern Pacific, Louisville & Nashville and some other roads, the section which received first prize would, by actual computation, have stood next the lowest on the list. This goes to show that in the awarding of prizes to trackmen the system of marking on at least some of the roads of the country are necessarily based upon an erroneous recognition of the relative importance of the conditions which have to do with the excellence of track. The example just cited illustrates how a foreman, by paying special attention to side-tracks, which require the least expense for repairs, and which cut the smallest figure in wear and tear to trains, may take the prize, even though he may neglect those conditions which are by all odds the most important. Under some systems of marking, a section of track in excellent line and surface, but with a spear of grass or a weed here and there on the roadbed, and perhaps a little ballast not trimmed up on the shoulder, would be rated considerably lower than some other section with no better riding qualities but with the weeds all cut and the ballast trimmed to an exact distance from the rail; and still, the material difference of the conditions might be no greater correspondingly than exists in the same man before and after having his shoes polished.

Track Inspection Apparatus.—Mechanical appliances for indicating the condition of track depend for their operation either upon the relative movements of car wheels or upon the throw of the car body. The most primitive device for testing line and surface is an ordinary water glass filled about three quarters full and set upon a window sill over one of the trucks of a passenger coach. If, in running at good speed, no water is spilled the track is considered to be in good condition in the respects noted. This was a test frequently referred to in the "old days," but obviously the record made by an instrument of this class is not of a permanent character, and rough places in the track are neither closely located nor readily traceable. Another indicating contrivance that is sometimes improvised is a level board rested crosswise a hand car and run over the track to indicate places where the rails are out of level. At any considerable speed the jar of the car separates the bubble and the scheme does not work very satisfactorily.

The best known apparatus for track inspection is arranged in a combined dynagraph and track indicator car devised and built by Mr. P. H. Dudley, inspecting engineer with the New York Central & Hudson River R. R. This car has been in service since the year 1881, with more or less regularity on the Boston & Albany and the New York Central & Hudson River roads, but occasionally on other roads. It is 58 ft. long, weighs 72,000 lbs., and in its exterior appearance resembles an ordinary day coach. The interior is conveniently fitted up for the special service to which it is devoted, about half of the car being occupied by apparatus and the necessary facilities attendant upon the taking of records, and the other half partitioned off into living rooms. Under one end of this car there is a 6-wheel truck with a wheel base of 11 ft., and the springs and side bars are so arranged that the load (39,000 lbs.) is evenly distributed among the six wheels. This weight has not been changed since the first records were taken, in 1881, which enables a comparison of results under the same conditions of weight for all the variations in track construction since that year.

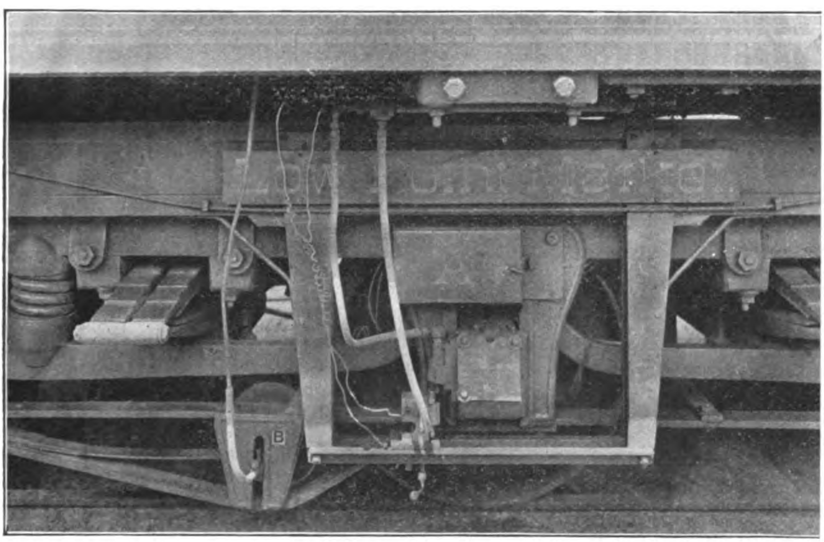

Fig. 530.—Part of Truck, Dudley Track Indicator Car.

The principle upon which the car, with its appliances, indicates the condition of the track is that automatic records are taken of the movement of the middle wheels of this truck relatively to the other two pairs of wheels. Although the middle wheels sustain their share of the load, their connection with the truck frame and with the other wheels is such as to permit freedom of movement vertically, so that the middle wheel on either side moves in response to the irregularities in the rail quite independently of the other two wheels on that side. The wheels on the middle axle are 33 ins. in diameter, with cylindrical treads (not coned), and they are mounted on the axle to run snugly on standard-gage track—that is, with less side play for the flanges than is permitted by the M. C. B. standards. Considering one side of the track, for convenience, it is readily seen how that the movement of the middle wheel relatively to the other two must indicate the amount of surface undulation in the rail and irregularity of alignment within any stretch of 11 ft. of track; in other words, all abrupt irregularities in line and surface are detected. Sags or other irregularities extending over a considerable stretch of track (comparatively with the wheel base of 11 ft.) are not discovered. The middle axle is connected by worm gear with the recording apparatus in the car, which is placed directly over the truck. The journal box movement of each of the middle wheels is transmitted to small levers or recording pens in the car above, which reproduce the movements of the wheel upon a roll of paper drawn over an iron table with a convex top. This roll of paper is 20 ins. wide and is moved at a rate proportional to the speed of the train—one inch of paper to 50 ft. of track. The markings for the irregularities in the rail (vertical scale), however, are to full scale. The gage of the track is detected by a pair of small disks running between the rails, each being pressed against the side of the rail head by springs, which compel the disk to follow the inequalities in the gage and cause the transmission of a record of the same to the paper diagram in the car above. The disks are carried on an auxiliary axle journaled in the pedestal marked "B," Fig. 530. This axle rises when either of the disks strikes the point of a facing frog, and to throw them into gage again requires the attention of an operator. As seen in the figure, the axle is in the raised position and each disk stands over the rail head instead of between the rails, as in the service position.

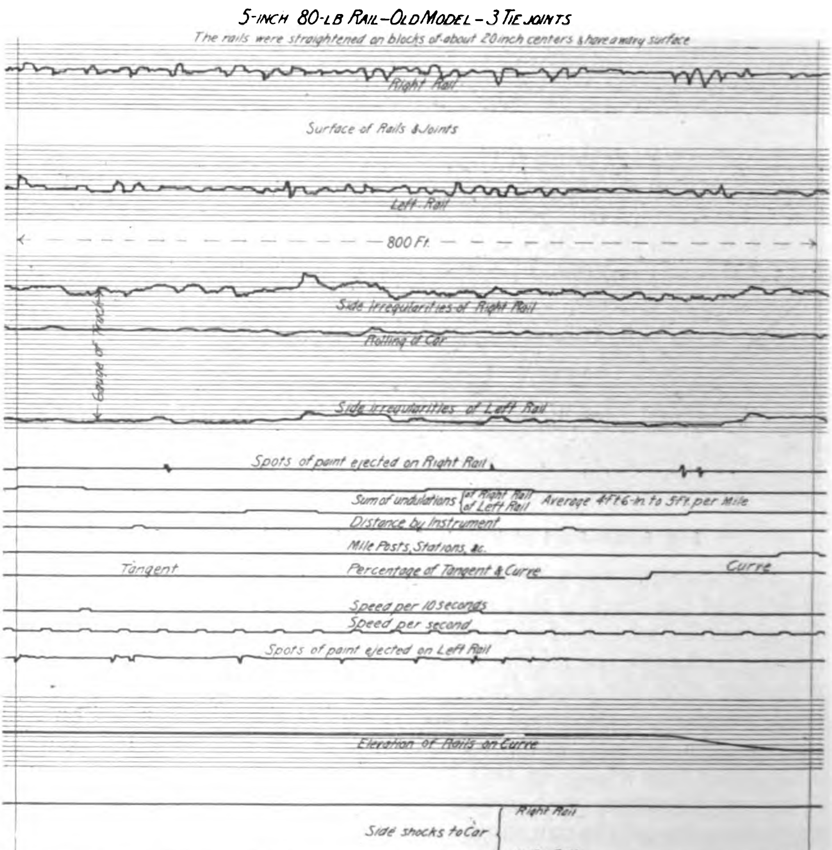

Fig. 531.—Complete Record of Track Inspection by Dudley Indicator Car, New York Central & Hudson River R. R.

The recording pens are 17 in number, showing the surface irregularities and alignment of each rail, the gage of the rails, the rocking or rolling of the car, the spotting of each rail; the summation of the undulations in each rail, in feet and inches per mile, recorded in amounts of 6 ins.; the distance traveled by the car, the same being indicated every twelfth of a mile or 440 ft.; the location of mile posts, stations, bridges, etc.; the percentage of tangent and curve, the speed of the car during each 10 seconds, the speed at the end of each second, the elevation of the outer rail on curves; and the side shocks to the car body, in distinction from side shocks to the truck in following the rails. Figure 531 is a reproduction, to reduced scale, from a complete record showing the markings of all the pens during an inspection of a stretch of 800 ft. of track on the New York Central & Hudson River R. R.

The record made on the paper by each pen is a continuous line traced in red ink. There is a chronometer pen which marks on the paper every second, and as the movement of the paper is proportional to the distance traveled, this time register serves as a means of determining the speed of the train at any instant. The pen which marks the location of stations, bridges, etc., is operated by an observer, who presses a key when the car passes any point the location of which is desired on the diagram. By setting the mechanism when a mile post is found, this pen can be made to record mile posts automatically, and in addition to this a bell is made to ring in advance of each mile post. The change from tangent to curve, or vice versa, is indicated by an offset in the line traced to show that feature. The relative length of the offsets determines the percentage of tangent and curve. For each red line giving information regarding some feature in the condition of the track a number of straight blue lines are marked one tenth of an inch apart, which serve as reference lines for the curved or irregular red line denoting the record. By an exceedingly ingenious arrangement the dropping and rising of each end of the middle axle is made to work a ratchet which sums up the amount of the undulations in the rail, however small—that is, whether of sufficient magnitude to be registered or not. As soon as the undulations amount to 6 ins. one of the pens on the recording table makes a mark on the diagram, so that it is possible to get the summation of the undulations in a given distance, as one mile, for instance. The apparatus for indicating the elevation of curves consists of a pair of pipe-connected cylinders, one on each side of the truck, each cylinder being partly filled with water and carrying a float.

Of course the exact location of any irregularity in the condition of the track is determinable by the relative position of the record mark on the paper, but a more convenient arrangement for the information of the trackmen concerning the track surface is provided. Hanging against each side of the truck, on a light frame supported by the end wheels, independently of the frame which carries the weight of the car, there is a device for marking the location of rough track surface, known as the "low point marker" or "spotter," The mechanism consists of a small force pump or pneumatic squirter in connection with a tank of blue paint in the car above. This apparatus is supplied with pressure by a branch from the air brake system, and it is fitted with an adjustable valve so arranged that it may be set to open upon the depression of the middle pair of wheels in excess of any desired amount. The precision with which the undulations are measured is so fine and the adjustment of this valve so sensitive that the valve will open or remain closed if the depression is but one thousandth of an inch greater or less, as the case may be, than that for which the mechanism is set. Upon the opening of the valve a quantity of the paint is splashed against the web of the rail, opposite the point of depression, thus indicating where rough places in the track surface are to be found. As previously stated, a pen on the recording table, for each rail, makes a mark on the diagram every time paint is ejected. Formerly the spotting apparatus, as used on the Boston & Albany R. R., was set to discharge at a depression of $^5/_{16}$ in., but as heavier and stiffer rails came into use the surface conditions of the track were so largely improved that the apparatus was set to discharge at a deflection of $\frac{1}{8}$ in.

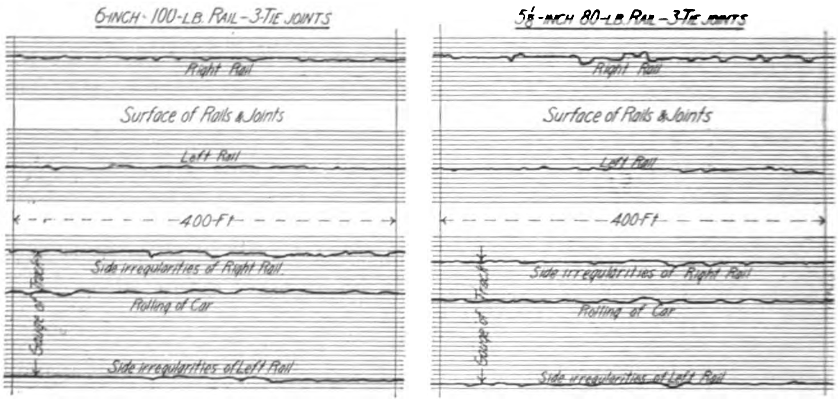

Fig. 532.—Partial Records of Track Inspection by Dudley Indicator Car, New York Central & Hudson River R. R.

The left-hand diagram in Fig. 532 is a record of the surface undulations and irregularities of alignment in a stretch of track on the New York Central & Hudson River R. R., laid with 6-in., 100-lb. rails. This may be taken as a sample of track in good surface, the extreme undulation in either rail being within one tenth of an inch. The alignment of the rails, as shown by the diagram, is not quite as smooth as the surface. The right-hand diagram in the same figure shows the irregularities of surface and alignment in 80-lb. rails $5\frac{5}{8}$ ins. high, on the same road. Numerous features of track condition, apparent upon inspection and comparison of the diagrams in these three illustrations, are left to the study of the reader. It should be understood that the record for "surface of rails and joints" makes the track appear rougher than it really is, because when the head wheel of the truck drops into a low joint, for illustration, the middle or registering wheel is high, relatively to the other two wheels. Again, after the middle wheel has passed the low joint the dropping of the rear wheel into the sudden depression causes the middle wheel to again register high. Thus, where a low joint or other spot occurs abruptly in a stretch of track the surface of which is otherwise smooth, with no point higher than the general surface, the record on the diagram shows both high and low. In studying the diagrams this fact should be borne in mind.

On the New York Central and the Boston & Albany roads the results of an inspection of the track with this car, as shown by the continuous record sheet, are plotted on a condensed diagram of the whole road, an example of which, portraying the condition of 40 miles of double track, on the New York Central road, is shown as Fig. 533. On this diagram the space between each two vertical lines represents one mile of track, and each space between horizontal lines represents the one-hundredth part of an inch. The heavy, plain, wavy line indicates the condition of the track surface as ascertained by one of the annual inspections, and the broken line the condition of the track at the inspection made four years previously.

The average condition of the track for each mile is indicated at the middle of the space for that mile by the hight of the line above the base line, which shows, in hundredths of an inch, the average amount of undulation per rail length. It should be explained that in plotting these lines the summation of the undulations in the rails for a mile, as indicated by the recording apparatus on the car, is divided by 176, the number of 30-ft. rails in a mile. Thus the results for each mile are relative to the base line and may be compared with each other. The line marked "Age of Steel" gives the length of service of the rails, each horizontal line representing one year. Thus, the diagram shows that, at the time the inspection was made, the rails in the west-bound track at Mile 318 had been in service four years, and those in the east-bound track, at the same point, two years. The line marked "Percentage of Tangent and Curve" shows the approximate alignment of both tracks, per mile, the percentage of tangent being marked on the left side, and that for curvature on the right side of the space for the mile, each space between horizontal lines representing 10 per cent. Thus, for instance, in the 311th mile it will be noticed that there is only one mark, which extends across all the 10 lines, at the left, indicating that the entire length of track for that mile is tangent. It will be noticed that in the 310th mile the mark at the right extends over four lines, and the mark at the left over six lines, indicating that 40 per cent of the track is on curve and 60 per cent on tangent. The line marked "Profile" shows the gradients of the road which, of course, are common to both tracks. For the profile scale each space between horizontal lines represents 10 ft. of elevation. As the gage of the track was found to be "perfect" the line showing this condition was, of course, straight, and therefore eliminated from the diagram, as was also the line showing "side irregularities of the rails," the track being in "perfect" alignment.

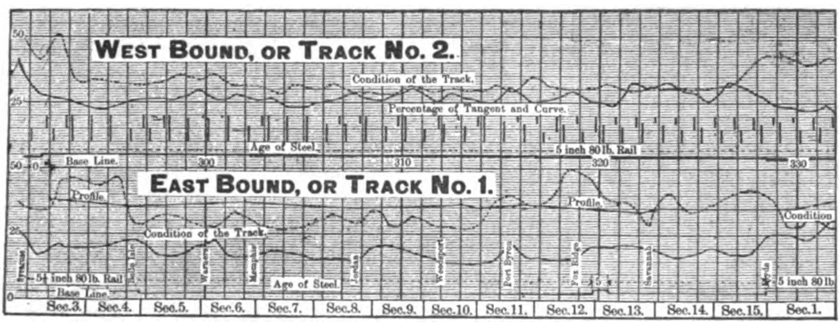

Fig. 533.—Condensed Diagram of Track Inspection (40 Miles), New York Central & Hudson River R. R.

Such diagrams are of value chiefly to compare the condition of the track one year with another. The roughness of the rail from unequal wear, producing a wavy surface, is readily shown, and also the weakening at the joints due to the wearing of the splice bars. A comparison of the surface indications in Fig. 531 with those in the right-hand diagram in Fig. 532 shows the effect of improper straightening of the rails, as explained under the head line (Fig. 531), both rails being of the same weight. As to the relative surface conditions of rails of different section, the sum of the undulations of the 100-lb. rails, of which record is made in Fig. 532, averaged 1 ft. 9 ins. to 2 ft. per mile. The average for the 80-lb. rails, the record of which is shown in the same figure, was 2 ft. 6 ins. to 3 ft. per mile. The average for 4½-in. 65-lb. rails was about twice that for the 80-lb. rails. As the track in every case had been maintained in first-class condition, the relative summations of the undulations for the rails of the various sections is some measure of the influence of stiff rails on track surface. Information deduced from the study of these diagrams from year to year has been an important consideration in deciding upon the increase in weight of rail by the New York Central road; particularly in the year 1883, when Mr. Dudley designed for that road an 80-lb. rail 5 ins. high. This rail was put in service the next year, at which time it was the heaviest rail in use on any road in this country.

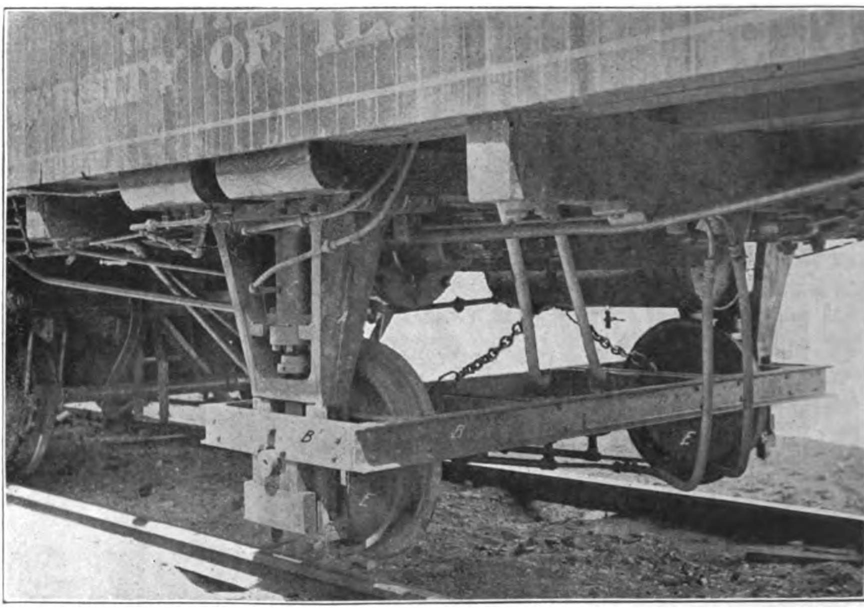

Fig. 534.—Track Indicator Car No. 609, C., C., C. & St. L. Ry.

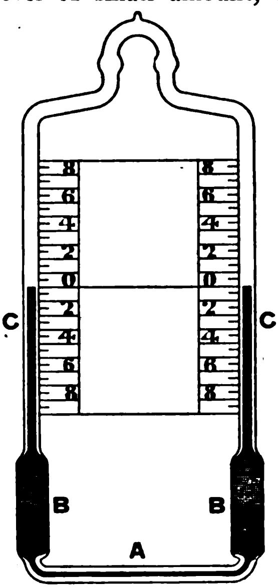
Another track indicating equipment of equally elaborate construction, but designed on a different principle, is contained in Dynamometer Car No. 609 of the Cleveland, Cincinnati, Chicago & St. Louis Ry., owned jointly with the railway engineering department of the University of Illinois. This car was equipped for dynamometer tests of engine capacity, train resistance, tonnage ratings, locomotive road tests, air brake tests and, in addition, for automatic inspection of track. The car is 35 ft. long, patterned after the style of a freight caboose, and is carried on two four-wheel passenger trucks. The car weighs 33,000 lbs. The apparatus for track inspection is entirely separate from that used in taking train resistance. It was designed to record autographically the following conditions: (1) irregularities in track surface; (2) variations in track gage; (3) superelevation of the outer rail of curves; (4) time intervals. The recording part of the mechanism consists of charts or long sheets of paper drawn over rollers, with pen markers controlled by the motion of the receiving apparatus under the car. The rollers or cylinders over which this chart is drawn are geared with the car axle, producing motion in the chart proportional to the speed of the train. Referring to Fig. 534, the receiving part of the apparatus, or that which is acted upon direct by the irregularities of the rails, consists of two wheels of 20 ins. diameter, one for each rail, attached to separate axles which are journaled to a rectangular frame (B), built of channel irons and supported upon cast hangers (A) rigidly attached to the car midway between the trucks. The wheel bearings and the frame (B) are free to move vertically in the guides of the hangers. The axle of each wheel is short, extending to inner bearings attached to cross pieces of the frame B and terminating in collars which limit the outer motion of the wheels. These wheels, by their weight and by spring pressure acting outwardly against them, are constrained to follow the rail in all its irregularities in surface, gage and alignment.

These wheels, through their axles and bearings, are in communication with cylinders, the pistons of which follow all the movements of the wheels due to changes in alignment or surface. These cylinders, known as "receiving" cylinders, are connected by means of $\frac{3}{4}$-in pipes filled with oil with small recording cylinders located on a table in the car above. The piston rods of these recording cylinders carry marking pens which trace records of the motion of the wheels upon the moving chart, as above explained. The piston which receives motion from each wheel due to vertical undulations in the rail surface is in a vertical cylinder (C) which stands directly over the wheel bearing. The piston rod is attached to the top of the journal box, so that any vertical motion of the axle sets the apparatus at work. The piston which receives motion from the wheels due to variations of gage is in a cylinder interposed between the ends of the short axles of the two wheels. One end of this cylinder abuts against the axle of one of the wheels, and the end of the piston rod abuts against the end of the other axle. The end of this piston rod is provided with a collar, between which and the stuffing box is a heavy helical spring, the pressure of which serves to hold the flanges of the wheels against the rails. It is evident, therefore, that any relative horizontal movement of the wheels causes movement of the piston rod, which acts upon the fluid in the cylinder and in this way transmits motion to the recording cylinder above. On the axles there are collars to prevent the two parts being forced apart far enough to take the wrong side of frog points when passed in the facing direction. The record of the elevation of one rail above the other is obtained by attaching a marking pen to a cord passed over pulleys and attached to two lignum-vitae floats in iron mercury cups placed on opposite sides of the car and pipe-connected underneath. When the apparatus is not in use the receiving wheels and axles and the bearing frame (B) are raised from the track by an air lift and locked in position, as shown in the illustration. The wheels can be quickly lifted out of action at any time. When the car is to be used for track inspection it is raised and blocks are inserted in all the springs, giving the car body rigid support and preventing motion relatively to the wheels. To obtain good results the car is run at a speed of 10 to 15 miles per hour. The record paper is 24 ins. wide and the rate of travel is 26.4 ins. per mile. The paper is in rolls of sufficient length for inspecting 400 miles of track and it may be made to feed ahead whichever way the car is moving. The recording apparatus includes several pens electrically operated, for recording from the observation tower of the car.

The Chicago Great Western Ry. has used a track indicator devised by Mr. Chas. A. Stickney, assistant to the president of that road, which was put into regular service in 1896. This indicator is arranged to show sharp defects in the surface and alignment of the track; is simple in construction and is operated by the lurching of the car body. It consists of three flat spring levers each about 10 ins. long, clamped at one end, and lying horizontally in a direction lengthwise the car or parallel with the track. The free end of each lever terminates in a heavy tip, or hammer head, the inertia of which, when motion is imparted to it by the throw of the car, causes the lever to vibrate. Two of the spring levers (one for each rail) are clamped so as to vibrate horizontally, or in obedience to the side throw of the car body, one responding to a throw toward the left, the other to a throw toward the right. The third lever is clamped in a manner to vibrate vertically, or in response to a jolting of the car up and down. Each lever is put in tension by a bearing screw so adjusted that the lever will not vibrate from the usual motion of the car but will respond to a sudden jolt or lurch. The vibration of the lever causes it to strike against a binding post, the contact so made closing an electric circuit and setting in action the registering apparatus, which consists simply in an electro-magnetically operated needle, which punctures a paper ribbon passed between guides at a speed proportional to that of the train. This ribbon or strip of paper is unwound from one roller and wound up on another, and is moved between a pair of feed rolls belted to the car axle. It is not possible, from the mark registered on the paper (since the vibration of all three levers causes the registration of the same kind of mark), to determine whether the irregularity in the track at any point where a mark is registered is a defect in surface or alignment, or upon which side of the track it is located. The record simply indicates that the track is rough at that point. When starting out upon an inspection trip a reference mark or puncture is made upon the paper, by a push button arrangement, and the same is done when passing mile posts, bridges, stations or other points desired for reference. Irregularities in the track can thus be located closely by scaling off the distance from the reference point marked upon the paper.

This instrument is placed in a box or chest about 24x24 ins. x2 ft. high, which is set permanently upon the floor of one of the regular coaches of the road, over a truck. When not in service the lid of this chest is kept locked. This car makes its runs on the regular trains of the road, and at regular intervals an attendant is placed in charge of the indicator, the intention being to make an inspection of the whole road twice each month. During the remainder of the time this attendant is employed at plotting the results of his inspection trips. Each indication of the instrument for each trip is plotted upon a diagram, the results of a number of trips being recorded upon the same diagram, the intention being to compare the condition of the track as registered on the various trips. It is also the business of this attendant to notify the section foremen as to the location of defective points in the track, and if upon successive trips an indication appears repeatedly at the same point, the matter is brought to the attention of higher authority and an investigation is made to ascertain the reason why the defect has not been corrected, or what the difficulty may be at the particular point, in case the section foreman has made effort to repair the track.

On the Chicago, Milwaukee & St. Paul Ry. use has been made of an instrument for inspecting the elevation of curves. This is known as the "equilibristat" and was contrived by Mr. D. J. Whittemore, chief engineer of the road. Briefly stated, the purpose of the instrument is to determine whether the car floor remains parallel to the plane of the rails, or in a state of equilibrium, while rounding a curve, and, if not, to measure the amount of deviation from the position of equilibrium. The instrument is essentially a U-shaped liquid level, the readings of which are magnified by causing the upper portion of the liquid, in the two branches of the "U," to pass into capillary tubes. The instrument consists of a continuous glass tube in the shape of a rectangle about 4 ins. wide and 10 ins. high. The tube is sealed and unobstructed throughout the entire circuit of the rectangle and has three different calibers as follows: Across the bottom of the rectangle the section (*A*, Fig.535) is quite small, comparatively, and is known as the "retarding" portion; just above the lower side of the rectangle the section (*B*) on each side is expanded to bulbous proportions for about 2 ins. in length and is called the "containing" portion; above this the sides and top of the rectangle are contracted to a section of $^3/_{32}$-in. caliber, or to a size something like that of an ordinary alcohol thermometer; this latter portion of the tube (*C*) on each side, is known as the "indicating" tube. The relative calibers of the retarding, indicating and accumulating sections, respectively, are as 1, $2\frac{1}{4}$ and 10. The lower portion of the rectangle, up to the middle of the containing tubes, is filled with mercury, and above this the indicating tubes are filled with colored alcohol. The mercury is free to flow from one containing tube to the other, through the retarding tube, the purpose of restricting the diameter of the latter being to make the instrument insensitive to rapid changes of level of small amount, or shocks caused by small inequalities in the



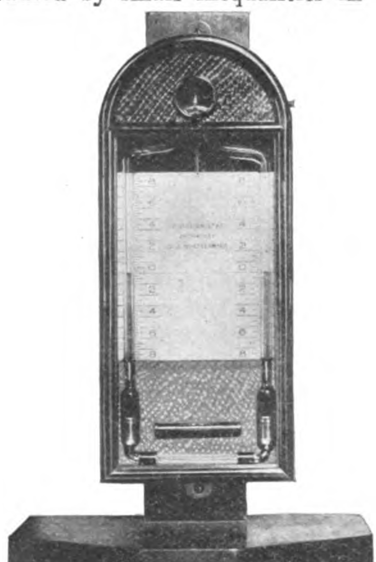


Fig. 535.—Whittemore Equilibristat—Fig. 536.

track surface. A scale plate is hung within the rectangle, with zero marks at the top of the alcohol columns in the indicating tubes. This scale plate is adjustable by a screw, to compensate for change of temperature. For an obvious purpose a level bubble is attached to the instrument. The whole is placed upright within a glass-covered case (Fig. 536), the instrument complete occupying about the same space as an ordinary cigar box.

The instrument operates on the principle that if placed on the floor of a car, with the rectangular tube transverse to the axis of the car, the inequality of the liquid in the two indicating tubes will show the inclination of the car floor. Thus on track level across, the liquid in the indicating tubes ought to stand at zero; that is, at equal hights in both tubes. On a curve, however, with the car standing still, the reading of the liquid column in either of the indicating tubes will give the elevation of the outer rail of the curve in inches, the unit of the scale division and the calculation of the instrumental dimensions being arranged to this intent. When the car is in motion, however, the centrifugal force acting upon the mercury in the tube tends to raise the fluid in that side of the rectangle which is toward the outer side of the curve; and if the curve is properly elevated for the speed at which the car is moving, so that the car floor remains parallel to the plane of the rail surfaces, the liquid within the indicating tubes will stand opposite the zero of the scale. An improper elevation of the curve for the speed at which the car is moving is indicated by the reading of the liquid columns, on the scale, as so many inches excess or deficiency, as the case may be. Thus, to use the instrument it is only necessary to place it on the floor of the car (adjusting it so that it rests level transversely of the car when the same is standing on track level transversely, if such may be necessary, owing to an unequal loading of the two sides of the car or by the unequal action of the car springs) and to run the car at the speed for which the elevation is desired. If the elevation in the rails is suited for the speed the instrument will read zero, but if not, the reading of the instrument will indicate the number of inches in the way of correction which must be made to properly elevate the curve. The instrument was intended for the use of roadmasters and to be placed at convenient points in business cars.

Perhaps a word should be said regarding the practical benefits of track-indicating instruments. While the foregoing account shows that such instruments undoubtedly give reliable indications of the condition of the track, it is rather too much to say that the use of such devices is essential to a high standard of excellence in track. It is proper to state that, so far as practical results are concerned, an expert trackman is equal to any task of track inspection. If such was not the case one would be led to inquire how track could be put into smooth condition to start with. All that any indicator can do is to point out the need of repairs, but the final test of line and surface is always the "eagle eye" of the section foreman. As a means of keeping tab on the work of the section foremen, these instruments may be of some value. In this connection, however, it seems that the Stickney instrument, on the Chicago Great Western Ry., is the only one which has been put to regular use. For use on official inspections such devices undoubtedly have their value. Thus, for instance, the Dudley car has been used for many years on the Boston & Albany and the New York Central & Hudson River roads to ascertain the progress which has been made on those roads in reducing the amount of surface irregularities in the rails, one of the chief factors of which has been a more or less gradual increase in the weight of rails, on considerations already stated. While it was known that an increase in weight would produce a stiffer rail, the records obtained by this car have shown just what the relative decrease in the surface irregularities has been as heavier rails have been laid from time to time. In all cases where there is inaugurated a definite policy to progress toward some standard of excellence in track surface and alignment it would certainly seem worth while to make use of scientific apparatus of this kind. One trip over a road or division tells the story, and no part of the track escapes attention. An inspection of the track on foot, by visual observation, taking note of all the details disclosed by such apparatus would never be attempted. The most convenient method of inspection for the trackman, and one that is sufficiently accurate for every practical purpose coming within his supervision, is to ride over the track on the engine of a fast train, following up the trip by a careful inspection on foot of the rough places noted from the engine.

There are other track-indicating devices that have been in service. The Pennsylvania R. R. has a track indicating car less elaborate than the Dudley car, and the Pennsylvania Lines West have another. Portable instruments devised on the principle of the pendulum, for service in passenger coaches, have been used on some roads. Paint squirters, to mark the track at rough places, have in some cases been attached to ordinary business cars to be operated by hand control. The chief engineer's car on the Michigan Central R. R. is so equipped.

The Premium System.—The premium system is understood to mean the practice of awarding prizes to division roadmasters or supervisors and to section foremen whose track is found in the best condition, as announced by the results of the official inspections. Quite frequently also there are prizes for division officers and foremen standing second best, third best, etc. Such prizes usually consist of gold medals; money, in amounts from $25 to $100, and sometimes more; gold watches, gold-headed canes and perhaps other desirable things. On the merits of the premium system the opinions of experienced maintenance of way officials and employees differ. Some engineers who claim to have watched closely the results of the annual inspections and the awarding of prizes think they are a grand success, while others who profess a similar experience declare that, as conducted on some roads, at least, they are nothing better than a "grand farce." On the part of those who favor the system it is claimed that enthusiasm in the work is aroused among the persons eligible to the prizes; that these men, as well as the employees working under them, appreciate the recognition of the company for the ability and faithfulness displayed; that the pride of all the men in the work is stirred; and withal that the results of the system certainly show in better and safer track at a reduction of maintenance expenses. Mr. Geo. R. Brown, formerly general superintendent of the Fall Brook Ry., has stated that the adoption of the premium system for section foremen on that road (three premiums of $40, $20 and $10 on each division), resulted in an improvement of at least 25 per cent in the condition of the track, with annual pay rolls $37,000 to $42,000 less than the average for eight years before premiums were given. The road was 257 miles long, all single track, the tonnage averaged about 6,000,000 yearly, and there were no conditions of maintenance essentially different under the two systems, except that an average of 4½ miles of new side-track was built each year for ten years under the new system, and the expense of maintaining this was included in the comparison. Another idea which has weight with some managements is that yearly inspections and the awarding of prizes surround the work with an aspect of form, and instill into the minds of the men proper respect therefor. On the other hand, it is contended that the practice of giving prizes for excellence in the performance of duty is not promotive of a high order of discipline, and in the reasons offered there are evinced various shades of opinion.

In the first place, it is claimed that some compromise with good reasoning is essential to the assumption that all section foremen or division track officials can compete on the same footing. Like effort, even if judiciously directed, will not always produce results which are visibly alike; and it seems to be quite generally admitted that the task of determining which is the best piece of track, where differences are slight, is a difficult matter. A great many people believe that close contests cannot be decided with a certainty of fairness where the decision is dependent in large degree upon human judgment or where the results of the contest cannot be positively determined. Where men contest as in a foot race or in shoveling dirt the conditions may be made equal and the results of accomplishment show indisputably on the face of things; but where a contest must be decided by striking an average of opinions the determination is not positive. The reward, however, is something positive and substantial. As an illustration of the difficulty of deciding upon the relative condition of two pieces of track one might consider what fine points of judgment would need to be exercised to tell to a certainty the difference between two pieces of track often found alongside of each other, as in comparing the two tracks of a stretch of double-track road. How much more difficult then would it be to decide fairly between two sections of track in nearly the same condition, but where some hours have intervened between the time when each was seen. On these questions some quotations from a discussion before the Eastern Maintenance of Way Assn.. in 1901, by Mr. F. C. Stowell, its secretary, and roadmaster with the Boston & Maine R. R., are much in point. He said, in part:

"Much mystery has always obtained in my mind as to the possibility of arriving at a just distribution of awards by the method of inspection and basis of award commonly prevailing. It is inconceivable that any number of men, however fair minded, capable or discerning, can, as the result of a more or less flying trip over long stretches of track, pass detailed, comparative judgment on the numerous sections thereof, without liability, yes probability, to frequent and gross error. And this is not a suspicion of, or reflection on, either the efforts, good intentions or ability of the judges. Such observation is bound to be a too superficial basis of judgment, and though it may locate the prize or prizes, it will rightly lack the respect of the competing foremen, and so fail to encourage the 'morale' intended. Next, as to the significance of the conditions inspected. . . . . There are a limited few trunk lines in this country being put by tremendous appropriations of capital in such a state of physical excellence that the conditions of the various sections thereof are approaching such a state of similarity that it is fair, perhaps, to judge of the merits of the foremen by comparison alone of the physical condition of their respective sections. But beyond these isolated examples the great majority of track mileage presents such dissimilar physical conditions that the labor and skill necessary to reach a certain state of refinement on one section may be much more or much less than that required to reach a similar state on a neighboring section. What is it for which a prize is awarded? Is it not for the greatest amount of the most intelligently directed labor put forth per man? And what should be the evidence? Surely not always the best section on the road. It should rather be the best section, in view, briefly, of both the natural and accidental obstacles encountered in putting up the same between periods of inspection. In other words, the reward of merit should go to the man who has wrought the greatest improvement from prevailing conditions. What roadmaster has not, when accompanying his superiors on inspection trips, seen the most trivial circumstances of accident unknowingly turn the scale of opinion temporarily against his best foreman, and then perhaps some more fortunate circumstance (also accident) bring undue comparative praise to a much less worthy man on the very next section? Such, as it appears to me, is the twofold mistake of granting the palm of merit for maximum perfection of track only, and based only on superficial examination. I cannot dispel from my mind that such awards should go for conditions of maximum refinement, only when accompanied by equal evidence of improvement over previous condition. And I admit that this criterion of judgment makes the task of justly awarding prizes among foremen on the average properties most unsatisfactory, if not quite impossible. It necessitates that the judges should have the same detailed, day-to-day familiarity with individual conditions of maintenance of the particular track under inspection as the roadmaster himself, which is hardly practicable."

Again, it is believed by many that the customary awards for such contests are too disproportionate for the close degree of excellence between a high record and the highest; as, for instance, be the average markings of a number of section foremen as close as can be without being equal, one foreman, or at most, two or three, take the substantial recognition (the prizes) while the showings of the other foremen count for naught, at least so far as official recognition is concerned. If it was arranged to conduct a rigid inspection of each section by a party of experts traveling all the way on foot, and then to grant an increase of pay to all foremen whose track was found above some certain standard or marking, the increase to continue as long as that standard was maintained, such a scheme would conform more closely to business principles, because then it would be possible for each and every foreman to secure substantial recognition for results accomplished. By the prize system, as usually conducted, such a possibility is limited to one or two persons only, no matter how high the standing of all the others. In the natural order of things effort is rewarded somewhat in proportion to accomplishment, but in the ordinary prize system the reward for the efforts of all the foremen combined goes to one man. In its practical workings, therefore, the system is, in some of its aspects, like a game of chance. On this point an engineer of much experience, connected with one of the large railway systems of the country, where the prize system has long been in vogue, says: "Regarding the prize system, I have long held to the opinion that it ought to be abolished. As to the fixing of a standard of excellence, that is quite a different matter, and if some substantial recognition was given to them that attained it, some good might result, and there would be at least a great deal less ill feeling." The justice of the foregoing proposition was recognized by the Fall Brook Ry., as shown by the annual report of the general superintendent in 1898, in reference to this matter, as follows: "When the annual inspection was made this year it was found that the condition of the tracks, compared with the cost of maintenance, was so generally good that in awarding premiums to section foremen for the best track it was necessary to again depart from the usual practice of giving first, second and third premiums; and we have divided the total amount of premiums assigned to each division equally among seven of the best sections on each division."

Men of another persuasion consider that the offer of premiums for excellence in work performed is a reflection upon the integrity of the foremen; that where men of strong character are selected and put in charge of work the ordinary wages are a sufficient inducement to attend strictly to duty, which is all that should be expected of any employee. It is therefore the opinion of some persons that when there arises the need of stimulating the foremen to their work by prizes it is time to begin looking for a better class of foremen. The fact that many roads succeed in keeping up good track at economical expense without giving prizes is considered evidence that, under good management, good work can be done independently of the prize system. The competitive feature necessarily partakes of the idea of turning out work on the contract plan, and men who will jump in and exert themselves for artificial rewards are not always the men who have the interests of their employer most at heart. It is also said that, on general principles, the giving of prizes to adult persons is creative of jealousy and is never satisfactory except to the beneficiaries of the system. The love of prizes is "a root of many kinds of evil," the cause of much misery among men and the ruination of many a man. One of the manifestations of vanity is the desire to always place some man or thing the highest of a class.

It is quite commonly understood that in the majority of cases, the premium system works a decided hardship upon the employees or common track hands, and some have denominated it a "man killer." I have heard this view corroborated by fair-minded men in position to know, particularly by an intelligent division track official on one of the roads best known for its premium system to trackmen. It is proper to say that this man had himself, at one time, been the recipient of the highest prize to division track officers. Considering that many section foremen are men of limited education, it is to be expected that a system of awards in which physical exertion is one of the factors essential to the showing of the successful competitor, would lead to a good deal of driving of the men in their work. In this connection, also, the system would seem to be lacking fairness in the respect that the men of the section have no participation in the prize which goes to the section; which makes it appear that the result of their extra effort is monopolized by the foreman. The official distribution of prizes among track laborers is rarely or never heard of. Drawing a mental picture with these facts in the background the system appears like a scheme whereby the foremen are urged to fret and the track hands to sweat, all summer, in order that the foreman may "win the gold watch" in the fall. It is safe to say that in the work and conduct of section foremen there are aims more commendable than that of getting all the work possible out of the men. This fact might be borne in mind wherever it is the practice, in making promotions to the position of supervisor, to consider only those foremen who have been recipients of premiums.

Another objection to the prize system is that, in its practical workings, there is a tendency to spend too much time on finery that should be put on track surface. Some interesting stories are told of efforts to put the gilt edge on things just before the day of inspection. Section men have even gone to the pains to sweep the track with splint brooms, and foremen have been known to get their men out in the night to attend to some ornamental feature that had been overlooked during the days of "preparation." On the other hand men have been known to grow weary of the competition and fail to maintain the intended esprit de corps. It has been stated officially that on one of the large railway systems there was, at one time, a secret understanding among the supervisors and foremen whereby certain of the forces would not compete for the prizes every year, thus conspiring to pass the honors around in turn, without overexerting themselves. On the real merits and workings of the premium system an outsider frequently finds roadmasters or engineers non-committal, out of desire not to contravene the opinions of higher authority. It is no secret that on some roads where prizes are given for excellence in track maintenance the system is more favorably regarded by the general officers than by those of division rank, like roadmasters and division engineers.

It is the opinion of many men who have had experience with the premium system that the inspections should not be made at regular or stated intervals; that to secure the best results the inspections should come at varying periods and without previous warning, or during any season of the year. It is believed that with periodical inspections the tendency is to devote too much energy to a particular end at the appointed time, when the principal aim of railway managements is to maintain the track up to a good standard at all times. From a business standpoint the railway company is not so much interested in what men are able to do by way of special preparation as in what they are in the habit of doing all the year round. A system which approximates to this idea is that of the New York Central & Hudson River R. R. On the main line of this road, between New York and Buffalo, the track is inspected three times a year, and the standing for premiums is based upon an average of the markings of the three inspections. In order to obtain the best results the standing should be based upon the general count of all the features marked. It has been the practice in some cases to give several prizes on each division of a road for excellence in different lines of work; as, for instance, one prize for best surface and alignment, another for joints and spiking, another for switches and frogs, another for ballast dressing and banks, others for ditches, policing, etc. Such a system might induce some foremen to neglect parts of the work in order to make a showing in others.

The practice which many roadmasters have of watching closely the reports from the various sections and discussing the same with the foremen is considered to be wholesome, and many think it exerts a sufficient moral effect to enliven the proper amount of interest. As part of this plan it is well to watch the distribution of the labor among the various kinds of section work, commenting upon the results accomplished and upon comparisons with the showings of other sections, where it is thought that a little urging is necessary. It is also the plan of some roadmasters to prepare at the end of the year a condensed statement of the cost of the different kinds of work on each section, giving the length of track worked, the number of switches, length of side-tracks, etc., and send it to the foremen for their information, without comment. Many roadmasters believe that this method of enthusing the foremen is going sufficiently far to produce the results desired; that it touches the pride of the foremen and, all things considered, produces a better moral effect than is liable to result from enforced competition; that while the prize system may be productive of immediate results, the incentive to excel lasts only temporarily; and that it is wrong to force human judgment to discriminate minutely as to the work of the foremen where no necessity exists.

The idea that annual or other official track inspections are advantageous to the work of track maintenance seems to be quite deeply rooted with not a few maintenance officers, but of these many men of experience consider that results superior to those which may be had by the giving of prizes may be obtained simply by announcing the findings of the inspection, without awarding prizes, and that in this way good feeling among the men is better maintained. On some roads where this principle is observed the section which maintains the highest standing receives a mark of distinction in the form of a "blue board," on which is inscribed "The Best Section," or words to similar effect. Such a board is also used on some roads where the prize system is in force. Still another class of thinkers favor omitting any mention of the highest standing, but grade the sections into first, second and third classes, according to the ratings of the annual inspection. And still another class think that it answers the purpose sufficiently well to get the section foremen together once each year and give them a trip over the road on an observation car in company with a number of the higher officials, without announcing results. On such a trip the foremen are invited to criticise the track under one another's charge, and as there is no compulsion in the matter of expressing opinion, each man feels a greater freedom in forming his opinions than would be the case if a prize was at stake. In this way the foremen get to see one another's track, get the benefit of one another's criticisms, learn new opinions, and undoubtedly receive a good deal of benefit from the trip. By winding up such an affair with a banquet or something of that sort, with encouraging speeches from the officials, there can be no doubt but that the foremen would return to their work with renewed ideas as to their importance in maintenance-of-way economy, and with more nearly equal satisfaction than would be the case were the foremen to remain at home while the officials make the trip and dismiss the affair with the cold announcement that some foreman had been selected to receive a prize. After all, what does it matter if there be no formal decision, or even united opinion, as to whose track is the best? The philosophers tell us that contest between man and man is not the ideal state of living. Why then should it be considered the ideal condition of labor?

The Unit of Maintenance of Way Organization.

SUPPLEMENTARY NOTES AND TABLES.

196. Tile Drainage.*—In the construction of a tile drain the first thing necessary is to have accurate levels run and true grades established. Too much care cannot be taken in this part of the work, for if the levels are not accurate the best results cannot be expected. In beginning the work it is well to stretch a line in the direction of the proposed drain and then take a spade and cut the earth to this line. The line should then be changed over to the other side of the drain, which should be about 14 ins. wide at the top, and the earth cut to the line in this position. With a drainage spade the drain is then dug down to within about 16 ins. of the bottom, before grade stakes are set.

In setting stakes for grading the bottom my practice has been to first set two stakes 50 ft. apart, one at the outlet and the other further back, or in the direction of the flow of water, and then to wrap an envelope or piece of white paper on each of them at convenient hight. With a leveling instrument I arrange the hight of the envelopes to correspond with the grade of the drain; that is, if the survey calls for a fall of 3 ins. per 100 ft., I place the envelope on the stake at the outlet 1½ ins. higher than the envelope on the stake 50 ft. back. I then take a stake and notch it at a hight equal to the depth of the drain below the top of the envelope on the stake at the outlet. This notched stake I make use of in sighting for the bottom of the finished drain, at intervals of a few feet, the requirement being, of course, to dig the trench to such depth that the notch on the stake, when the latter is stood in the trench, shall be on the line of sight with the top edges of both envelopes. Other means are sometimes taken to maintain a uniform grade, some stretching a line over the tops of leveled stakes along the side of the drain, and then using a pole with a gage arm to reach out to the line and ascertain if the bottom of the trench is at proper depth. One fault with this method is that a damp line on a dry day is liable to sag, and if not carefully watched the bottom of the trench will be finished to correspond with it. In tile-draining a railroad cut where the grade is already established, a survey would, of course, be unnecessary, as reference can be had with the grade stakes or the rail.

The bottom spading is taken out with a round-pointed spade a little over 4 ins. wide at the point, and every little while the drain cleaner, which is a scoop with a long handle that pulls toward the operator, should be used. Under ordinary circumstances one should not get into the bottom of the trench with his feet. With a good drain cleaner in the hands of an expert the bottom of the trench can be shaved off smoothly and nearly as true as a carpenter would plane a piece of board. The trench is now ready for the tile laying and should never be left too long open, as the sides may cave in or clods of earth may fall into it.

In laying tile one should not stand in the trench, since on soft material one's feet will puddle up the bottom and render it unfit to receive the tile. For placing the tile in position, an implement known as a tile hook is used. It consists of a small scoop about 1 ft. long, with a crane neck or shank, attached to a handle about 7 ft. long. This blade hangs not far from a right angle, with the handle, but the angle may be adjusted to suit the user. The blade will easily go inside of a 3-in. tile. The tiles are distributed along the trench within convenient reach of the tile hook, and the man who does the laying stands straddle of the trench and lowers the tiles to place with the hook, giving each length a tap with the heel of the hook, to settle it firmly to place. If the section of tile laid does not make a close joint on top it should be lifted up and pressed against the side of the trench, so that by pushing down the tile will revolve on the hook until a close joint is obtained. If there is much water in the trench a small piece of board should be stood in front of the last tile laid, to prevent obstructions from being carried into the tile. The tile is

---

***By courtesy of Mr. Alexander Birss.**

then covered over, first rolling in the material which was taken from the bottom of the drain. No particular care is required in doing this except to see that stones do not drop upon the tile and break it. This is what we call "securing the tile," and the rest of the filling may be done in any manner to suit convenience or to expedite the work, a swing plow being much used in filling in drains in farm practice.

I shall now try to say a few things about tile and explain the working of a tile drain. When tiles are burned they nearly always bend just a little, owing to the fact that one side becomes a little hotter than the other, the side which is burned the most thoroughly being the shorter, and slightly concave. In laying the tile the convex or longest side should be on top, as then an opening will be left in the bottom of the joint—usually about ¼ in. wide. It is through this opening that the water should, and by nature does, enter the drain. Comparatively little goes in at the top. There are many things that seem to have an affinity for water and they will "root" down and enter the tile, and it is always in the bottom that they make their entrance. I knew of a case in Green County, Iowa, where a tile drain was constructed parallel to a hedge of willow trees, 33 ft. distant and 4 ft. deep. The willow roots crept out that distance and entered the tile, completely filling it inside. Sunflowers should not be permitted to grow over a tile drain, as they will soon root down to the tile, enter it from below and fill the interior of the drain full of fine roots much resembling corn silk, which will in a little while effectually choke the drain.

Perhaps the most interesting work to be found in tile drainage is in laying tile in quicksand. In such material many a man has worked hard all day without succeeding in laying a single section of tile that would remain in place; and a man who will not display temper in laying a tile drain in quicksand is too good for this world. The best time to undertake tile drainage in quicksand is after a long spell of dry weather, but one never knows until he is strictly in it how quicksand will act, if once let loose. Ordinary curbing is of little account, as the sand will run into the ditch in spite of it. I once knew of a bad case where boiler iron was secured from the railroad shops and used for curbing, but the pressure was too great even for that. My best success in managing quicksand has been through the use of a sheet iron box about 5 ft. long, without top or bottom or rear end; that is to say, a strip of thick iron plate about 11 ft. long bent into the shape of a long "U." The front end should be rounded, with a handle attached to pull it through the quicksand, and the sides at the rear end are held apart by a strong stay in the form of an arch, which resists the side pressure. Sheet iron is too thin and boiler plate too thick for constructing this implement. In operation the sides of the box stand edgewise and the rear or open end is always kept one or two tile lengths behind the last tile laid, to keep the sand out of the tile while at work, for in bad cases it floats around nearly as freely as water. The box is made wide enough to permit clay to be packed about the sides of the joints and remain undisturbed when the box is pulled ahead. The box is pushed down into the sand until the material can be taken out to the proper depth and then two lengths of tile are laid in the open space and covered over and packed about the sides before the box is pulled ahead again. I have used pieces of plaster lath to lay on top of the tile and keep them even and continuous while covering it over with clay. Filling material must be placed upon the tile as soon as possible, to weight it down, for the tendency of the sand is to lift the tile. A piece of board is kept in front of the tile to prevent the sand from getting into it, but a great deal of sand does get in and cannot be prevented. If the tile is laid to uniform grade, however, there is no danger that the drain will become seriously obstructed. When working in quicksand the drain should be opened but a short distance ahead of the tile that is being laid, especially if close to the track, as in that case the pressure from passing trains might cause the trench to cave and undermine the track. For the same reasons the drain should be filled in and finished as close as possible to the work of laying the tile.

Collars on tile joints interfere with the entrance of water at the natural inlet—the bottom of the joint. I have sometimes laid a 1x6-in. fence board on a soft bottom which would not carry the tile, but except in a case of this kind a board under tiling is not a good arrangement. The accuracy with which the tile is laid has an important effect on the capacity of the tile drain; as for instance, if there is a sag of one inch the tile will fill up that much and its capacity will be reduced; and, of course, the same result must be expected where one or a few lengths of tile are laid an inch too high. To do a first-class job in laying tile is indeed a fine piece of work.

197. Some Details of Steel Working and Departures in Rail Design.—During late years various experiments have been made with the intention of adopting radical departures in steel rail manufacture. In order to understand these experiments and the reasons therefor, it is essential to comprehend some of the elementary facts embraced in various processes of steel production. To such as may not be familiar with the metallurgy of steel the brief exposition which follows may be of some assistance.

Steel used for construction purposes generally is manufactured by either of two processes, the Bessemer or the open-hearth. The object of either process is to regulate the amount of carbon and other alloys found in the cast iron. In the Bessemer process this regulation is effected by forcing small streams of cold air through the molten metal, which is poured into, and held in, a large iron pot called a converter. The presence of the air within the mass of the heated metal oxidizes or burns out the carbon, silicon and manganese. The process may be arrested at the point where the desired percentage of carbon has been reached (Swedish practice), as indicated by the appearance of the shower of sparks issuing from the converter, but in the largest practice it is continued until all of the oxidizable elements are burned out (as indicated by the appearance of the flames), when melted spiegeleisen or ferro-manganese, containing known proportions of carbon, manganese and silicon, is added to recarbonize the iron. In the latter practice better control is had in proportioning the alloys.

In the open-hearth process the regulation of the alloys is effected by the action of an oxidizing flame from a coal fire in a reverberatory furnace, or from heated gases in a regenerative gas furnace, the latter type of furnace being the more common. The iron is usually melted in this furnace. In the open-hearth process the carbon is not all burned out, as it usually is in the Bessemer process, for the oxide of iron formed while the cast iron is being melted down forms a slag over the bath of molten metal and protects the iron, carbon and silicon from further oxidation; in the meanwhile, however, the carbon and silicon have become partly consumed. It is also possible to introduce foreign slag or to vary the proportion of oxygen in the flame, so that the metal can be held in the fused state without considerable change until samples can be taken from the furnace and tested, to determine the extent of decarbonization. These tests are simple, and quickly made, consisting merely in dipping out a small quantity of melted iron in a ladle, when a casting is made, cooled and broken. By observing the fracture an experienced operator can estimate closely the carbon ingredient. The usual method of reducing the percentage of carbon is to introduce uncarbonized metal in the form of wrought iron and steel scrap in sufficient quantity to produce the desired mixture, but in any case the proportioning of the alloys is well under control, there being plenty of time to introduce modifications. Excess of carbon may be removed by charging oxide of iron in the form of ore, to supply oxygen for further decarbonization, or, in time, as the temperature rises, the carbon will combine with some of the oxygen of the iron oxide slag which becomes mixed through the mass by ebullition from escaping gases. This action restores some of the iron of the oxide to the metal product. To remove the remaining iron oxide of the slag spiegeleisen rich in manganese is charged, the manganese uniting with the oxygen of the slag and restoring the iron of the oxide to the bath. In case the percentage of carbon should at any time be found too low recarbonization is readily effected by adding cast iron.

It may now be explained that in the ordinary manner of operating a Bessemer converter or an open-hearth furnace, as above described, a sand or (acid) silica lining is used and the product is known as acid steel. The open-hearth process of making acid steel is sometimes called the Siemens-Martin process. The fact of particular significance about the production of acid steel is that no phosphorus or sulphur is eliminated—and this applies to both the Bessemer and open-hearth processes. This means that in the production of acid steel of good quality only ores that are comparatively low in phosphorus and sulphur can be utilized; hence the terms "non-Bessemer," as applied to ores high in these elements, and "Bessemer pig" as applied to cast iron which is comparatively free from them. The removal of an excess of phosphorus and much of the sulphur, thus making cheap ores available, may be effected by fluxing the steel with lime, which unites with the phosphorus and carries it off in slag. As, however, this slag will attack and chemically destroy a silica lining it becomes necessary in dephosphorizing to equip the converter or open-hearth furnace with a basic lining, which usually consist of lime, as found combined in magnesite or dolomite, made into bricks or applied in some other form. Steel produced in this manner—whether in a Bessemer converter or in an open-hearth furnace—is known as basic steel. In the basic Bessemer process the elimination of the phosphorus by reaction between the charge and the basic substances takes place during the "afterblow"; that is, the blow is continued after the complete oxidation of the carbon, instead of terminating it on the drop of the carbon flame, as in the acid process, and the very high temperature then causes the phosphorus to combine and separate. As there is no pronounced indication of the elimination of the phosphorus, the duration of the afterblow is to a large extent regulated by the judgment of the operator, who stops the blowing when he thinks it has continued for a sufficient time. Tests are then made and if the amount of phosphorus is too great the blow must be renewed.

The chief distinction between acid and basic steel is therefore the elimination or the partial removal of phosphorus in the latter. As between the two the basic process, although adapted to the use of cheaper ores, is the more expensive. Basic linings are less durable than acid linings and the basic process wastes more pig iron than the acid process. Moreover, the basic Bessemer process requires a special iron ore which must be low in silicon and comparatively high in phosphorus. The adaptation of the process to high phosphorus ores is therefore to some extent limited. In England there is a by-product from the basic process which is used as a fertilizer. It sells for about $1.00 per ton.

As between the Bessemer and open-hearth processes, the Bessemer is the cheaper, but the open-hearth is generally considered the more reliable. Open-hearth steel is considered to be more uniform in composition or more homogeneous than Bessemer steel. Whatever differences may exist in this respect are explainable on the fact that open-hearth steel remains at all times during the process of manufacture more thoroughly mixed with its alloys. As the carbon is not all burned out, and seldom burned to a percentage lower than that finally retained, the distribution is not seriously disturbed. On the other hand, in the ordinary Bessemer process the entire carbon component must be added to the metal after the blowing of the metal has ceased, and the only mixing operations to which the metal is afterward subjected is when it is poured from the converter into the ladle and drawn from the bottom of the ladle into the ingot molds. Some think that these operations do not sufficiently agitate the metal to secure a uniform distribution of the carbon and that injurious segregation is liable to occur. At any rate it is not an uncommon experience to find widely varying physical properties, and even chemical composition, in test pieces cut from different parts of the same piece of Bessemer steel. Mention of a single instance will serve to illustrate possibilities. Chemical analysis of a sample taken from the point of fracture on a broken rail showed the following variations from the average composition of the heat, the latter being mentioned first in each case: Carbon, 0.45 to 0.61 per cent; phosphorus, .09 to 0.20; sulphur, .076 to 0.22; manganese, 0.93 to 1.03. As already explained, the opportunity to test open-hearth steel at any stage of the process, while such cannot be done with the Bessemer product, carries the general impression that the former is under better control.

Comparing the expense of the two processes, the open-hearth plant is the cheaper, but the longer time required to produce a given output by this process very much augments the cost for labor. The capacity of Bessemer converters in ordinary use runs from 5 to 17 tons, 10 tons being perhaps the capacity most commonly found. In a converter of this size the 10 tons of metal is usually blown in about 15 minutes, which includes the time between pouring the metal into the converter and pouring it out into the ladle. With metal which is low in silicon a heat is sometimes blown in 8 or 10 minutes. Speaking in a broad and general way, a Bessemer plant of two converters will average about 160 blows in 24 hours. The time of blowing a 15-ton converter is a little longer than one of smaller size. Open-hearth furnaces are built of all capacities from 10 to 60 tons per heat, although for special purposes there are some in operation of smaller capacity. In American practice 30 and 40-ton furnaces are perhaps the most commonly found. The time required to work a heat in an open-hearth furnace is 8 to 12 hours, depending upon the strength of the blast and variations in the raw material. In ordinary American practice an average of about 16 heats are worked per week.

The unsatisfactory service from the metal in rails made during recent years has turned the attention of railway men and manufacturers toward basic steel. Both basic Bessemer and basic open-hearth steel rails are used in Europe, but in this country basic steel rails have been used but little, and then only by way of experiment. In 1896 the Northern Pacific Ry. laid 2000 tons of basic open-hearth steel rails, of the following composition besides the iron: carbon, 0.65 to 0.75 per cent; silicon, 0.10 to 0.16 per cent; manganese, 0.65 per cent; phosphorus, .03 per cent; sulphur, .05 per cent. At the first reweighing the results apparently indicated a rate of wear hardly exceeding one third of that of adjacent Bessemer rails laid at the same time, in which the carbon is not in excess of .50 per cent. The Baltimore & Ohio R. R. also has experimented with basic open-hearth steel rails, laid on curves alternately with rails of Bessemer steel. Comparison of results after 20 months of service under heavy traffic showed that on the low side of the curve the rate of wear for the Bessemer rails was about 62 per cent greater than for the open-hearth rails; on the high side of the curve the rate of wear for the Bessemer rails was about 50 per cent greater than for the open-hearth rails. The wear of both kinds of rails on the low side of the curve (elevation 4 ins.) was about double the amount on the high side. The lateral wear on the high side was not abnormal for either kind of rail. The Pennsylvania R. R. has experimented with small lots of open-hearth rails laid in the same way. The composition is as follows: Carbon, 0.55 to 0.72 per cent; manganese, 0.72 to 0.79; silicon, 0.09 to 0.12; phosphorus, .03 to .06 The Louisville & Nashville R. R. has extended its rail specifications to cover basic open-hearth steel. The following tabulation contrasts the chemical composition of the two kinds of metal for 80-lb. rails:

	Acid Bessemer.	Basic Open-Hearth.
Carbon	.55 to .65 per cent.	.62 to .67 per cent.
Silicon	.15 to .20 per cent.	.10 to .20* per cent.
Manganese		.90 to 1.00 per cent.
Phosphorus not to exceed	.085 per cent.	.05 per cent
Sulphur not to exceed	.07 per cent.	.05 per cent.

* .15 per cent preferred.

The Talbot Process.—As already shown, both the open-hearth and Bessemer processes are subject to certain disadvantages. The open-hearth furnace in ordinary use is too slow of operation to produce rail steel at an economical price and besides this its output is intermittent and not well adapted to the continuous operation of a rail mill backed by a convenient number of furnaces. On the other hand, the Bessemer converter is wasteful of metal, the loss of pig iron being usually about 13 per cent when converted into acid steel and 17 to 19 per cent if converted into basic steel. In an open-hearth furnace the loss of pig iron varies from five to eight per cent. These considerations have made it desirable to devise some means of manufacturing steel which would give the continuous production of the Bessemer converter and reduce the loss in metal to or below that of the open-hearth furnace. One effort in this direction which is now receiving a good deal of attention is a new method of producing open-hearth steel continuously, known as the Talbot process, from the name of the inventor, Mr. Benjamin Talbot.

This process was first worked at Pencoyd, Pa., in 1899, where a 75-ton furnace of the tilting type, with basic lining, was set up. As there are no blast furnaces in this vicinity the pig iron is melted in cupolas, and the first charging of the furnace, which takes place on Sunday evening, is made with about 50 per cent of melted metal and 50 per cent of scrap. This heat is worked down to steel with ore and lime in the usual way, and when the bath has reached the proper condition the furnace is tilted and about one third of the metal is poured off through a tap hole lower than the top level of the bath, so that no slag is run off. This metal is poured into a ladle and cast into ingots. Oxide of iron in a finely divided state is then added to the slag, and as soon as this is melted, about 20 tons of molten cupola metal is poured in to replace the steel tapped out. The bath then begins a vigorous boiling, much resembling the blowing of a Bessemer converter, and the carbon of the newly added metal is rapidly burned out, the fuel gas being meantime cut off from the furnace. The high heat developed by burning the carbon of the metal with the oxygen of the slag supplements the effect of the fuel gases and there is an economy in fuel and operation over ordinary open-hearth practice. In the course of 10 or 15 minutes the slag, which by this time has lost most of its iron oxide, is partly poured off and by the addition of iron ore and lime the bath is worked down to finished steel, when about one third of the steel is again tapped off. The foregoing operations are then repeated and kept up during the whole week, the furnace being completely emptied on Saturday, for repairs. In this manner a regular supply of steel at frequent intervals is obtained, with all the advantages of the open-hearth process and none of the disadvantages of that or the Bessemer process. Not only is waste of pig iron avoided, but the yield is actually increased from six to eight per cent of the pig iron poured into the furnace for conversion, the gain being due to the direct reduction of the oxides added in the form of iron ore. Each furnace will cast about 30 heats per week.

The Bertrand-Thiel Process.—The Bertrand-Thiel process of steel making, now being promoted in England, bids fair to work some changes in rail manufacture. This process consists in refining pig iron by two successive operations in basic-lined furnaces worked in pairs. The molten iron is poured into the primary furnace at a comparatively low temperature, and by additions of iron ore and lime about 90 per cent of the phosphorus and silicon, most of the manganese and 30 per cent of the carbon are eliminated, in the course of three hours, the phosphorus uniting with the lime to form slag and the carbon being burned out by the oxygen set free from the ore. At this juncture the bath is tapped into the secondary furnace, which has previously been charged with scrap and brought to an oxidizing heat. The primary furnace is usually set at a higher level than the secondary or finishing furnace, so that the transfer of metal takes place by gravity. During the transfer the slag is skimmed and run off. The removal of the slag protection causes the further oxidation of the carbon from the iron, in the secondary furnace, where the components can be regulated at will, adding spiegeleisen if necessary. After further treatment of about three hours steel of any desired quality can be obtained. Either all pig, or part pig and part scrap can be used. In the former case the process shows a gain of 2 to 3 per cent in yield on the pig iron charged, owing to the direct reduction of iron from the ore. The slag, being highly phosphoric, is a valuable fertilizer and sells for a good price. Eight heats can be worked every 24 hours from each pair of furnaces, which can be made of any capacity convenient for open-hearth work.

Nickel-Steel Rails.—The hardening and toughening effect of alloying steel with nickel, so successfully practiced in the manufacture of armor plate, has naturally suggested a like treatment for experiments with rail steel. Such experiments are now being conducted on a small scale with steel made by both the Bessemer and the open-hearth processes. On the Cleveland & Pittsburg division of the Pennsylvania Lines West some nickel-steel rails were laid on a 5-deg. curve, and after four years' service were said to be wearing better than rails of ordinary steel. Another quantity of nickel steel rails was laid in the west-bound track at the Horse Shoe Curve, on the Pittsburg division of the Pennsylvania R. R. These rails are of 100-lb. section and were rolled in an order of 300 tons, the metal being handled by the Bessemer process. Owing to "red shortness" the actual output was only 277 tons of rails, and 57 tons of these were of second quality. Following is the average chemical analysis: carbon, .504 per cent; phosphorus, .094 per cent; manganese, 1 per cent; nickel, 3.22 per cent. In the straightening process the rails showed much greater rigidity than is developed in the cold-straightening of ordinary steel rails. The rails were also found to be very hard, so much so that ordinary drills were not found equal to the work of drilling the bolt holes. The price of these special rails is said to have been very high. These rails have given good satisfaction from the standpoint of wear. Some of them laid alternately with ordinary Bessemer steel rails on 6-deg. curves had shown but little wear in four years, whereas the regular rails in service the same length of time had been turned and become considerably worn on the other side of the head. The result of these experiments was the placing of large orders for nickel-steel rails by the Pennsylvania R. R. and the Pennsylvania Lines West, in 1903, for further trials. At that time the Baltimore & Ohio R. R. began to experiment with these rails. These various orders were rolled by the Edgar Thomson Works of the Carnegie Steel Co. The angle-bar splices were also rolled from nickel-steel, the nickel content for both purposes being 3¼ to 3½ per cent. It has been proposed that trial should be made of frogs and crossings made of nickel-steel rails, to determine whether such material might not be found more serviceable for the purpose and more economical, notwithstanding the higher price. More recent progress with nickel-steel rails is mentioned in Sec. 220.

Wheeler-Process Rails.—The Southern Pacific Co. has made trial of rails rolled by the Wheeler process, whereby two grades of metal are so manipulated that the outer or wearing surfaces of the rail are of very hard high-carbon (0.785 per cent) steel, with a soft steel core (0.476 per cent carbon). The core occupies about half of the space in the head and flange and nearly all the space in the web. During 1897 thirty-nine of these rails were laid on the outside of curves in three places, 30 being on 10-deg. curves and 9 on a 5½-deg. curve; and after a service of a little more than 3 years, under traffic of 12 to 15 million tons, the rate of wear of the Wheeler rails was found to be just about half that of rails of ordinary steel of same weight and pattern laid immediately adjoining them on the same curves. These rails were traversed by the heaviest mountain locomotives of the road. During the three years 11 of the 39 rails failed by pieces of metal breaking from the side of the head, and had to be removed. The manner of failure indicated an imperfect union between the hard and soft steel.

The Manning Unsymmetrical Rail.—Mr. W. T. Manning, consulting engineer of the Baltimore & Ohio R. R., is the designer of a rail with an unsymmetrical head, conceived with the idea of prolonging the life of the rail on the outer side of curves. The section differs from that of ordinary rails in having an excess of metal on the gage side of the head, thus interposing additional metal for wear. Experiments with rails of this design are being tried on the Baltimore & Ohio and Pittsburg & Western roads. The form of section is illustrated by Fig. 15A, in which $A\ B\ C\ D$ represents the American Society section and $A\ H\ G\ J\ C\ D$ the Manning section. The excess material includes, therefore, some metal added to the top of the rail, as well as to the side of the head. In 85-lb. rails the distance BH is ¼ in., and the vertical portion HI is ¼ in. in length and runs into a curve of 1 in. radius extending to the lower corner of

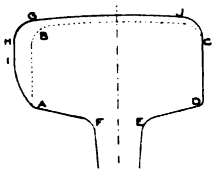

Fig. 15 A.

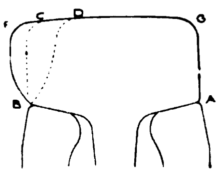

Fig. 15 B.

the head. The intention of the latter feature is to delay a full flange contact as long as possible while the side of the rail head continues to wear away. In a comparison of the two sections with respect to wear of head the limit of abrasion is based upon the state of wear when the wheel flange cuts the angle bar. Referring to Fig. 15B, in which the "Society" section is represented within the lines $BCDGA$, it will be seen that the "Society" section is limited for flange wear to the portion BCD and the Manning section to BFD, thereby prolonging the wear in such proportion as BFC stands to BCD, which is calculated to average 66 per cent. The distribution of metal in the 85 and 90-lb. sections is, head 45 per cent, web 20 per cent and base 35 per cent. The excess metal amounts to about 3 lbs. per yard or 2½ tons per mile of rail. Another advantage in the use of this rail, said to have been shown by experience, is that, owing to the excessive bearing on the inside of the rail, the track has a greater tendency to hold to gage than is the case with rails of symmetrical section.

The first experiment with these rails was with 1000 tons of 85-lb. section laid on heavy curves in the mountains in sections adjacent to rails of American Society section of the same weight and material. After a service of 16½ months at some points a comparison of results showed up very favorably to the Manning rail. In that time the rails of the American Society section had worn away to the angle bar limit, thus rendering them unfit for further service, whereas the wear on the Manning rails had reached only to a point which would correspond to the gage line of the top corner of the American Society section. In ultimate wear these results indicated a service 125 per cent greater for the Manning section than for the American Society section on curves.

198. Material Yards in Track-Laying.*—The location of material yards and the handling of the material on new lines depend a great deal upon the conditions under which the work is done. It is a very different matter in laying track on some new road that is being built in ten-mile stretches, where it is necessary to finish the first ten miles in order to pay for the grading of the next ten miles, from what it is on a long road where the work progresses continuously. Then, again, there is the small company that gets only a few cars of rails at a time, and begins to operate its road before it is built. (In this connection I have seen a road put on trains to do local business when some of the track was only half tied and only two or three ties spiked to a rail—track that I would not advise running a construction train over at any considerable speed.) For a road that gets only a little material at a time and is a long time building, and where only a few miles of track are laid each month, no special rule can be laid down for placing material yards or for handling the material trains. For short lines of this kind but little need be said about the material yard, except that what little material is to be stored should be unloaded with as much regularity as possible.

Where long lines are being built the material yard should be planned out in advance, and the material should all be unloaded according to this plan and with the object in view that it will have to be reloaded, probably in a hurry, and that a delay to the track-laying force for an hour will amount to as much as, or more than, the wages of the unloading gang for an entire day. The mistake usually made is at the very first in not providing sufficient room, by laying out side-tracks, to hold the material. Never unload any material off from the main line, either the new main line or the old one, and especially the old one. Never unload material off from a side-track on the old main line that is being used to operate the old road. Never unload material off from a Y-track, either old or new. Never unload material into borrow pits or off from a high fill; and, above all things, never unload the cars just where the freight train happens to set them, unless it is the proper place. Never send a young man out from the engineer's office to "pick up a few men and get those cars unloaded as quick as possible." Never send a section foreman on the operated road to unload material for the construction or engineering department unless you tell him what you want done, and how.

In level country a satisfactory material yard can be easily planned and quickly and cheaply laid out. The number of tracks and their location will, of course, depend upon the conditions at hand, but have at least two side-tracks. It is well to have at least two side-tracks on the same side of the main line, about 12-ft. centers for about 300 ft., when the outer track should swing out farther away from the first. At least one of the tracks should be connected at both ends, and if any of the tracks are to be "stubs" or "spur tracks" (which, for temporary use are about as good as any), the switches should be at the end opposite from the direction in which the track is to be laid—that is, if the road is to be built towards the west the switches should be at the east end of the yard. As many tracks should be laid as may be necessary to hold all the material that may be on hand at a time. Temporary tracks can be laid with about 12 ties to a rail, and should be surfaced up only as much as may be necessary in order to prevent the rails from being bent. In other words, don't go to the expense of laying a full tied, full spiked, full bolted and surfaced track for a temporary one.

In unloading the ties pile them at right angles to the track and in not more than two piles on one side of the track. Do not carry them away off, 25 to 100 ft. from the track, and do not pile them up in cribwork style, half one way and half the other. This is sometimes done with the idea of letting the air get at them to dry them out. Rails should always be unloaded lengthwise the track, and do not unload one car-load "here" on a couple of ties and another car-load "there." I saw, in one instance, 85-lb. rails piled up 10 or 12 ft. high, with every other layer at right angles to the track. The cost of unloading them must have been ten times as much as it would have been to have done it right. It took 20 men to load them and it required twice as long to do it as it would have taken ten men if they were unloaded properly. Rails should not be unloaded and piled up close to the track when there is plenty of room, but as far out from it as possible without going beyond the point where a 30-ft. rail can be used for a skid to unload and reload them. By doing this the piles can be

*By courtesy of Mr. John Smith.

made about 50 per cent higher than if the rails are piled close to the track, and they can be reloaded in half the time with a smaller force than if they are piled close to the track. Four men will skid up rails from this pile about as quickly as ten or twelve men will load them when they are close to the track. Angle bars as well as the spikes and bolts should be unloaded near the rails. A cribwork of ties with a floor of ties or crossing plank about 2 ft. above the track should be made and the kegs unloaded on this. If the material yard is on a grade put the spikes etc. at the down-grade end of the piles of rails, so that after a car is loaded with rails it can be started with a bar and run down opposite the "trimmings" (spikes, bolts, and angle bars). I have seen a few very nice examples of this arrangement.

I might say that a well arranged material yard is something that is seldom seen, and that, except on the long western lines, where men have learned from experience, material is seldom unloaded correctly. One great mistake, for a small matter, is to place kegs of spikes or bolts on the ground and a thousand feet or more from the rails. I might explain in this connection, even if partly by repetition, that each car of rails should be "trimmed" when loaded; that is put on all the angle bars for the rails and usually all of the spikes, bolts and nut locks necessary for them. The exception in the latter case is where a "spike car" is used in connection with the track-laying. When the last method is practicable it is about the best, in my opinion, the spikes for the "back work" then being carried on a separate car and distributed from this car as may be required. At one end of this same car there should be carried crossing plank and surface cattle guards, when the track force is putting them in. What I mean by properly unloading spikes and bolts is that they should never be rolled into borrow pits or be placed several feet below the level of the track; and they should never be unloaded directly on the ground, as the dampness, caused by rains etc., will rot the kegs and rust the bolts. The practice of unloading them low down, off a fill, will also cause the kegs to be broken, so that they cannot be reloaded. Always build a platform with a cribwork of ties about half the hight of the floor of the car. It will pay, as it will save breaking the kegs in unloading upon it, they are easily reloaded, and moisture of the ground will not affect them. It is my observation that many men unload track materials with only one idea in mind, and that is to get them off the cars with the least amount of work and trouble and to unload every car wherever the train happens to leave it. For example, in a material yard I have in mind, the spikes and bolts were unloaded at the west end of the material side-track, while the rails were unloaded at the extreme east end of the yard, 1-3 of a mile from the spikes, with 30,000 or 40,000 ties piled up along the track in between them.

All material loaded in the material yard should be loaded properly. When curved rails are being laid they should be curved before loading them to go to the front; and don't forget to curve just enough "short rails" for them, and don't load the short rails all on the bottom of the car under the rest of the curved rails—place them on top, as it is then easier to get at them at the front; otherwise it is necessary to "dig" for them when wanted. In laying right and left-hand rails, that is, using a certain side for the "running" side, as when laying old rails, for example, arrange them on the cars so that they will unload properly. Where the Harris track-laying machine is being used they may be loaded on the right and left-hand sides of the cars, but for other track-laying machines, where the rails are all run forward on one side of the train, it is necessary to load the rails for one side of the track on one car and the rails for the other side of the track on another car, alternating the cars loaded with right and left-hand rails. It is then always necessary to bring out the cars in pairs.

Personally, one of the best material yards I ever saw was at Fremont, Neb., in 1887, where the material for more than 100 miles of track was piled up. We laid this track by contract, and on only one instance was the "front" delayed for failure of the prompt delivery of the material to the last side-track, and, as a rule, we laid more than two miles of track per day. An excellent illustration of modern practice in handling material for long stretches of track-laying, especially in the West, was afforded in the methods employed by the Burlington & Missouri River R. R. in the Guernsey extension, in 1899 and 1900. The same practice was also employed not only on previous extensions of this same company but on other western roads where there was considerable work to do from one point. The material yard on the Guernsey (Wyo.) line was located at Alliance, Neb., the point where the new work started. When the work of laying track started there were vast quantities of ties unloaded and piled up, not promiscuously here and there, but all in one place, along two or three "tie tracks." The rails were unloaded along both sides of a track used only for that purpose. The man who unloaded them did so with the idea that it would be necessary to again load them, and he did it right.

On this extension (as is the practice on most of the western roads in laying new track) the telegraph wire was brought up to the end of the track every night and an operator was employed, so that all reports and orders could be sent in daily. The speed of track-laying was about 1¼ miles per day. The supply train left the material yard at Alliance each evening at about 7 o'clock, carrying material for the next day's track-laying. The selection of the late hour for leaving was to give opportunity to send in special messages by wire late in the day and have the things ordered brought out to the front the same night. In making up this train the cars loaded with the material for the next afternoon's work were placed ahead, with the cars carrying material to start the work in the morning coupled in at the rear of the train. The purpose of this arrangement was to save switching at the farthest side-track, or the point where the material was left, as the car-loads of material for the morning's work were then pushed in at the rear end of the side-track, in position for "first out" in the morning, leaving the other division of the train on side-track to be taken out after noon. This arrangement of running the supply trains at night also afforded the best economy in the use of cars, as the cars unloaded at the front during any certain day could be returned to the material yard in time for reloading early the next morning. The ballasting of the track followed close upon the track-laying, so that the material trains were able to make good speed.

199. Rules on Care of Lamps, A., T. & S. F. Ry.—The following are the rules of the Atchison, Topeka & Santa Fe Ry. issued to all employees using or caring for signal and all other oil lamps:

1. Standard headlight oil, as furnished by the company, must be used in all signal lamps, except hand lanterns. Signal oil is furnished for lanterns only. No attempt must be made to improve the quality of signal oil by adding lard or kerosene oil. Signal oil is rendered explosive if the lard and kerosene oils are mixed in the wrong proportions. If the oil does not give satisfaction the trouble must be reported.

2. Lamp fonts must not be filled above a point at least ½ in. below the top of the font.

3. The wick must be long enough to touch the bottom of the font, and must fit in the burner properly. Wicks that will not move freely by turning the ratchet shaft are apt to clog the burner, preventing a free flow of oil to the flame, causing the burner to overheat, encrust the wick, give a smoky flame, and sometimes cause an explosion.

4. When the ratchet wheels will not properly raise or lower the wick, the wick should be drawn up through the wick tube with the fingers, and then moved back to place by the ratchet wheel. If a wick is too large for the wick tube it can be reduced by drawing out a few threads.

5. The wick must be kept below the top of the burner when lamp is not lighted, to prevent oil flowing from the wick over outside of font.

6. All lamp fonts must be emptied and drained once every week and refilled with new oil. At points where a number of lamps are used the old oil thus removed must be poured into a can kept for that purpose, and marked "Old oil only." When filled, this can must be sent to the nearest roundhouse or car-yard, and the oil used for such purposes as cleaning trucks etc., but on no account must it be used for lamps again.

7. Once a month all oil cans and lamp fonts must be thoroughly rinsed with clean boiling water and then thoroughly drained and dried. Soap or soda must not be used in the water, as they will leave a residue or coating on the font or can that is injurious to the oil.

8. Lamps must be cleaned, fonts filled, wicks trimmed and burners cleaned daily. All vents in lamp body must be kept open and clear of soot and dirt, so that lamp will receive the proper amount of draught. Special attention must be given to the lenses to keep them clean, and to the top of lamps where the soot is most likely to collect. Lenses must be kept clean of all grease, oil, soot or dirt. If they cannot be cleaned in the lamp, lenses should be removed, cleaned with clean boiling water, care being taken to remove all grease and soot from the corners and angles on the corrugated back of lenses.

9. If the burners become fouled with oil, soot or incrustations from the wicks, they can be cleaned thoroughly by dipping in boiling water. The gas escape vent in the burner must never be allowed to become closed.

10. All lamps should be lighted for a short time before turning the flame up to its full hight, which should not be more than one inch above the top of burner. All lamps should be examined after fonts are put in place to see that they do not smoke.

11. The sulphur must be burned off the match before it is applied to the wick, to avoid encrusting the wick with sulphur.

12. In no case will employees be allowed to make alterations in lamps. If they do not give satisfactory service the trouble must be reported.

13. When a lamp through any cause becomes unserviceable a requisition must be made for a lamp to replace it, and as soon as the latter is received the defective lamp must be sent to the general storekeeper with a "Defective Lamp Report" (Form No. 872), properly filled in and attached to the lamp as a shipping tag. The stub of this report must also be filled in and mailed to the lamp inspector at the same time, care being taken to quote the requisition number on which the lamp to replace the defective one was ordered.

14. In taking down or replacing lamps at semaphores, the glasses in the semaphore arm spectacle frames must be inspected to see if they are clean and in good condition. A broken glass must be reported by telegraph to the trainmaster and the signal engineer.

200. Distributing Ties.—(By courtesy of Mr. J. C. Rockhold.) The varying conditions which one has to contend with when distributing ties for renewal make it practically impossible to follow any set rule, or method, as that would call for equally set conditions. For instance, it often happens that, on account of heavy commercial business, we find ourselves short not only of suitable cars in which to load the ties, but power as well. Under such circumstances the ties come dragging along in small lots, and we are not justified in organizing a work train for this work. In such cases as it is necessary to release the cars without delay I have been in the habit of using the local freight trains and one or two gangs of section men, or enough to put four men to the car if we were handling oak, treated pine, or water-soaked ties; or if seasoned redwood, or dry, untreated pine, then two men to the car are sufficient.

When ordering ties for renewal I always make it a practice to go over the ground personally with the foremen, marking each tie with an adze which it is found necessary to remove; and whenever possible to do so, I make it a point to superintend in person the distribution of the ties, as I have learned from experience that it is not safe as a rule to rely too much in such matters on the average foreman's judgment. He usually errs in favor of his own particular section, or if he is an extra foreman, his chief object is to get the ties unloaded. Whether he gets too many or not enough ties off in certain limits, whether they lie at the top or at the bottom of a 30-ft. embankment, are matters which chiefly concern the man who puts them in the track, and for this reason are a secondary consideration with him. A great deal of the expense of renewing ties may often be traced back to careless or slipshod methods of distributing. Except in the case of high, narrow fills, narrow cuts, or tunnels there is no good reason why ties should not be so distributed that the push car need never be brought into service. I always unload the new ties on one side of the track and take out the old ties on the opposite side. In this way the men do not have to climb from one side of the train to the other when loading up the old ties for fuel, fence posts etc.

Whenever practicable, ties for renewals should be unloaded on a face. If this is not done, when the gaps are finally closed up there is generally a shortage or a surplus, and either these places are left short of ties or else more are unloaded than can be used, and later on have to be redistributed. This takes time, and this is one of the cases where time is money. Again, unless ties are distributed on a face it is a difficult matter to get an accurate check of the number unloaded from each car. This results in no end of trouble for the office force.

The size of the crew used for unloading depends: first, on the grades, and the number of cars the engine can handle; second, upon the distance between side-tracks; and third, upon the number of trains to contend with. But, suppose conditions are normal: i. e., plenty of power, no lack of equipment, and ties coming along regularly. I find it is then preferable to do the unloading with a regularly organized force, and work train. The reason for this is obvious:

they soon become expert in the work of "opening up the cars" and handling the ties, and will easily unload a third more in a day than men who are not accustomed to the work. As a general proposition it is best to handle short trains, say ten cars, as you can start them quickly, stop them exactly where wanted, make good time getting out of the way of trains, and a very short siding will hold them. My plan is to put either two or four men in each car, according to the kind of ties being handled, as already explained. I find how many rail lengths this particular train covers before leaving the station, stop the train one train length short of the point where I intend to begin unloading, and while the men are "opening up the cars" go ahead and count the number of ties that are to be taken out in the number of rails covered by this train. I then divide this number by the number of cars in the train, the result being the number of ties to be unloaded from each car. By a prearranged signal I apprise the foreman how many ties I require from each car, and he in turn communicates it to the men. The train is then moved forward and while the men are unloading I again go ahead and count the number of ties to be removed from the required number of rails, and again signal the number to the foreman. The train is again moved forward one length.

This plan is pursued until the cars are all empty. Should one car become empty before the others, as frequently happens, count the full number of rails covered by the original number of cars in the train, but in the division reduce the number of cars one or more as the case requires, which will of course raise the number to be unloaded from the remainder accordingly. The advantages of this plan are as follows: First, each man has to do his share of the work, as there is no possible opportunity for shirking if one was so disposed; second, any number of cars can be unloaded without confusion, and an accurate check can be kept on each car; third, you get just the number of ties unloaded you require—no more, no less.

201. Tie Preservation in Europe.—In Europe, particularly in England, France, Germany and Austria, where lumber is generally high in price, the preservation of railway ties by chemical treatment has been practiced longer than in this country, and more scientifically. In the first place, the timber that is cut into ties is more carefully selected there than here, and the ties are bought to closer specifications. After that more attention is paid to natural seasoning than is the rule in this country. The ties are carefully piled and allowed to season 6 to 18 months before treatment. An allowance of 8 months to a year for seasoning is quite general practice. And then the ties are more carefully handled in other ways; as, for instance, measures are taken to prevent splitting and checking, which has never been done in this country. If ties exposed to the sun show signs of checking or splitting at the ends they are bored and bolted, to draw the fibers together, or S-clamps are driven into the ends. The latter device consists of a piece of sharpened hoop iron or bar of edge-tool section, ⅝ or ¾ in. wide, bent into the form of a double hook or letter "S," in sizes 3 to 7 ins. long. Ties piled for seasoning are frequently inspected, and wherever there is an indication of incipient cracking one of these clamps is driven into the end of the tie, across the line of cleavage, to hold the fibers together and prevent them from opening further. Beech ties, like chestnut and some varieties of oak in this country, are especially subject to checking. And then in Europe ties are generally adzed at the rail seats, if necessary, and bored for the spikes, by machinery, before being treated. In connection with boring holes for the fastenings at the time the ties are treated, it is found that the gage can be established with greater precision than results when boring the holes at the time the tie is placed in the track. If screw spikes are used the spacing of the holes bored in the ties does not vary, the widening of the gage for curves being provided for by means of adjustable clips or adjustable gage pieces in the fastening for the tie plate.

The antiseptic most largely used for tie treatment in Europe is coal tar creosote. Of 87 railways reporting to the International Railway Congress in 1900, 28 were using untreated ties and 59 had adopted some process of treatment. Of these 59 roads 38 were using creosote, 18 were using zinc chloride, four were using zinc-creosote, three were using copper sulphate and one was using brine. Five were using two processes. In Great Britain the creosoting process is used exclusively, and practically all the ties are treated. The timber is imported Baltic pine (also known as redwood and Scotch pine) from Norway, Sweden and Russia. The ties are injected with 7 to 9.6 lbs. of coal tar oil per cubic foot, and the average life is 15 or 16 years. The average life of the untreated tie is about 8 years. In France about 60 per cent of the ties are oak, 22 per cent beech and 18 per cent pine. The beech is native wood, the oak mainly so (some of the supply being obtained from Italy), and the pine is imported. The use of oak is diminishing and the use of beech and pine increasing. Creosote in large quantity is the antiseptic chiefly used, but zinc-creosote is used on the state railways. All of the beech and pine and nearly all of the oak ties are treated. The oak ties take from 9 to 13 lbs. of creosote each and the beech and pine ties generally 35 to 60 lbs. each. The standard tie is 8.53 ft. long, 5.1 ins. thick and 10.2 ins. wide. The Eastern of France and the Paris, Lyons & Mediterranean roads inject 60 lbs of oil per tie, for beech wood, and the Western Ry. 44 lbs. per tie. The life obtained is 16 to 30 years, according to the quantity of antiseptic used. In a report to the International Railway Congress, in 1895, based on data from 54 railways, the average life of creosoted oak ties was placed at 25 years, of creosoted beech ties 30 years and of creosoted pine ties 20 years. A report of the German Railway Union (which includes the countries Austria-Hungary, Roumania, Netherlands, Luxemburg, Germany and Switzerland) in 1896 gives the life of treated pine ties at 20 to 23 years, beech 30 to 34 years, and oak 24 to 28 years. The life of untreated oak ties in France and Germany averages 13½ years; of untreated pine ties 7 to 8 years; and of untreated beech ties 2½ to 3 years. The Southern Ry. uses the sulphate of copper (Boucherie) treatment, injecting solution in sufficient quantity to get 0.4 lb. of the dry salt per cubic foot. On the Eastern Ry. oak ties are generally allowed to season 15 to 20 months and beech ties 6 months or longer, before treatment. The piles, which are isolated, contain 100 ties each, with 10-in. air spaces between the pieces in each layer, and the top layer is made with sawed ties laid close and sloping. To protect the ties from rail cutting use is made of creosoted poplar tie plates about the thickness of a shingle, and costing 0.8 cent each.

In Germany native oak and pine were the timbers mostly used for railway ties in times past, but owing to a decrease in the supply of these beech has come to be used on a large scale. Until comparatively recent years the zinc chloride treatment was the one most largely used. Creosoting had been practiced to a limited extent for many years, but was usually considered too expensive for economical results. For some time extensive trials had been made with beech timber for railway ties, but so far as beech treated with zinc chloride was concerned the results were not satisfactory. The objection with this method of treatment was that the preservative solution leached out, sooner or later, leaving the timber unprotected, and the additional life thereby secured was not sufficiently remunerative for the expense involved. In this way attention came to be directed to the application of creosote to beech timber, for it had been demonstrated beyond question by certain of the French railways, particularly the Eastern of France, that beech timber thoroughly impregnated with creosote becomes a durable and desirable material for railway ties. The scheme is also acceptable from the fact that a large percentage of the forest area of Germany is in beech timber, which, without some effective means of preservation, is of but little use except for fuel. The records of some of the railways of Alsace-Lorraine show in one case that 86 per cent of a lot of creosoted beech ties were in service after being 29 years under traffic.

With a view to economize in cost of materials a good deal of work is being done in Germany with the zinc-creosote process. It is the aim to reinforce zinc chloride solution with enough of creosote oil to prevent the washing out of the zinc salt, and still not use enough of the creosote material to greatly increase the expense. To the ordinary zinc chloride solution is added 5 to 8 per cent of creosote at a temperature of 149 deg. F., and the whole is thoroughly mixed together by compressed air. The extra cost due to adding the creosote amounts to about 1½ cents per tie per 2.2 lbs. of creosote injected. The amount of creosote actually injected per tie is about 4.4 lbs., and the timber takes 0.50 to 0.55 lb. of dry zinc chloride per cubic foot. The cost of impregnating a pine tie with the mixture where 4.4 lbs. of creosote is used, is about 20 cents, and about 25½ cents where 13.2 lbs. of creosote is used per tie. In Germany the expense of impregnating a tie with creosote exclusively, where 66 to 80 lbs. of creosote is used, is 50 to 59 cents.

The efficacy of this method of treatment is illustrated by statistics published by the Hungarian State railway directors, whereby it is shown that out of 9455 beech ties impregnated with chloride of zinc exclusively and laid for the purpose of a test in 1885, 81 per cent of the same had been renewed on account of decay at the end of 10 years. In another instance, of 34,175 ties so treated, 59 per cent were renewed on account of decay at the end of nine years. In another test with 25,133 ties so treated, 34 per cent were renewed after a period of seven years, and 59 per cent after a period of eight years. On the other hand, in a batch of 17,400 beech ties treated for the Prussian State railways with chloride of zinc reinforced with 4.4 lbs. of creosote per tie, there were renewed at the end of the sixth year on account of decay, 67 ties, or 0.4 per cent; 287 ties, or 1.6 per cent, at the end of the seventh year; 704 ties, or 4 per cent, at the end of the eighth year; 1450 ties, or 8.5 per cent, at the end of the ninth year, and 2280 ties, or 13 per cent, at the end of 10 years. Of 79 cubic meters of second-class beech siding ties treated at the same time, and in the same manner, only 2.6 cubic meters, or 3.3 per cent, had been renewed on account of decay at the end of 10 years. The Prussian State railways have made extensive use of this process in treating pine ties, the work being done under contract by the well-known firm of Julius Rutgers, of Berlin. The result of the treatment on pine and beech ties is a life of 15 to 18 years, and the use of zinc chloride alone has generally been given up. Following are comparisons of cost of the two processes: With the zinc chloride treatment the average cost for pine ties is 15.6 cents; for oak ties, 12 cents; for beech ties, 18.8 cents. With the zinc-creosote treatment the average cost for pine ties is 19.2 cents; for oak ties, 15.6 cents; for beech ties, 20.4 cents.

In European practice the steaming of timber for the extraction of the sap previous to the injection of creosote has been largely discontinued. Such is the case in England, where use is made of the vacuum only (Bethell process) before the creosote is let into the treating cylinder. An explanation for the English practice is that the ties, which are imported, are for the most part floated in streams after being cut in the mountains of Norway and Sweden, so that the sap becomes largely dissolved and washed out before the ties arrive at their destination. Then, after arriving in port the ties are carefully piled and permitted to season for fully eight months before they are treated so that but very little of the sap remains in the timber. In other quarters considerable objection is raised against the steaming or Blythe process. The only road in France which uses it is the "Nord." German experts claim that while steaming may serve as an effectual method of removing the sap, the condensed steam will remain in the cells to obstruct the penetration of the oil, and that it will also dilute the preservative solution to an appreciable extent. Before applying zinc-creosote, which is an aqueous solution, the timber is sometimes steamed, but even then the effect on the general result is considered doubtful. In place of steaming, where creosote is being applied, two methods of treatment are resorted to, as productive of superior results.

The first of these, and the most expensive, is that employed on the Eastern Ry. of France, namely, that of kiln-drying the timber before the creosote solution is applied. Where this method is practiced the ties are first thoroughly dried in the open air, being carefully piled for several months. The ties are then bored for the fastenings and adzed for the rail seat, and, after being run into drying ovens, are subjected to hot air at a temperature varying from 95 to 176 deg. F. for about three days. On leaving the ovens the ties are straightway conveyed to the treating cylinders, where they are subjected to a vacuum of about 26 ins., for a half hour, when the creosote is let in at a temperature of 176 F. and injected into the timber under a pressure of about 75 lbs. per sq. in., which is maintained for about an hour. This method of treatment is considered very thorough and is conceded to produce the most effective results. In some of the German plants an attempt has been made to hasten the process of kiln drying by raising the heat as high as 212 to 230 F., in order to cut down the time of application to eight or ten hours, but experience has demonstrated that such treatment subjects the timber—particularly beech—to unusual liability to checking.

The other method of treatment consists in drying out the timber in the presence of the impregnating solution. It is claimed that by this process, which was put forward by Mr. Rutgers, of Berlin, the wood need not be seasoned previously to treatment. It is placed in the treating cylinder, wherein is first produced a vacuum of 23 or 24 ins. for about 10 minutes, when the tank is filled with creosote, covering the timber, and as high as possible without reaching the pipes communicating with the air pump. The oil is then heated by steam pipes for about three hours to a temperature of 220 to 240 deg. F., and this heat is maintained about an hour longer. The effect of the heated solution is to evaporate the sap and other moisture in the timber. The theory of this action is that the temperature of the solution exceeds the boiling point of the sap. The evaporation of the sap bubbles to the surface of the hot creosote and is removed by condensing apparatus, and afterwards measured. After the sap has been expelled from the timber sufficiently the tank is then completely filled with creosote, and a pressure of about 105 lbs. per sq. in. is maintained for about a half hour, in the case of beech ties, injecting about 20 lbs. of creosote per cu. ft. or 80 lbs. per tie. More time is required by this method of treatment where the timber is not seasoned. It is claimed that by this process the ties are not so liable to check as when seasoned in drying ovens; that the sap can be extracted from the timber more thoroughly; that greater quantities of creosote can be injected into the ties than by the other treatment. The Rutgers firm guarantees an absorption of at least 24 lbs. per tie for oak ties, 79 lbs. for pine ties and 79 lbs. for beech ties, the tie being 8.85 ft. long, 6.3 ins. thick and 10¼ ins. wide. While it is assumed that this process is preferable to that of the drying-oven treatment, at least in those cases where there is not time to slowly and thoroughly season the timber, or when green timber must be employed, experience is wanting to demonstrate whether the results will be as effective.

Of all woods in Europe sound beech is the most thoroughly susceptible of impregnation. This fact is due to the circumstance that beech is mostly sap wood, and consequently all the pores, which, in their natural condition, serve to transmit water, remain permanently open; whereas, in the case of oak and pine the creosote penetrates only through the sap portion of the wood, while the heart wood absorbs but very little or not any of it. Beech wood considered most suitable for ties is furnished by trees at the age of 80 to 120 years. In France all red-hearted beech is rejected, as it is found that such timber is in most cases superannuated, and that the impregnating solution cannot be forced into the pores, which have ceased to be of use for conveying the nutritive fluids of the tree and have become closed or clogged. Results reported by certain of the French roads show that creosoted beech ties harden with age or service and eventually surpass oak ties in both durability and hardness, so that they are preferably used on lines of heavy traffic. In consideration of the foregoing qualities and the fact that the first cost of beech is less than that of oak or pine, it is therefore considered by all odds the most suitable timber for ties.

One other process which has been experimented with in Germany is the water-creosote process. This consists in injecting an emulsion of water and creosote. In European practice the strength and purity of the treating solutions are tested constantly and all stages of the processes of impregnation are watched with minute care. The use of dating nails and the keeping of careful records are generally established. Thorough seasoning before applying the antiseptic is characteristic of nearly all the work. The specifications of some of the German railways require that oak must be air-dried until it weighs not to exceed 49.8 lbs. per cu. ft., beech 45.1 lbs. per cu. ft. and pine 39.2 lbs. per cu. ft.

Notwithstanding that the zinc chloride treatment has been abandoned by nearly all, if not all, the railways of Germany, the records of some of the roads show fairly good results. In 1888 and 1889 experimental sections of track on the Bavarian State Railways, near Munich, were laid with ties of various kinds of timber, both untreated and treated with various processes, in sets of 121 ties each. In 12 years all the untreated spruce ties had been renewed twice and a few of them the third time, the average life being slightly under 5 years. In the set of spruce ties impregnated with zinc chloride none of them had been renewed at the end of 7 years, only 16 at the end of 9 years, and 43 were still in the track at the end of 12 years. The average life of kyanized spruce ties was about 9.1 years, a few of them lasting longer than 12 years. The data of the untreated beech ties are not itemized for the early years of the renewals, so that the average life cannot be computed with reasonable assurance, but nearly all had come out in 5 years, and at the end of 12 years all had been renewed twice and 106 of them the third time. In the set of beech ties impregnated with zinc chloride none was renewed until the 10th year, and 68 still remained at the end of 12 years. In some extensive experiments by the Imperial Elizabeth R. R., of Austria, the untreated beech ties were all removed in 4 years, the average life being 3.2 years. Of the beech ties impregnated with zinc chloride, 50 per cent had been renewed in 11½ years and 82 per cent in 15 years, the average life for all being about 11.4 years. The untreated spruce and fir ties were all removed in 7 years, the average life being 4.9 years, but of the spruce and fir ties treated with zinc chloride only 50 per cent had been removed in 9½ years and 73 per cent in 12 years, the probable average life for all being 9.8 years.

202. Tree Planting.—Among various proposed measures for conserving the supply of railroad tie timber tree cultivation by the railroad companies themselves has long been suggested. Between 1880 and 1890 the subject began to receive some attention on the part of railway managements, and during those years the experiment of tree planting was taken up on a few roads. On the whole the work then begun has been rather disappointing as to rate of growth. It is admitted, however, that at least some of these experiments were tried at random, without investigating the conditions most suitable for the growth of the trees, and the results are therefore not to be taken as conclusive. These failures or partial failures led to a closer study of the conditions essential to profitable growth, and eventually the business came to be better understood.

The tree generally recommended for this purpose is the catalpa, particularly the variety catalpa speciosa or "hardy catalpa," as it is commonly known. It is indigenous to the valley of the Wabash river, in Indiana and Illinois, but proven to be hardy between latitude 29 and 44 deg. north, wherever the proper conditions of soil and atmospheric moisture obtain. The utility of this timber for ties seems to be well established. Catalpa ties on the Erie R. R. and on the Cairo division of the Cleveland, Cincinnati, Chicago & St. Louis Ry. are reported to have given a service of 20 years. Under favorable conditions the tree grows quickly. Measurements of a large number of catalpa trees of known age, in Kansas, Nebraska, Iowa, Missouri, Illinois, Kentucky, Ohio, District of Columbia and Indiana, have shown an average growth of 1 in. diameter increase each year after planting. Trees six years old were found to be 6 ins. in diameter and trees 16 years old 15 ins. in diameter; trees 20 years old, from the seed, have measured 21 ins. in diameter and 50 ft. in hight. The tenor of the claims is that wherever conditions are favorable a growth of 16 to 20 years will produce trees large enough to make three to five ties. It is said that in the warm and moist climate of Louisiana the rate of growth for catalpa is almost double the above figures.

The usual scheme of planting is to set out one-year-old seedlings in regular rows, in deeply plowed ground harrowed down smooth. Until the trees grow large enough to shade the ground and keep it clear—say two to four years—the ground should be loosened occasionally by cultivation and the weeds and grass should be kept down. Young catalpa trees will not thrive well where the surrounding earth is covered with sod. The contract price for the young trees, including the work of setting them out and taking care of them two years, has in some instances been one cent per tree. A number of plantations have been set out with as few as 600 to 1000 trees per acre, but some forestry experts recommend planting them as close as 4 or 5 ft. apart each way, which requires 1750 to 2700 per acre.

The question as to the best distance for spacing the trees in planting is unsettled. The thick planters hold to the view that in early life the trees should be grown close together, so that their branches will interfere, causing a straight and tall growth of trunk, clear of limbs near the ground, and shading out grass and weeds. As the trees increase in size they begin to crowd one another and to shade off one another's branches, and about this time some of the trees will begin to fall behind. This is an indication that the ground is being overtaxed, and then the weak trees should be thinned out, in order that the others may get proper sustenance. It is expected that in six to ten years the trees will be large enough for fence posts, and then the thinning-out process should be continued to the finish, leaving only 600 to 800 of the most vigorous trees to the acre, with room to expand their limbs and thicken out their trunks. Working to this plan there will be, at the time of the final thinning down, a forest floor of decayed leaves and branches to protect the remaining trees from growth of grass from that time on. Those who favor this plan do not think that natural forest conditions can be obtained in any other way.

The thin planters claim that the trees should not be planted closer than 8 ft. apart each way (680 trees per acre) or in rows 8 ft. apart with trees 5 ft. apart in the rows, at closest, which requires about 1090 trees per acre. Their argument is that when catalpa trees are planted closer than this the roots will overcrowd the soil in a few years and stunt the growth. Then it is recommended that as soon as the trees are large enough for fence posts they should be thinned out to 16x16 ft. (170 trees per acre) or 10x16 ft. or 8x16 ft. (270 to 340 trees per acre), at most, for the trees intended for tie timber. To keep down the grass when setting the trees thinly it is considered good practice to plant corn or some other subsidiary crop between the rows of trees, for a season or two. Whatever is planted should be in rows, so that the trees may get the benefit of cultivation. To enforce a straight and tall growth with small trees that stand so far apart they are cut back and pruned. After two or three years of growth from the time of transplanting, the tree is cut off at the ground and allowed to sprout for one season. The next season all the sprouts are cut away except the most vigorous one, and that is allowed to remain to form the final tree. These sprouts from the old root shoot up amazingly tall and straight the first season, and in about four years from the time of cutting back they will make post timber. Cultivation must be continued until the trees shade the ground effectively.

The tendency late years seems to be toward thin planting, or to the extent of about 1000 trees per acre, reducing the number by thinning to about 500 trees in the period from the eighth to the twelfth year from planting. By whatever plan the trees are planted they should be systematically pruned, cutting the lower branches off close to the trunk. The first general pruning is usually done when the trees are five or six years old, and by the tenth year they need it again, but dead limbs and a tendency to fork near the ground should be attended to promptly, as soon as conditions require. The fallen branches should be allowed to lie and decay on the ground, as they assist in forming the humus of a forest floor.

It has long been a favorite idea with many persons who have given attention to timber culture that the spare land on railroad right of way might be utilized to grow catalpa trees. It has been figured that trees could be grown thickly enough along the right of way to fully supply all requirements for fence posts, telegraph poles and ties for the adjoining track as such supplies would be needed. The practicability of such a scheme has not, however, been demonstrated, and so far as there has been any experience in this direction the results have been disappointing. The weight of expert opinion and of experience seems to be that the width of available right of way on each side of a railroad track is not sufficient for the maintenance of forest conditions. During the year 1883 the Pennsylvania Lines West set out 86,000 catalpa trees along both sides of the track, on the right of way. Some of these were planted on the line between Richmond, Ind., and Indianapolis, and others between Richmond and Logansport, Ind. After 19 years some of these trees had attained a diameter of 12 ins., but generally not exceeding 8 ins., and not enough of them worth speaking about were of a size or shape that would make track ties, and only about 40 per cent of them were suitable for fence posts. The experience was that the branches grew very rapidly, and much labor was required in trimming, to keep them clear of the telegraph wires, but the increase in size of trunk was slow. But, after all, it is not a question of great importance whether or not the right of way can be utilized for timber cultivation. What railroad companies are most concerned about is whether durable ties can be grown in a reasonably short time, and at moderate cost, compared with past prices, or say 40 to 50 cents apiece. If such can be done there would seem to be but little question as to the proposition of maintaining the supply of timber for track purposes indefinitely, for if such were once demonstrated to be practicable farmers would undoubtedly go into the business.

Experience shows that a satisfactory growth of catalpa requires at least a moderate amount of moisture in climate or soil. About the year 1880 the Southern Pacific Co. planted catalpa trees quite broadly over the State of California, and after 20 years of growth the average diameter of the best specimens was only 4 ins. The best growth was where there was most moisture. In dry places the plants did not grow into trees at all. In 1882 the Kansas City, Ft. Scott & Memphis R. R. and other parties finished planting a portion of two square miles of land in eastern Kansas with catalpa trees 4x4 ft. apart. At the age of 10 years about one fourth of the trees were cut and allowed to lie on the ground, not being of any value. During the next 10 years 500 to 600 posts per acre were obtained by the thinning process, some acres yielding 1200 to 1500 posts. During the 18th and 19th years 120,000 posts were taken off and some pole timber 26 ft. long, with a tip diameter of 6 ins., was obtained. After

20 years the trees had been thinned to about 1800 per acre, and some of them had attained a diameter of 12 to 20 ins. and a hight of 40 to 45 ft. The diameter of some of them, however, was only about 6 ins., the largest trees being found on the best soil. It was observed that on parts of these tracts where corn had not grown well in previous years the trees did not thrive. It is a point emphasized by authorities on forestry that land for satisfactory growth of catalpa should have a porous subsoil and be able to produce good corn or wheat. The whole cost of the land, the trees, the planting, the cultivation, the interest on the capital and the general attention for 15 years was about $100 per acre. The following information regarding this plantation was kindly supplied in July, 1902, by Mr. Geo. E. Kessler, superintendent of parks for the Frisco System:

"The catalpa plantations along the former Kansas City, Fort Scott & Memphis R. R., now part of the Frisco System, are on the prairie lands about 17 miles south of Fort Scott, on the Joplin division. The property belonging to the railroad company, at Farlington, Kan., contains 640 acres, of which about 400 acres are in catalpa trees, the remaining lands in some miscellaneous and practically valueless plantation, but largely in grassy swails. The other property, containing 800 acres and belonging to Mr. H. H. Hunnewell, of Boston, lies about 4 miles southwest of Farlington, and of this something less than 500 acres are planted in catalpa trees. The planting of both properties was done between the years 1879 and 1882. Except for a small portion of the work done in 1879, the rest was planted afterward by Messrs. Robert Douglas & Sons, nurserymen of Waukegan, Ill. The trees were planted in rows 4 ft. apart and 4 ft. apart in the rows, and were cultivated for a few years until they shaded the ground, and then allowed to grow undisturbed. About ten years ago the first thinning was made, taking out about one fourth at that time, and since then a very large amount of thinning has been done. The first cutting was valueless, but the next time a small number of posts were cut, and in recent years the entire cutting has been utilized for fence posts, largely by the railroad company for its right of way fences.

"The trees now stand about 45 ft. high, at maximum, but along the edges of the bad lands some of them are not over 10 ft. high; generally, however, about 40 or 45 ft. high, and in diameter about one third are from 12 to 20 ins. at the bottom, the remainder being from 6 to 10 ins. During the past 5 or 6 years the trees have made very slow growth, and have to some extent suffered from a fungus growth in the heart, as a result of the dead branches remaining on the trees, the fungus entering at the points of juncture with the trunk. The past 5 years have, however, been exceedingly dry ones in that region, and trees standing out alone have suffered just as much and show the same conditions of lack of growth, as well as the fungus effects, as those within the plantation, planted as closely as they were. We are cutting a large number of trees in the course of systematic thinning and these will develop fence posts only. The trees have barely reached the size sufficient to make poles for telephone lines, and are certainly very far from supplying ties. Both of these plantations are on very thin prairie soil underlaid with gumbo, and this, together with the dry seasons, has not given the plantation the vigorous condition it should have at this time."

Previous to setting out this plantation the company had experimented with a 100-acre tract near Farlington, Kan., planted with the following varieties of trees: White ash, black walnut, wild cherry, osage orange, ailanthus, catalpa bignonioides and catalpa speciosa. After carefully noting the annual growth and general appearance of the trees for some years the decision as to best progress was in favor of the catalpa speciosa. It not only proved to be the strongest grower, but was also the most tenacious, standing dry weather better than any other species. The catalpa bignonioides, also called catalpa catalpa, is of small growth, crooked and seldom forms a well-shaped tree. It is native to the southeastern states. The speciosa has heart-shaped leaves. The flowers are 2 ins. long, nearly white but faintly spotted, the lower lobe being notched. The seed pods are thick, 12 to 14 ins. long and ¾ in. in diameter. The flowers of the bignonioides are smaller than those of the speciosa and bloom two weeks later. They are much spotted with yellow and purple and the lower lobe is entire. The pods are thin, and of less diameter and shorter than those of the speciosa. The bark is scaly, peeling off in strips like that of wild cherry; many of the leaves are three pointed. The seed is plentiful and easily gathered, while that of the speciosa is scarce on the tree, hard to collect and comparatively expensive. The speciosa has deeply furrowed bark, like the ash, and it does not peel off in scales.

The fact that there are two varieties of catalpa native to this country is important to bear in mind, for the bignonioides is worthless for timber, and there are many hybrids, all of which are inferior to the speciosa. For a long time it was not generally known that two varieties of catalpa existed in the United States, it being supposed that the smaller tree of the Carolinas and southeastern states was due to less favorable conditions of climate and soil. The discovery was made in 1853, by Dr. John A. Warder, of Dayton, Ohio (hence the botanical name "catalpa speciosa, Warder"), but only an informal announcement was made at the time. It seems that it was not until 1880 or 1881 that the distinction was made known to science in a formal manner, and it was some years later before it came to be generally understood. This explains why so many experiments with catalpa in this country have been unsuccessful, and in this connection the following incident in the history of railway tree planting is in point.

One of the earliest railways to commence tree planting for growing post and tie timbers was the St. Louis, Iron Mountain & Southern. During the '60's this road planted 50,000 catalpa trees on the right of way near Charleston, Mo., and a farm of 100,000 trees on the Belmont branch, 18 miles from Belmont, Mo. These trees were all raised from the seed. In 1880 a farm of 150,000 trees was set out at Bertrand, Mo., making, altogether, about 200 acres of catalpa trees. Some seed of the catalpa kempferi (another variety inferior to the speciosa), imported from Japan, had been planted along with the rest. Some years later large seed firms began to collect seed from one of these plantations, and thousands of pounds were distributed to all parts of the country. Eventually the distinction between the two American varieties came to be generally known, and then it was discovered that not one of the trees of this plantation was catalpa speciosa: it had grown up with the bignonioides and kempferi varieties and hybrids of the same, and in course of time most of the trees were cut down as worthless.

On the profitableness of tree planting the division of forestry of the United States Department of Agriculture has issued a publication treating of the limitations of catalpa growth as affected by the soil, moisture, etc., and examples are cited in some detail which show the results of experiments in this field. In 1890 Mr. L. W. Yaggy started a plantation of 440 acres of catalpa trees in the valley of the Arkansas river, near Hutchinson, Kan., where the natural conditions were favorable and well adapted to tree growth (sandy soil subirrigated from natural sources). The trees were set, 3½x6 ft. apart, and the farm produced, after eight years of growth, fence posts, 4 to 6 ins. in butt diameter. This time included two years of growth from which the trees were cut back to the ground in order to produce a straighter growth. From figures prepared by government experts who investigated the products of this farm it appears that the gross value of the marketable timber crop produced in ten years was $267.15 per acre. The total cost of growing and marketing the timber was $51.70 per acre, and allowing 6 per cent compound interest on all expenditures incurred from the time of planting, including the purchase price of the land, $25 per acre, the total expense per acre was found to be $69.60, leaving a net profit of $197.55 per acre. The only other of these early plantations, not already mentioned, which seems to have been commercially successful is the farm of Mr. Geo. W. Tincher, near Wilsey, Morris Co., Kan., on high prairie upland. It was started by planting 31 acres in 1885, with trees 4x4 ft. apart. After 17 years this plantation was thinned out one half by removing every other row. At that time some sections of the forest were able to furnish 2000 fence posts to the acre, but "not a single tie." The trees averaged an annual increase in diameter of 1-3 to ½ inch. The owner concluded that the trees in this part of the farm were set too close, and in 1899 nine acres were planted with trees 5x7½ ft. apart, and in 1900 twenty acres with trees 5x14 ft. apart, which give promise of better growth.

From the foregoing it appears that more than 30 years of experimenting with forest cultivation has failed to produce tie timber. Experience, has, however, shown some bad mistakes and no small deficiency in knowledge of timber cultivation in general, and the results are not by any means considered final. About the year 1900 the question was revived, and the result was that a number of railroads started catalpa plantations for the purpose of growing tie timber. In 1899 the Cleveland, Cincinnati, Chicago & St. Louis Ry. set out 30 acres of land with some 30,000 catalpa trees. At Brightwood, Ind., this company has a farm of 20 acres, 1000 trees to the acre, planted in 1900. Besides these it has other small tracts planted with catalpa. In April, 1901, the Rio Grande Western Ry. planted a nursery of 60,000 catalpa trees on irrigated land near Provo, Utah. The trees made a strong, healthy growth of 6 to 8 ft. during that season and the next year were transplanted at points along the line of the road. In the year 1902 the Boston & Maine R. R. planted 10,0.0 catalpa trees on waste land, outside of location, in the Merrimac river and Shawsheen river valleys, 20 to 30 miles from Boston. The trees were set 8 ft. apart each way, with the intention of thinning to 16 ft. apart when large enough to make fence posts. During the spring of 1903 this company set out a plantation of 6,000 chestnut seedlings near North Wilmington, Mass. Chestnut is a rapidly-growing tree that is hardy in all of southern New England and is found abundantly in the middle Atlantic states. It will grow on a great variety of soils, and as it makes excellent ties the experiment of this company should be watched with interest. During the year 1902 the West Virginia Central & Pittsburg Ry. set out 5900 catalpa trees, 3500 near Kerens, W. Va., and the remainder near Shaw, W. Va.

The Illinois Central R. R. has two catalpa plantations set out in 1902: one of 225 acres, at Harahan, La., near New Orleans, and a smaller tract at Tucker, Ill., planted with 20,500 trees. In the scheme of planting, seedling trees were set 8 ft. apart, with the intention of thinning them out when sufficiently grown to make fence posts. At the Harahan farm cultivation during the early years was provided for by allowing market gardeners to work the land between the rows of trees, without charge for rent, upon the condition that the weeds should be kept down and no injury done to the trees. At the Louisiana State Experiment Station, which directly adjoins this tract, catalpa trees have grown at the rate of 2 ins. increase of trunk diameter per year. Near Newton Hamilton, Pa., the Pennsylvania R. R. has a grove of 15,000 yellow locust trees planted in 1902, and at Conewago, Pa., 43,000 of these trees were set out in 1903. The trees were set out 10 ft. apart. It is estimated that a growth of 15 years will be required to make tie timber. The Michigan Central R. R., during the years 1900-02, planted some 34,000 catalpa trees at various points along the Canadian division. Some experimental planting has also been done by this company at Glenwood, Mich.

203. Metal Ties in Foreign Countries.—As elsewhere stated in this volume, the results of extensive and long-time experiments with metal ties are not to be found in the United States. In many of the foreign countries, however, the use of metal ties is beyond the experimental stage, and the mileage of track laid with such ties is increasing. In countries where suitable timber is scarce and costly the use of metal ties has been found economical, and in some parts of Asia and Africa the destructive work of white ants on wood ties practically compels the use of some form of metal track support. About 1889 the Forestry Division of the United States Department of Agriculture went into the subject of metal railroad ties very thoroughly, inquiring into the extent to which such ties were used in all the countries of the world, the practical experience in the use of such ties, and data were collected on their durability, efficiency, the economy in their use, methods of manufacture, etc. These investigations were made by Mr. E. E. R. Tratman, by direct inquiry of official sources, and the results were published in detail in Bulletin No. 4 of the Forestry Division, issued in 1890. Again in 1894 the matter was taken up and thoroughly investigated by Mr. Tratman, mainly for the purpose of ascertaining the progress and experience in the use of metal ties and longitudinals subsequently to the previous investigation. The results of this investigation were published at length in Bulletin No. 9 of the Forestry Division, as supplementary to Bulletin No. 4. The report of 1890 shows that 24,802 miles of track was laid with metal ties and longitudinals, or 13.2 per cent of the mileage of the entire world at that time, excluding the United States and Canada. The report of 1894 shows that the length of track laid with metal ties and longitudinals had increased to 34,978 miles, or 17.2 per cent of the entire mileage of the world at that time, outside of the United States and Canada. By continents the mileage of metal track in 1894 was divided up as follows: Europe, 13,404 miles (longitudinals 3645 miles, plates 257 miles, cross ties 9502 miles), out of a total of 137,000 miles of track; Asia, 14,586 miles, out of a total of 22,000 miles of track; Africa, 2326 miles, out of a total of 5675 miles of track; Australia, 234 miles, out of a total of 12,000 miles of track; South America, Central America, West Indies and Mexico, 4416 miles, in a total of 21,500 miles of track. The general summary in 1894 stood as follows: Metal longitudinals 3645 miles; metal bowls and plates, 12,375 miles; metal ties proper, 18,958 miles. It is known that since 1894 the mileage of all-metal track in foreign countries has been increasing, but since a general summary of subsequent date has not been made, the data of the total mileage at the present time are not available.

The countries that were using all-metal track most extensively in 1894 were Germany, with 11,605 miles, including 3580 miles of track laid with metal longitudinals; British India, with 13,655 miles, including 7595 miles of track laid with bowls and plates; and the Argentine Republic, with 3638 miles, including 3438 miles of track laid with bowls and plates. Ten other countries had between 200 and 900 miles of track laid with metal ties and six more had between 100 and 200 miles so laid. In nearly all of these countries the mileage of track laid with metal ties had materially increased between the years 1890 and 1894. On 54,742 miles of line of the German Railroad Union, in Germany, Holland, Austria, Hungary and Roumania, in 1897, 15,774 miles of track was laid with metal supports, of which 2095 miles was metal longitudinals. This was an increase of about 3600 miles of all-metal track over the mileage so laid in 1894, but the mileage of track supported on metal longitudinals had decreased 1547 miles.

Metal Longitudinals.—In 1894 the use of metal longitudinals was confined to two countries, namely, Germany and Austro-Hungary. A common type in use is an inverted flanged trough, placed longitudinally under each rail and held to gage transversely by tie bars. The Haarmann compound "self-bearing" girder rail, 8 ins. in hight and 12 ins. wide at the base, is laid upon the ballast without intermediate supports, and is held to gage with tie bars. The rail is rolled in two halves, separable through the middle vertical plane of the web, and to hold the two halves in their proper relative positions a tongue and groove are provided along the middle line of the surfaces in contact. The halves are put together to break joints and are held with bolts 12 ins. apart, on a line just under the head. The joints are spliced with long angle bars. The bottom or base is held together by small transverse channel-iron clamps bolted to the under side. The edges of the base or flange have depending ribs or beads, and the rail weighs 116 lbs. per yd. In laying the rail it is buried to the head in ballast. The Haarmann-Vietor rail is another that is laid on the "self-bearing" plan. It is 8 ins. high and 8 ins. wide on the base and weighs 127 lbs. per yd. The rail is rolled with an unsymmetrical head, or with the "web aside" with respect to the head, so that the webs may lap at the joints. The lap joint, which is 10 ins. long, is made by scarfing the head and base of each rail, on line with the side of the web, so that no part of the web is removed. The splices are 6-bolt angle bars 29¼ ins. long.

The expense of maintaining track surface with longitudinal supports is excessive and it is also difficult to detect defects in the ballast support, unless it is watched while a train is passing, as the combined stiffness of the rail and sleeper frequently causes the track to spring to even surface as soon as the load passes. It is also difficult to obtain proper drainage, particularly on grades, where the water tends to follow the lines of the rails. At frogs and switches the construction is complicated. The roads which have experimented with metal longitudinals to greatest extent are the Alsace-Lorraine, Bavarian State, and Prussian State railways. The report of 1894 showed that the use of longitudinal supports was being gradually abandoned, as was also the case with bowls and plates, which were in service mainly in tropical countries. In the evolution of railroads it seems to have become quite definitely settled that the cross-tie system is destined to remain the leading, if it does not become the exclusive, system in use.

Metal Cross Ties.—Generally considered, the predominating type of metal tie in use in foreign countries is of inverted trough section, with closed ends, designed on the principle of the Vautherin tie, invented by a French engineer of that name and first used on the Paris, Lyons & Mediterranean Ry., in 1864. (The first metal cross ties were used in 1860, by Mr. Le Crenier. The form of tie was U-shaped in section, 7 ft. 10 ins. long, 10 ins. wide, weighed 52 lbs. and was laid under T-rails) The original Vautherin tie was sectionally an inverted trough, with flaring sides, having a rib or narrow horizontal flange on each lower edge. In 1894, 104 miles of the State Railways of France were laid with Vautherin ties of uniform section, first put down in 1887. These ties are 8.2 ft. long, about 10 ins. wide over all, with a top width of 4.8 ins., and the average weight is about 125 lbs. In 1901 this railway system had 600,000 metal ties in the track.

The Post Steel Tie.—The Post steel tie is very well known in foreign countries and is quite extensively used in most of the countries of Europe, in the

East Indies, South Africa and the Argentine Republic, 1,500,000 of these ties having been in service since 1894. This tie, which was designed by Mr. J. W. Post, divisional chief engineer with the Netherlands State Railways, is shown at the right, in Fig. 485. It is of rolled steel, with closed ends, and has a thickened rail seat with an inclination of 1 in 20. The standard tie of this design is 8.36 ft. long. The tie is of "variable profile." The cross section at the rail seat is polygonal, 4.4 ins. wide on top, 10.2 ins. wide across the bottom and about 3 ins. deep. The cross section at the middle is an inverted V, 4.38 ins. deep, with a top radius of 1 in. and a bottom width of 5.4 ins. The sides of the tie are about ¼ in. thick at the lower part and ⅜ in. thick at the upper part. The thickness of the top table varies from .52 in. at the rail seat to .24 in. at the middle. The intention of deepening and narrowing the section of the tie at the middle is to give transverse strength and to decrease the bearing area where it is not needed, thus decreasing the tendency to center-binding. The fastenings consist of bolts and clips. The weight of the tie of these dimensions is 118 lbs., but as used on some roads it is made considerably heavier.

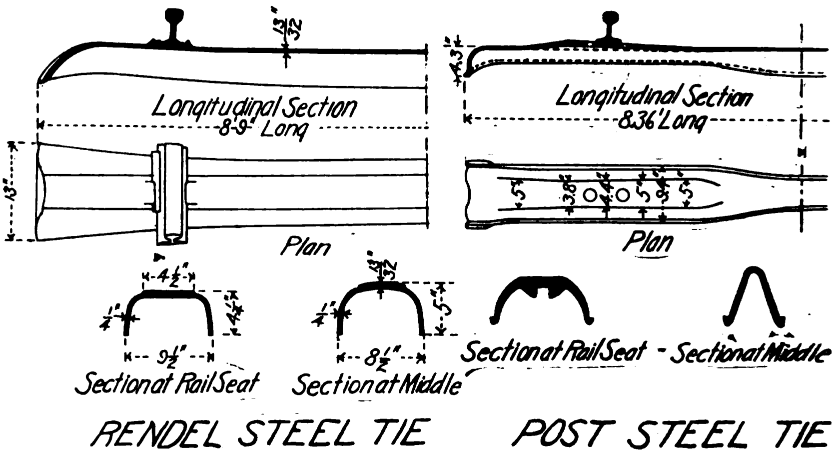

Fig. 485.—Types of Steel Ties Used in Foreign Countries.

The Post tie as used on the Liege & Limburg division of the Netherlands State railways, in Belgium, takes two forms respecting the middle portion, one being belly-shaped, as shown in the figure, and the other straight on the bottom and humpbacked on top, and known as the "dromedary" type. According to official reports the latter form gives the better satisfaction, as the middle portion of the tie is not bedded in the lower and firmer portions of the ballast, and therefore not so liable to center-bind the track. On this road metal ties have been in use since 1865. In an official report of the road published in the Bulletin of the International Railway Congress for July, 1898, an account is given of the experience had with steel ties on 27 trial sections, during the preceding 17 years. The trial sections were all single track, ballasted with slag, sand or gravel, and laid with rails weighing 76 lbs. per yard, ties 3 ft. apart centers. The heaviest engine weighed 68 tons, with a maximum axle load of 13.9 tons; the traffic over the lines was from 14 to 29 trains per day, the highest speed 47 miles per hour, and the ultimate traffic 100,000 to 150,000 trains. The steel tie most favorably reported upon was of the Post pattern, first laid in 1884, and the conclusion was that the life of a steel tie equals several times that of an oak tie. Cracks and breaks in steel ties noticed in the beginning were due to the fact that the holes for the fastenings were punched. When these holes were drilled the evil disappeared. A plate between rail and tie increased the durability of the latter. It was also found that with steel ties of the Post design there was less danger of the rails spreading than with oak ties. Some exceptions are cited where preference should be given to oak ties, such as on badly drained lines, on new track that has not fully settled, on swampy ground, and on clay or other ballast which has a high tendency to retain water. In 1901 the St. Gothard Ry. of Switzerland had in use 400,000 iron and steel ties (about 70 per cent of all ties), the most approved type being the Post steel tie. As there made the tie was 8 ft. 10 ins. long, 15-32 in. thick and weighed 163 lbs. The maximum locomotive axle load was 15½ tons and the maximum speed 53 miles per hour. On the German railways which use steel ties the maximum locomotive wheel load is 8 tons.

The Rendel Steel Tie.—Another familiar design of steel tie is the Rendel pattern, shown at the left in Fig. 485. It is in extensive use in India (where it is known as the "peapod sleeper") and in Mexico. As made for the Indian State railways it is 8 ft. 9 ins. long (gage 5½ ft.) and weighs, exclusive of fastenings, 120 lbs. The tie is stamped from a steel plate ¼ in. thick on the sides and 13-32 in. thick at the middle portion, which forms the top table, uniformly 4½ ins. wide. At the rail seat the depth is 4¼ ins. and the bottom width 9½ ins.: at the middle the bottom width is 8½ ins. and the depth 5 ins. The fastenings consist of two lugs stamped up out of the top table, for each rail, and a flat tapering key, which is driven between the outer lug and the rail flange. As made for the Mexican Ry. the ties are 8 ft. 3 ins. long and weigh 124 lbs., exclusive of fastenings. In 1900 this road had 287¼ miles of track (including all of the main line) laid with steel ties. With the ties in use on this road a key fastening is used, but the lugs punched out of the tie are reinforced by a small rib. This road is standard gage and the locomotives in use are of Rogers, Brooks and Baldwin make, of good weight. There are also in use a number of Fairlie double-ended bogie mountain engines, weighing 100 tons each, all the weight being carried on the drivers. Each of these engines has two boilers which rest upon two trucks having three pairs of drivers each, or twelve wheels in all. The ballast in use is a kind of volcanic substance called "tisontli." This material is porous, rather light and not hard, and is said to answer the purpose of ballast excellently.

The Mexican Southern Ry. has 139 miles of track laid with Rendel steel ties, the oldest of which were put down in 1891, and after 11 years of use no appreciable corrosion could be detected except in alkali soils. The ties laid on most of the line are of the design illustrated in Fig. 486. They are of pressed steel, 5 ft. 5 ins. long, the gage of the track being 3 ft. and the weight of the rail 50 lbs. per yard. The top of the tie is not exactly straight, the middle portion being depressed 9-16 in. below the ends, which gives the rail an inward cant of 1 in 24. The weight of the tie is 64 lbs. The rail fastening consists of two lugs 3 ins. wide, struck up out of the top table, and a tapering key 6 ins. long, 1⅛ in. wide and ⅝ in. thick at the larger end, and ⅞ in. wide and ½ in. thick at the smaller end, as shown by the plan and sectional drawings. The small end of the key is split, so that it may be opened out and resist any tendency to work loose. In laying track to gage, the key is driven under the lug on the outside of the rail, but in widening the gage on curves the adjustment is effected by changing the key from the outside to the inside of the rail. Experience with this tie has shown that it is weakest at the rail seat, owing to the large amount of metal stamped out of the top table to form the lugs, and to correct this evil a new tie was designed in 1899, with an improved fastening. This tie, shown as Fig. 487, is 6 ft. long and 5 ins. deep at both the ends and the middle. The width of the tie at the end is 13 ins., the width across the bottom at the middle, 8½ ins., and the width of the top table 4½ ins. The weight of the tie is 84 lbs. The rail fastening consists of a U-bolt, passed up through the tie from underneath, and clips. These clips are reversible, but unsymmetrical with respect to the bolt passing through the same, so that by turning the clips over, an adjustment of the gage may be effected, thus providing for widening the gage on curves. On this road steel ties are not used on bridges, in switch leads or in and around shops or roundhouses. Experience has shown that around such buildings metal ties corrode very rapidly. Before laying the ties it is the practice to coat them heavily with coal tar, to prevent oxidation. On curves the ties are spaced at 2-ft. centers and on tangent a little farther apart.

Concerning the advantages and disadvantages in the use of steel ties, as learned from experience with the same on this road, the following are some of the points observed. It is found that a longer time is required to obtain good alignment and surface than is the case on track laid with wooden ties. Against the steel tie there is the disadvantage of increased first cost. On the other hand the steel tie is considered safer than the wooden tie, especially on curves, as no rail braces or tie plates are required, and spreading of the gage or tilting of the rails is impossible. It has been found that with steel ties there is a reduction in the cost of maintenance of fully 50 per cent, compared with track laid with wooden ties. The ties are of uniform size, and, so far as this matter is of any importance, they afford uniform support to the rails. Line and surface are better preserved, and there is a reduced cost of handling and laying track, as compared with wooden ties; and there is said to be less noise in the running of the trains. The ties cannot be burned and the damage to track in case of derailment is less than occurs with derailments on wooden ties.

The most suitable ballast for steel ties, as ascertained through experience with the same on this road, has been found to be gravel or very coarse sand. Broken rock or slag, especially when broken as coarsely as it usually is for track laid with wooden ties, does not give satisfaction. In fact, the difference between the relative merits of gravel or sand, and broken rock, as a ballast for track laid with steel ties is regarded by the officials of this road as amounting to the difference between success and failure in the use of such ties. The ballast is filled in to cover the tops of the ties, and to keep down the dust in the dry districts the track and shoulders are covered with a layer of broken stone about 2 ins. deep. The heaviest engines in use on this road are eight-wheel English engines weighing 56,000 lbs., one class of ten-wheel English engine weighing 68,000 lbs., another class of ten-wheel English engine weighing 76,000 lbs., and Baldwin consolidation locomotives weighing 88,000 lbs. The engines of the latter class have 14,000 lbs. on each of the rear driving wheels. These engines pull net train loads of 120 tons up 4 per cent grades on a very crooked mountain division 40 miles long. In this distance the road rises through an elevation of 4300 ft. The maximum grades are 4 per cent, compensated on curves sharper than 9 deg. Many of the curves are as sharp as 17½ deg. It is claimed that the steel tie has nearly every advantage over oak ties on these steep grades.

Since both oak and steel ties have been used on this road under the same conditions of climate, soil and traffic, there has been good opportunity to observe the relative merits of each. The following interesting statement of the cost of track maintenance with the two kinds of ties was prepared by Mr. T. A. Corry, resident engineer of the road. The oak ties referred to were 6½ ft. long, 8 ins. wide and 7 ins. thick.

Mexican Southern Ry., Ltd., Puebla, Mexico, Jan. 8, 1900.

Comparison of Maintenance Expenses—Steel with Oak Ties.

1 kilometer=1000 meters=3280.87 ft.

No.	Items.	Track with Steel Ties.	Track with Oak Ties.
1.	Number of kilometers of track (main line)	223.9	143.1
2.	Number of ties per kilometer (1300 to 1600) average	1400	1400
3.	Estimated duration of ties in years not less than	30	5
4.	Original cost (1891) in Mexican currency	$1.42	$0.62
5.	Original cost (1891) per kilometer	$1988	$868
6.	Annual renewals per kilometer	*46 2-3	280
7.	Annual renewals cost per kilometer	$65.27	$173.60
8.	Daily renewals per section (approximate)	2.4	10.7
9.	Lengths of sections—kilometers	16	12
10.	Number of foremen per section, daily	1	1
11.	Number of laborers per section, daily	3	5
12.	Cost of foremen per section, daily	$1.50	$1.50
13.	Cost of laborers per section, daily	$1.50	$2.50
14.	Total wages per section, daily	$3.00	$4.00
15.	Total wages per day per kilometer—cents	18.75	33.33
16.	Cost of tie renewals per day per kilometer—cents	17.06	47.56
17.	Total wages and tie renewals per day per kilometer—cents	35.81	80.89
	Saving in favor of steel ties=55.73 per cent.		
	Supposing oak ties to last 6 years instead of 5, and price of steel ties to be $3 each, then item No. 16 would be, in cents	38.36	39.63
	And item No. 17 would be, in cents	57.11	72.96
	Saving in favor of steel ties=21.72 per cent.		

*None has been removed since first put in (1891).

N. B.—(1) The assumed life of steel ties (viz., 30 years) is evidently too short.

(2) The original cost of steel ties in 1891 was $1.42 each, delivered at Puebla. The Mexican silver dollar was then worth 38 pence—or about 79 cents

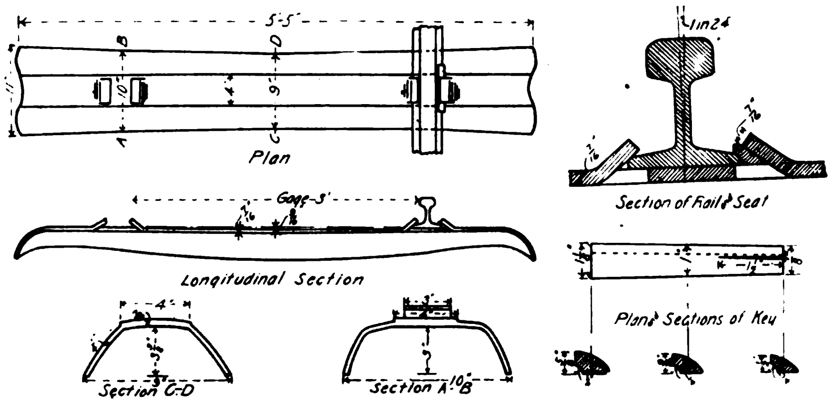

Fig. 486.—Rendel Steel Tie, Mexican Southern Ry.

U. S. currency. The Mexican silver dollar is now worth about 23⅜ pence, or say 47 cents U. S. currency.

(3) Original cost of oak ties (in 1891) was actually 95 cents each, Mexican silver. Same tie can be bought now for 62 cents, but the price is getting higher.

It will be noticed in this statement that the expense for labor reported for maintaining track laid with steel ties is very much less than that employed in connection with the oak ties. The length of sections where the steel ties are used is about ten miles, whereas the sections on track laid with oak ties are about 7½ miles long. The working force on the 10-mile sections, laid with steel ties, is a foreman and three men, while on the 7½-mile sections, laid with oak ties, it is a foreman and five men, or 50 per cent larger for a section of track only three fourths as long. It is the disparity in the amount of labor actually employed on the two kinds of track and the high cost of new oak ties for renewals which overbalance the additional investment required by the first cost of the steel ties, which, at the time these ties were laid, was about 130 per cent greater than the cost of oak ties. Taking interest charges (say 4 per cent) into account, there is still a saving of 40 per cent in favor of the steel tie. Mr. Corry then compares the cost of maintenance with the two ties on an assumed price of $3 for each steel tie, which was the price of these ties unloaded from the ship at Vera Cruz at the time he prepared his statement, there being, just about that time, a remarkable advance in the price of steel. Even at this high price there is a saving of current expenses in favor of the steel ties, but figuring interest charges at 4 per cent there is a showing of about 21 cents per kilometer per day in favor of the oak ties, which illustrates the advantage of buying metal ties when the price of steel is down. Mr. Corry states it as his belief that if steel ties laid in a wet climate are coated with coal tar once in about every 10 years, or ties laid in dry climate once every 15 or 20 years, they will last indefinitely, so far as the matter of corrosion is concerned.

In 1900 the Interoceanic Ry. of Mexico, the gage of which is 3 ft., had 163 miles of track laid with Rendel steel ties weighing 90 lbs. each. The design

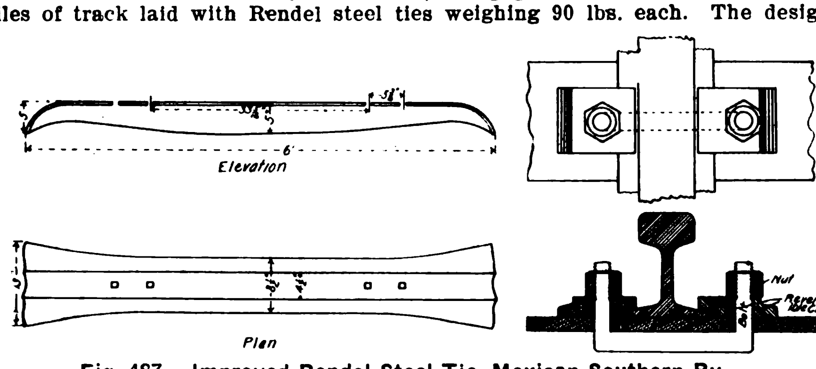

Fig. 487.—Improved Rendel Steel Tie, Mexican Southern Ry.

is similar to that of the Mexican Southern ties, and the experience extends back to about 1890. After being in service 10 years there were no visible signs of deterioration. The total life is estimated by the officials of the road to be at least 30 years. Regarding the question of economy Mr. W. T. Ingram, chief engineer, has stated as follows: "Unquestionably they are a great boon to us, with very heavy grades and curvature and a rail weighing only 40 lbs. to the yard—in fact there are portions of the road running through a zone of an almost perpetual rainy season, which could only be maintained at very great expense, were it not for the steel ties. The cost of maintenance is also an item of considerable importance, since the steel tie once laid and bedded on almost any kind of ballast, except coarse rock, keeps the track in good line and surface with but very little attention. Of course, their first cost is heavy, but unquestionably they are highly economical from all points of view." In 1898 the Interoceanic Ry. purchased 90,000 of these ties, costing £6, English money, per ton at Glasgow, the sea freight and charges bringing the price up to $2.32½, Mexican money, per tie, at the ship's side at Vera Cruz. During the succeeding year, however, the price gradually advanced until it was £7½ per ton at Glasgow, or about $3 Mexican money, per tie, at Vera Cruz. It thus appears that, after all, the "rapidly vanishing" wooden tie is a much steadier article in price than the metal tie.

The Boyenval-Ponsard steel tie is of corrugated shape, the section being that of three united parallel troughs, the middle trough open at the top, the two outer ones open at the bottom and closed at the ends with riveted angle pieces. The size is 8.2 ft. long, 8 ins. wide on top, 10.2 ins. wide across the bottom and 2.8 ins. deep. The upper face is made up of two bearing surfaces each 2.4 ins. wide, with a channel 3.2 ins. wide between them. The outer channels have flanges 0.7 in. wide. The thickness of top and bottom is .32 in., of the sides .20 in., and the weight is 130 lbs. In 1894 this tie was used on 375 miles of railway, in a number of countries, including France, Algeria, Egypt, Argentine Republic and Brazil.

The Webb Steel Tie.—The metal tie that has been used most extensively in England has been the Webb pattern, which in 1890 was in use on about 56 miles of track. These ties are of inverted trough section and straight, with open ends, flaring sides and small flanges on the bottom edges. They are of rolled steel 5-16 in. thick and 9 ft. long. The top width is 6 ins. and the bottom width 11 ins., the depth 2½ ins. and the weight, exclusive of fastenings, 136 lbs. The fastenings consist of chairs, for the double-headed rails, the chair being in three parts (a base plate and two jaws) riveted to the tie. The rail is secured by a wooden wedge driven in between the rail and the outside jaw of the chair. These ties are in use on the London & Northwestern Ry., where 1738 were laid as early as 1880 and enough to lay 9 miles of track were put down between that year and 1883, when 15,882 were in service. At the beginning of the year 1900, 13,418 of these ties had been taken up, 10,479 being scrapped and 2939 relaid in sidings. Of those scrapped 7454 were cracked or broken, 2481 had either loose rivets or broken or loose chair jaws, and 544 had failed by corrosion. The age of the ties taken up was 1 to 19 years, and the average age 8 years. Out of 100,000 steel ties laid on this road between 1880 and 1890, 54,000 had been scrapped or relaid in sidings, and 46,000 were still in main-track service, in the early part of 1900. No steel ties were laid after 1890. The officials are not in favor of extending the use of steel ties. Those in use are rather light for the service, and if any more were used a heavier pattern would have to be adopted. The first cost of the steel ties is more than that of creosoted pine ties, and the average life not so long. One consideration in adopting this design was that the open ends offered better facilities for tamping than ties of similar section with closed ends, like the Rendel tie, for instance. But notwithstanding this point in its favor, the section men have found that rather more labor has been necessary to maintain the steel-tie track in line and surface than that laid with wooden ties. The above record shows that corrosion has been only a minor cause of failure. Trouble from this cause has been experienced only in thickly populated districts, in tunnels, in manufacturing areas, or where the ballast was of such character that rapid corrosion might be expected. About 800 of these Webb steel ties were experimented with on the Pennsylvania R. R. for some years (including the year 1889), but the results were not satisfactory.

Iron Plate Ties.—The Denham-Olpherts cast iron plate tie, used on a number of railways in India, notably the East Indian; Delhi, Umballa & Kalka;

Eastern Bengal; Indian State; and Northwestern roads, consists of two flat-bottom cast iron ribbed plates 2 ft. long, 10 ins. wide and 9-16 in. thick, weighing 176 lbs., united by a tie bar ½ in. thick and 2 ins. deep. The fastening consists of two cast iron jaws weighing 26 lbs. and two pairs of gibs and cotters weighing 3.8 lbs. The outer jaw is cast integral with the plate and the inner one is adjustable. These ties are said to give good satisfaction. On the East Indian Ry., where they are the standard form of track support, 2,483,600 of them were in service in 1895. On this road the plates are cast, and the tie bars are rolled, from scrap metal. The annual breakage has averaged 0.64 per cent.

Pot Sleepers.—Another form of metal track support that is in extensive use, particularly in India, consists of cast iron pots or bowls laid open side downward. Locally they are known as "pot sleepers." The gage is maintained by tie bars transverse to the track, uniting pairs of bowls, and adjustment of the gage is made by variations in the widths of the keys which secure the tie bar to the bowl. The style of rail fastening on the India Midland Ry. consists of a lug cast on the bowl, to engage the flange of the rail on the outside, and for the gage side there is a jaw or clamp which is held to its work by a wrought iron key. Each bowl weighs 92 lbs. and the weight of the tie complete, including tie bar and fastenings, is 217 lbs. On the Great Indian Peninsula Ry. this style of track support is used almost exclusively. In 1901 the whole of the main line, aggregating 1750 miles of single track, was supported upon pot sleepers, and a large proportion of the sidings, aggregating

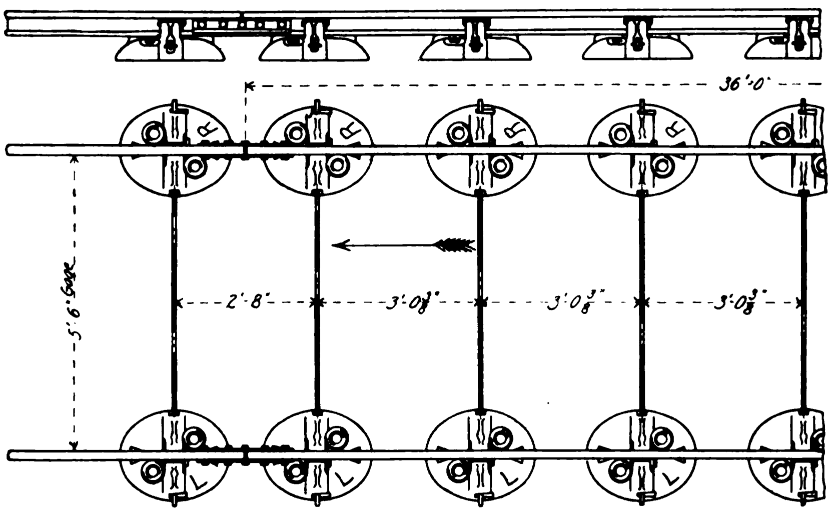

Fig. 488.—Cast Iron Pot Sleepers, Great Indian Peninsula Ry.

260 miles of single track, was of similar construction. Wooden ties were then used only upon bridges, and over such arches as had only a thin cushion of ballast between the crown and the rail level; and on two ghats, or mountain passes, aggregating 26 miles in length, where they were used mainly because the roadbed was rock. Just previous to the adoption of pot sleepers exclusively, in 1900, the proportions of the various kinds of ties in the track were as follows: timber cross ties (92 per cent of which were teak, having an average life of 13 years), 9.17 per cent; cast iron round pot sleepers laid prior to 1866, 11.36 per cent; cast iron oval pot sleepers laid since 1866, 79.47 per cent. It is seen that many of the pot sleepers originally laid in the line, more than 34 years previously, although of an inferior pattern to those then adopted as the standard, were still in use. A great many of these had been transferred, from time to time, from main line to sidings, in the course of continuous renewals of the former with the latest patterns of track material, and had thus passed through the "severe test of removal and relaying."

The pattern of pot sleeper now standard with the Great Indian Peninsula Ry. is shown in Fig. 488. It is known as the "R. & L." (right and left) sleeper and is laid under 82-lb. steel rails 36 ft. long. The pots are oval in plan, 24⅝ ins. over the long diameter and 20¼ ins. over the short diameter. When used on double track the style of construction of these pots (right and left) permits of both keys being driven in the same direction as the traffic. They have large "packing" holes in the top (for tamping) and the rail seats are cast on the pots. The weight of a "sleeper" is made up as follows: 2 pots, each 101 lbs., 202 lbs.; 1 wrought iron tie bar, 25.75 lbs.; 2 wrought iron gibs, 0.41 lb.; 2 wrought iron cotters, 1 lb.; total, 229.16 lbs. This sleeper was introduced in 1884, since when no other kind has been laid. The wrought iron tie bars used to connect the pots withstand corrosion very well, as none have been rejected on account of corrosion except at a few places near the sea, where they were placed in dirty, moisture-bearing ballast. At the joints (suspended) the pots are spaced 32 ins. centers, and under all other portions of the rail 36⅝ ins. centers. Under the heaviest traffic the ballast used is broken stone, but over a large mileage the ballast is sand of various qualities. In 1900 there were in service on this road four other patterns of pot sleepers, as follows: (a) one having plain round pots 22½ ins. in diam., with large packing holes, introduced prior to 1858; (b) one having ribbed round pots 22¼ ins. diam., similar to the foregoing, except for ribbing, introduced prior to 1858; (c) one having original "old" oval pots, 27x20¼ ins., without packing holes and with cells for wooden rest pieces, introduced about 1866, being made up of 2 pots, each weighing 93.3 lbs., and a wrought iron tie bar weighing 25¾ lbs., or a total weight, including gibs and cotters, of 213.8 lbs.; (d) one having "new" pattern oval pots 25x20¾ ins., with large packing holes, cells for wooden rest pieces, and strengthened chair jaws. The complete sleeper of this pattern is made up of 2 pots, each weighing 100 lbs., and a wrought iron tie bar weighing 25¾ lbs., or a total weight, including gibs and cotters, of 227.2 lbs. This sleeper was introduced about 1877. It thus appears that some of the oldest sleepers had been in service 42 years. Records on file since 1872 show the half-yearly renewals of pots, and the percentage per annum of breakages, as ascertained from them, is 1.66. This figure includes breakages due to derailments, and some removals due to regrouping of the several patterns of pots (different patterns, round and oval, having been laid promiscuously in the old days), so that the percentage is higher than that of actual failures due solely to ordinary wear and tear, and therefore represents the pots as having a shorter life than they really have.

In 1901 the Madras Ry. had 897 miles of main track and 149 miles of sidings laid with cast iron pot or bowl sleepers. The total number of pots then in service was 3,318,427, and the renewals for the preceding two years averaged 2.88 miles or 9135 pots per annum, which was 0.275 per cent renewed per annum. Timber ties of many descriptions of local wood were originally tried, but their life was very short, being only 4 to 5 years. These were replaced by creosoted pine ties sent from England, and these were after some years' trial replaced by cast iron pot sleepers, which are now used almost exclusively on this road, timber sleepers being used only on bridges, including masonry arches, and under switches and frogs. Cast iron pot or bowl sleepers were first laid on this road in 1861, and after 40 years of service most of these were still in the track. Prior to 1892 six patterns, varying in weight from 89 to 110 lbs. each, were used, but in that year a large number of drop tests were made on the pot sleepers then in use, by Chief Engineer E. W. Stoney, the results of which were described in a report by that gentleman in 1892. In 1894 he designed a stronger sleeper, with pots weighing 112 lbs. each, which is now standard, and is used to renew the older, lighter and weaker patterns as they become unserviceable. The details of the design of this sleeper are illustrated in Fig. 489. The heaviest engines in use are 6-coupled freight locomotives, with a wheel base of 15¼ ft., carrying 14½ tons on each axle, and a total load of 73¼ tons. Mr. Stoney states that these cast iron sleepers joined with wrought iron tie rods make an excellent road. To insure this, however, it is necessary that they be tamped with good, clean sand ballast. Broken stone has been found to be unsatisfactory for ballast. The standard ballast material is sand, covered with a layer of broken stone 1½ ins. thick to keep down the dust. The rails are of the bullhead pattern, 30 ft. long, and the sleepers are spaced 2½ ft. centers at the joints (suspended) and 36.66 ins. centers throughout the intermediate parts of the rail. The following extracts from a report by Mr. Stoney dated Aug. 5, 1899, on the relative life and cost of timber and cast iron sleepers, give some further information of interest:

"About 898 miles of the total 912 on the Madras Ry. are now laid with old-pattern pots weighing from 90 to 98 lbs. each, and 14 miles with the new pattern, 112 lbs. each. No person can at present say what the ultimate life of the component parts of our cast iron sleeper road is, the oldest portion put down in 1861, or 38 years ago, being much too short a time laid for any portion to have reached its life limit. In the absence of such positive data it seems to me that the only way to arrive at a fair conclusion as to the ultimate ages required is to take the actual renewals per annum of each item for the past few years, and compare those with the total number of each article laid during this time.......... From personal observation extending over a period of 30 years, in charge of permanent way, I can say that almost all renewals of pots were owing to their being found cracked or broken, hardly any being removed owing to rust or wear, those so taken out being chiefly in the salt depot, Madras, where the jaws dropped off. During inspections the road has been often opened out in all sorts of soil, and the pots, tie bars, etc., found practically free from rust, chiefly due probably to the use of sand ballast. Although our present average renewals show the probable life of a pot-sleeper to be 304 years, I have assumed an age of 60 years, only one fifth of this, in the calculations. The age of tie bars, gibs and cotters has been taken at 30 years, very much below that given from actual renewals. Keys have been assumed to last 6 years, steel rails only 36 years, fish plates 36 years and fish bolts 24 years.

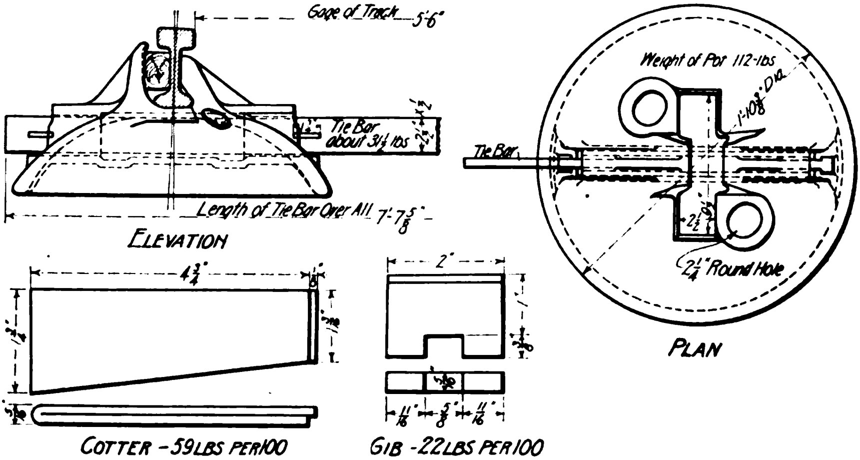

Fig. 489.—Cast Iron Pot Sleeper, Madras Ry.

"The relative capital cost at 4 per cent compound interest at the end of 56 years, of a pair of pot sleepers, with tie bars, gibs, cotters and keys costing Rs. 9.25, a jarrah sleeper costing Rs. 5.8, and lasting 14 years, and a junglewood sleeper costing Rs. 5.0 and lasting 7 years, is as follows: Rs. 166.45 for the junglewood, Rs. 109.71 for the jarrahwood and Rs. 83.18 for the pair of pot sleepers, no allowance being made for the scrap value of the sleepers at the end of their lives. This takes into account four renewals of the jarrah sleepers, and eight renewals of the junglewood sleepers, with compound interest. Another way of looking at the question is to compare the price which might be paid for the pots to make them equal in final capital cost to junglewood and jarrah. The result is that if Rs. 5 be paid for a junglewood sleeper lasting 7 years, Rs. 18.51 would be the value of a pair of pots lasting 60 years; and compared with a jarrah sleeper lasting 14 years, costing Rs. 5.8, then Rs. 12.20 could be paid for a pair of iron sleepers. These results show very forcibly the enormous influence the life of a sleeper has on its cost."

A comparative statement of the total annual cost per mile of 2000 sleepers represents the cost to be Rs. 1660 for the junglewood, Rs. 1100 for the jarrahwood and Rs. 653 for the pot sleeper (pair of pots), taking account of the value of the scrap at the end of 56 years. If the value of the scrap be not taken the cost for the pot sleeper is Rs. 832. The process of these computations, together with other information in detail, is shown in the Railway and Engineering Review for Apr. 6, 1901.

The pot sleeper is also in extensive use in the Argentine Republic. The form in use on the Buenos Ayres Great Southern Ry. consists of two cast iron bowls of oval plan, each 26 ins. long, parallel with the rail, and 18¼ ins. wide transverse to the track, connected by a wrought iron tie bar passing through the upper part of each bowl and secured by flat cotters 1¼ ins. wide and ¼ in. thick. The length of the bowl on top is 21¾ ins., the middle of the bowl being depressed like a saucer. The thickness of metal is ⅝ in. on top, 5-16 in. on the sides and 11-32 in. in the middle. The rail is secured by lugs and taper keys. The depth of the bowl under the rail is 5 ins. There are eight pairs of bowls per 25-ft. rail length.

Bowls or pots were at the first designed for use in sand ballast, under which condition they are said to give good satisfaction, as is also the case when laid on earth ballast or gumbo. On broken stone ballast they have in some cases been reported less successful, as already noted.

Features of Design and Maintenance.—Metal cross ties are usually made of mild steel, containing about a tenth of 1 per cent of carbon, and they are usually rolled, like rails, or pressed to shape from flat plates. Ties of the pot or bowl pattern are usually made of cast iron, although some of the ties of this type in India are of pressed steel. To preserve the ties against corrosion it is quite commonly the practice to dip them in some preservative like boiling coal tar mixed with turpentine or tar oil. After applying the coating the tie is sometimes dipped in sand, to give it a rough surface, so as to increase the friction of the tie in the ballast. Corrosion is most troublesome usually in tunnels, owing to the usual dampness in the bedding of the tie and to the corrosive effect of acids and gases from the smoke and the engine cinders. Ties laid in slag or cinder ballast or in salt or alkaline earth are also subject to corrosion of greater or less severity.

Bolts, with clips, clamps or jaws, and wedges, are quite common forms of fastenings, and there are various ways of effecting the adjustment or widening of the gage, as on curves. In some cases the adjustment is made by the use of different sets of clamps and bolts. In other cases the adjustment is effected by bolts with eccentric necks or eccentric washers. By making the bolt hole of a square washer out of center on two axes the four edges of the washer will be at different distances from the hole, and thus provide for four adjustments of the gage. With the Rendel tie the gage may be adjusted by placing keys on both sides of the rail, inside and out, or by placing a packing piece between the inner lug and the edge of the rail. On this tie the space between the tips of the fastening lugs is narrower than the width of the rail base, so that the rail must be canted in order to set it to place on the ties or remove it from its seat. It cannot therefore become detached from the ties by straight lifting should the keys slip out of place. In removing these ties from the track the rails must be taken up. The small end of the taper key is sometimes split, so that it may be spread open, to resist any tendency to work loose and slip out of place. With the clip fastening it is quite commonly the practice to use a bolt with a "T" head, secured to the tie by inserting it through a slot in the top table. The usual method of laying track where bolt and clip fastenings are used is to splice the rails and block them up high enough to leave sufficient clear space beneath to run the ties under. Men working in pairs then raise the ties to the rails and secure the fastenings, after which the track is ballasted. Under frogs and in switch leads, in connection with metal track, it is usual to lay wooden ties, but in some instances metal ties are used, such being the case with some roads in Germany and Switzerland.

As with wooden ties, so with metal ones, the question of maintaining a firm connection between tie and rail is in dispute. In order to prevent wear at the rail seat and resist creeping of the rails it is desirable to hold the latter down tightly to the ties. On the other hand it is undesirable to have any vertical movement of the ties in the ballast. One of the standing complaints in the use of metal ties in Germany is that the ties, held securely to the rail by their fastenings, rise and fall with the rail in its undulations and "grind the ballast to dust." To overcome this trouble the engineers of the Prussian State railways have made various experiments with loose fastenings. In one arrangement the fastening allows of a certain amount of vertical play (about 0.2 inch) between the rail and its seat, so that the undulating motion of the rail does not disturb the embedment of the tie in the ballast. Another arrangement consists of a wooden shim or cushion 1.3 ins. thick placed between the tie and a tie plate, with an allowance in the fastenings of about 0.2 in. (5 millimeters) of relative vertical movement for the rail. Both of these experiments are said to have resulted satisfactorily. The Eastern Ry. of France has used a tarred felt pad between the tie and the rail, to take the wear, keep the sand out and diminish the noise and jarring of the tie.

The tie with closed ends seems to meet with most favor, because it presents an end surface to resist lateral displacement. An inverted trough tie with closed ends offers a greater resistance to lateral displacement than a tie of solid section throughout, as the tie is then resisted not only by ballast piled against the end, on the exterior, but also by the core of ballast inside. Regarding the best ballast material for metal ties there is some disagreement in practice. Broken stone of the usual sizes is quite widely recommended and is extensively used for metal cross ties. The experience of the Mexican roads in this respect, however, is contrary to what is reported of results obtained in many other countries where steel ties are extensively used. On each of the three roads in Mexico whereon steel ties are used the officials emphatically declare that broken stone ballast of any size ordinarily in use is not suited to the maintenance of track laid with steel ties. How well a finer size of broken stone ballast might answer is not intimated, but gravel and sand seem to be preferred in any case. The explanation which most readily suggests itself is that broken stone, being less mobile in character than gravel or sand, is not so readily tamped into the hollow of the inverted trough tie. In some quarters, as elsewhere mentioned, broken stone has also been reported to be an unsatisfactory ballast for pot sleepers, which, for ordinary lifts in surfacing, are tamped through holes in the top.

In the work of ballasting, the material must be packed hard at the ends of the tie and under the rail seats, leaving the middle but loosely tamped. One method of accomplishing this is to place the ballast in two rows of heaps, spaced to correspond to the spacing of the ties. In laying the track the ties are placed across pairs of heaps and an engine is run over the track to settle them down into the ballast, which has the effect of packing and tamping it hardest under the rail seat. The ballast is usually filled in flush with the tops of the ties and frequently over the tops of them. It is said that after Boyenval-Ponsard steel ties have been some time under traffic the cores of ballast formed inside the two channels which open downward adhere to the tie, and are lifted with it when the tie is raised, thus giving virtually a flat under bearing surface which can be tamped as readily and as thoroughly as the bottom face of a wooden tie.

On track laid with metal ties the expense of maintaining line and surface during the first two or three years is usually more than that for wooden ties, but as the ballast becomes compacted under the ties the maintenance expense gradually decreases, and after some years the showing on some roads favors the metal tie, while on others the reverse obtains. On the Netherlands State railways the average annual cost of track work has been $141 per mile where wooden ties were used and $97 per mile where steel ties were in service. On some of the French lines the track labor accounts of six places for a period of 11 years showed an average of $112 per mile for track laid with wooden ties and $83 per mile for track laid with steel ties. The volume of the traffic over the ties is not stated. On other lines where steel ties have been tried, particularly where the traffic has been heavy, comparisons of maintenance costs have brought the steel tie into disfavor. Persons interested in the maintenance of track on steel ties should read an article by A. Flamache, on "Uses of Metallic Ties," published in the Railway Review for Oct. 14, 1893, wherein are pointed out some of the difficulties which stand in the way of economical maintenance with metal ties of inverted trough section.

Duration.—The life of steel ties is generally estimated at 30 years. So far as the matter of corrosion is concerned this is probably a fair estimate for ties laid in favorable soils or ballast, but of course the design of the tie, particularly with respect to its vertical stiffness, should greatly affect its strength, which is important as bearing upon the question of failure by breaking or cracking. Twelve years is the estimated average life of large numbers of pressed steel ties doing service in India, but the conditions of exposure are not stated. There are but few reports of metal ties which have actually been in service as long as 30 years, which, however, may be due to the fact that the early ties have probably in most cases been displaced by ties of improved design. In the year 1900, 10,000 iron ties of the Cosijns type (an I-beam laid with the web horizontal) which had been in use 35 years between Deventer and Olst, on the Netherlands State railways, under a traffic of 210,000 trains, were still in good condition, and the oak rail-bearing blocks in the top channel were being replaced by metal blocks, with the expectation that the ties would last many years longer. These ties, which weighed 125 lbs. in 1865, had lost only about 9 lbs. each by corrosion and wear in the 35 years. The ballast was gravel and sand, the maximum locomotive wheel loads 7 tons, and the speed of trains 46 miles per hour. Some Vautherin iron ties weighing 74 to 98 lbs., in the line from Algiers to Oran, in northern Africa, were still in the track after 26 years, under a traffic of 70,000 trains, maximum speed 31 m. p. h. Some Post ties on the Netherlands State railways were still in service after 25 years, under a traffic of 137,500 trains.

Cast iron corrodes far less rapidly than wrought iron or steel, under the same conditions of exposure, and cast iron ties are noted for their durability. Cast iron pot sleepers in India have been found to be serviceable after being under traffic more than 40 years, as elsewhere stated. It is of interest to note that in the experience on foreign railroads no serious loss of steel ties occurs from derailed cars. Ties which become bent from such cause are removed from the track and are usually straightened by hydraulic press without difficulty or without fracture. The wear at the rail seats of steel ties is said to be not serious, but for heavy traffic, especially on curves, tie plates are recommended. In calculating the economy of the metal tie it is important to take into consideration the fact that when worn out, if not thoroughly corroded, they have considerable value as scrap, whereas old wooden ties can seldom be disposed of to any profit.

204. Locomotive Counterbalance Experiments.—In the mechanical laboratory at Purdue University, Lafayette, Ind., there is an ordinary 8-wheel passenger locomotive mounted to run a tread mill, each pair of drivers being supported upon a pair of wheels of about the same size turning together upon an axle journaled in a pit. The locomotive is held fast, and as the driving wheels revolve they turn the supporting wheels in the pit, so that somewhat similar conditions obtain as when running upon ordinary track. By applying braking power to the pit wheels the conditions imposed are similar to those which obtain when the locomotive is pulling a load. The locomotive tested had drivers 63 ins. in diameter, fully counterbalanced for both revolving and reciprocating parts. The weight of the reciprocating parts on each side of the engine is 812 lbs., including the main rod, weighing 344½ lbs. Four tenths of the weight of the main rod was considered as a reciprocating weight, so that the excess balance for each side was taken at 605.3 lbs., 204.5 lbs. being placed in the main wheel and 400.8 lbs. in the rear wheel, or practically 66 per cent of the balance for reciprocating parts in the rear wheel. The weight of the side rod is 278 lbs.

The method of testing the behavior of the wheels at high speed was to pass a soft iron wire of .037 in. diameter under the drivers while they were in motion. The wire was straightened and cut into lengths of 20 ft. and fed under the wheels through a ⅜-in. pipe fixed in place just in advance of the point of contact of the driver. To connect the phase of the driver's motion with the effect produced on the wire the tread of the driver was nicked with a cold chisel, so as to stamp the wire at the point passing under that part of the wheel. The results of greatest interest were obtained under the rear wheel, which was the one most heavily counterbalanced. At a speed of 59 miles per hour this wheel, for an instant in each revolution, barely touched the wire, as indicated by the absence of any flattening effect. At a speed of 63 miles per hour it was found that the driver did not touch the wire for 41 ins. in each revolution; and at 65 miles per hour the length of wire not touched by the driver was 46 ins., or corresponding to about ¼ revolution of the driver. The maximum lifting effect was found to take place just after the counterbalance had passed its highest point. As recorded by the marks on the wire, the rise of the wheel from the track was more gradual than the descent, which would be expected from the inertia in the mass to be lifted. The flattened portion of the wire was uniformly about .01 inch in thickness for about half the revolution, and rolled so thin by the normal pressure of the wheel as to be not visibly affected by further increments of pressure. For this reason the damaging effect produced by the dropping of the wheel when the counterbalance passed below the center could not well be determined or estimated.

Under the forward driver no results were obtained which gave evidence that the wheel had left the track, although the wires used showed some variation in thickness, indicating that the wheel pressure had varied. From calculation it was estimated that the forward wheel ought not to lift from the track at a speed less than 80 miles per hour, but this speed could not be attained. It was ascertained that the rocking of the engine upon its springs affected considerably the vertical lift of the drivers, sometimes acting with them and accentuating the lift and sometimes opposing them and counteracting the lift; while at other times the rocking seemed to have no effect on either driver, as shown by wires passed under both at the same time. Observation was also made of a vibration in the driver of .002 to .004 inch in amplitude within 10 ins. of wire, or corresponding to .01 second in time.

Some of the conclusions drawn from this series of experiments were summed up by Prof. Goss, in substance, as follows: (1) Wheels counterbalanced according to the usual rules, where the revolving parts and from 40 to 80 per cent of the weight of reciprocating parts are balanced, the counterbalance being equally distributed among all the connected wheels, are not likely to leave the track unless the speed is excessive; (2) A wheel and load weighing 14,000 lbs., carrying a counterbalance of 400 lbs. in excess of that required for the revolving parts alone, will lift from the track at a speed of 310 revolutions per minute; (3) The rocking of the engine on its springs may assist or oppose the action of the counterbalance in lifting the wheel; (4) The contact of the moving wheel with the rail is a succession of impacts.

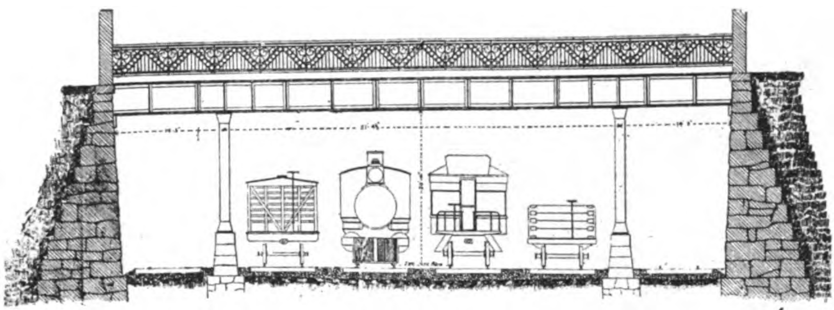

Fig. 510.—Section of Subway, P. & R. Ry., Philadelphia.

As the locomotive in these experiments was supported over masonry foundations, some engineers have raised a question as to whether, under the conditions, the results can be considered applicable to track on roadbed of the ordinary yielding character; and it has been asserted, without any offer of proof, however, that on account of the elasticity of the track a locomotive driver could not lift from the rail. I fail to see the force of these points. The experiments certainly show what the tendencies are when the counterbalance is excessive or improperly distributed, and as long as we know that great pressure and damage are caused by this overbalance it is of relatively small consequence whether or not the wheel actually lifts from the rail.

Those who may desire to study the subject of locomotive counterbalance more in detail are referred to papers by Mr. David L. Barnes and Prof. W. F. M. Goss, presented before the American Society of Mechanical Engineers, in December, 1894, and published in Vol. 16 of the proceedings of that association for 1894-95; also to Vols. 29 and 30 (1896 and 1897) of the proceedings of the American Railway Master Mechanics' Association, pages 148 and 117, respectively.

205. Track Elevation and Depression.—Some of the most intricate work of track depression which has been performed in this country was the lowering of the tracks of the Philadelphia & Reading Ry., in Pennsylvania Ave. and Noble street, between Poplar and Thirteenth streets, in Philadelphia, completed in 1899. This work accomplished the abolishment of 17 grade crossings at street intersections, by the construction of a subway and tunnel for the tracks, which involved also the reconstruction and lowering of about 3½ miles of sewers, much of which had to be done by tunneling 25 to 45 ft. under the surface. Between Thirteenth and Twenty-second streets there is 4180 ft. of open subway 80 ft. wide, carrying six tracks (Fig. 510), widening out at points into depressed freight yards. West of this there is a 4-track tunnel 2711 ft. long, west of which there is another open subway 2150 ft. long, the total length of the depression thus being nearly two miles.

While the work on the eastern half of this depression was being carried on (between Thirteenth and Twenty-second streets) traffic was maintained on a system of temporary tracks laid in Hamilton St., running parallel and one block distant. From Twenty-second St. westward, or over the western half of the depression, comprised by the tunnel and the open subway beyond, traffic was maintained while work was in progress by shifting the old tracks to the south side of the avenue until the north wall of the tunnel or subway had been constructed in a trench 33 ft. deep, after which the temporary tracks were shifted to the extreme north side of the avenue and supported partly upon the newly constructed wall. The material was then excavated, the south wall of the tunnel built and the open space arched over to form the tunnel, as illustrated in Fig. 511. This tunnel is 52 ft. wide and the headway over the top of the rail is 22 ft. The rise of the arch is 8 ft. 8 ins. and the radius of the arch 43 ft. 4 ins. The ring of the arch is of brick, 3 ft. thick at the crown and 4 ft. thick at the skewbacks. The clearance between top of rail and bottom of girders at street viaducts (Fig.510) is 20 ft.

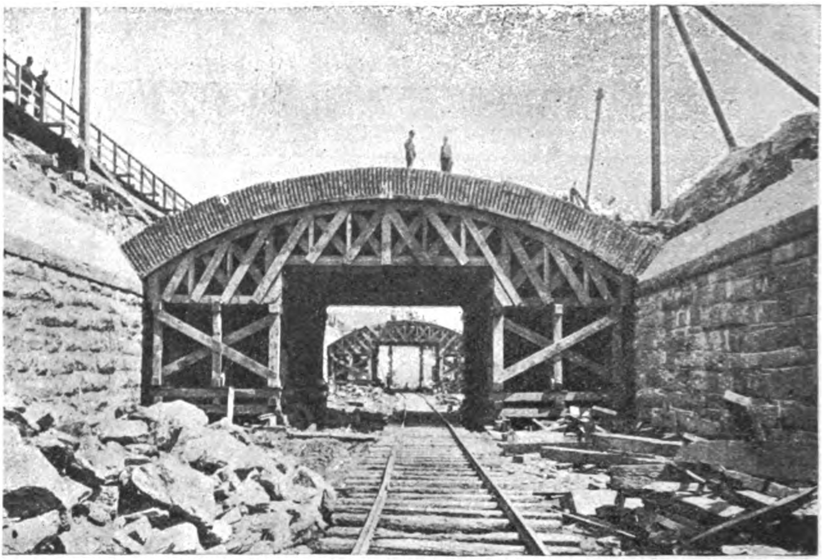

Fig. 511.—Method of Constructing Tunnel Arch, P. & R. Subway, Philadelphia.

In the construction of the retaining walls along some parts of the subway the fronts of high buildings had to be underpinned, and along other portions of the subway it was found necessary to construct temporary fronts inside the buildings, remove the old front walls, construct retaining walls upon the building line, and then reconstruct the front walls of the buildings. At still other points the retaining wall passed within the foundations of some of the buildings adjoining the avenue, so that it became necessary to remove a portion of the building, construct a temporary front, and after building the retaining wall construct a new front with the retaining wall for a foundation. The entire work of lowering the sewers and constructing the subway was in progress five years and cost, including damage to property, $6,000,000. Full details of the work. with illustrations, were published in the Railway Review of May 23, 1896, and in the proceedings of the Engineers' Club of Philadelphia for February, 1899.

In depressing 3.65 miles of four-track road on the Boston & Albany R. R., in Newton, Mass., completed in 1897, traffic was diverted during the excavation of the subway to two temporary tracks laid along one side of the right of way, part of the distance on trestle. Excavation was first made for two of the permanent tracks, which were laid, and traffic transferred to the same, after which the excavation of the subway was completed and the remaining two tracks were laid.

The Sixteenth Street Subway, in Chicago.—Another very complicated piece of work of changing the elevation of tracks, perhaps the most difficult ever

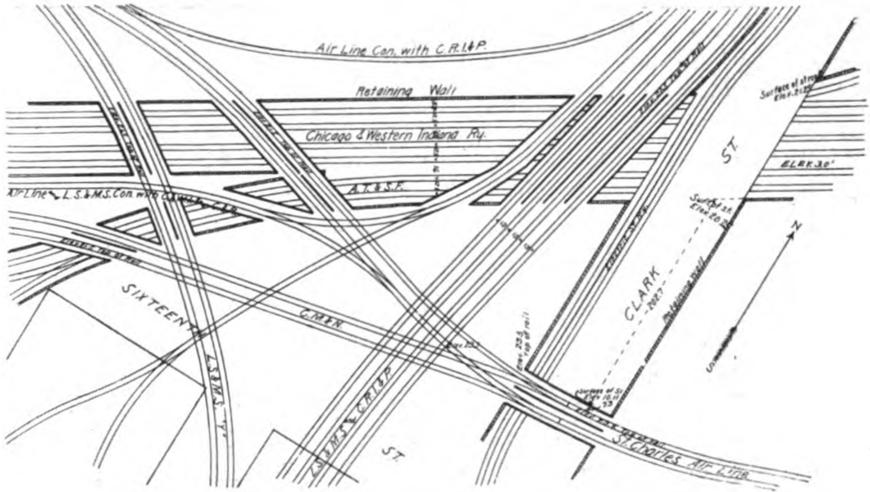

Fig. 512.—Sixteenth Street Crossing and Subway, Chicago.

undertaken in this country, was the combined elevation and depression of a network of tracks in the vicinity of Sixteenth and Clark streets, in Chicago, in 1898. The complicated nature of the conditions encountered at this point may be appreciated to some extent if the reader will picture to his mind four main tracks (Fig. 512) running north and south*, paralleled by a double-track street railway a few feet distant, all of which were crossed at grade by four main tracks running east and west**, and all of the foregoing tracks again crossed diagonally at grade by six main tracks running from northeast to southwest***, which for brevity and convenience, will be called the "northeast" tracks. The tracks crossing one another in this vicinity enclosed a triangular area measuring from 300 to 400 ft. on each side. Beside these 14 main tracks there were numerous interconnecting tracks used for switching purposes, so that, altogether, within a space covered by a radius of 300 ft. there were found 113 single-track crossings of steam roads and seven slip switches. The various lines of tracks were used by the trains of 15 different railroads, and the records show that the traffic passing this crossing averaged 5000 cars and 500 locomotives daily, not to consider that one of the busiest street car lines in the city, crossing 13 of these tracks, was operating cars and trains of cars on two minutes' headway over the crossing, and the congestion of vehicular traffic in the street (Clark St.) was very great.

The plan decided upon and carried out was to depress the six northeast tracks about 9 ft. in a subway about 1000 ft. long, elevate the four north and south tracks and the four east and west tracks about 10 ft., and to carry the street with its street car tracks over the depressed northeast tracks on a 4½ per cent grade and down under the elevated east and west tracks on a 5 per cent grade. The first work undertaken was to lay foundations for the concrete retaining walls and to build stretches of wall in such places as the tracks could be temporarily diverted for the purpose, the uppermost consideration which governed the work from beginning to end being to keep the traffic moving. After

*Operated by the Chicago, Rock Island & Pacific and the Lake Shore & Michigan Southern roads, and used also by the trains of the New York, Chicago & St. Louis Ry.

**The St. Charles Air Line (two tracks), operated by the Illinois Central, Michigan Central (freight), Chicago, Burlington & Quincy (freight), and Chicago & Northwestern (freight) roads; and the Chicago, Madison & Northern Ry. (two tracks).

***The Atchison, Topeka & Santa Fe Ry. (two tracks) and the Chicago & Western Indiana Ry. (four tracks). The tracks of the latter road carried also the trains of the Chicago & Erie, the Grand Trunk, the Wabash, the Chicago, Indianapolis & Louisville and the Chicago & Eastern Illinois roads.

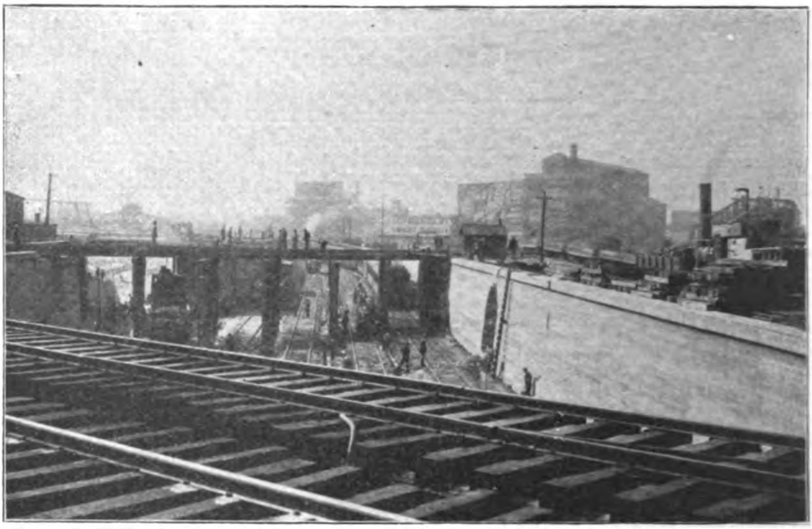

Fig. 513.—Progress View, Sixteenth Street Crossing and Subway, Chicago.

the retaining wall along the northerly side of the northeast tracks had been constructed (except where crossed by the east and west and the north and south tracks), two of the north and south tracks, two of the east and west tracks, three of the northeast tracks and both of the street railway tracks were abandoned and all of the remaining tracks were elevated simultaneously on sand filling, to the final elevation. The north and south and the east and west tracks were to remain elevated, while, as previously stated, the northeast tracks were to be depressed, the scheme of elevating them being to carry the traffic until part of the subway should be excavated and tracks put in order therein.

The northerly side of the filling for the elevated northeast tracks was retained by timber cribbing based on the second northeast track from the north side. The elevation of all the tracks was accomplished while traffic was being moved over them, and as soon as the final elevation was reached piles were driven through the filling for the support of the north and south and the east

Fig. 514.—Depressed Tracks of the C. & W. I. and the A., T. & S. F. Roads at Sixteenth Street Crossing, Looking Northeast.

and west tracks where they crossed the space to be excavated for the subway. In the meantime excavation had been made along the northerly retaining wall of the subway for one track, and as soon as the elevated tracks crossing the site of the subway had been supported upon piling the filling underneath the same was removed and the track was connected through the subway. One of the elevated northeast tracks was next abandoned, the filling material underneath it removed, using the track through the subway as a working track, when a second track was laid through the subway and part of the traffic trains over the northeast tracks were diverted through the subway. One by one the elevated northeast tracks were abandoned, as the excavation through the subway was widened out, until all of the northeast tracks were relaid in the subway, when the principal object of the scheme was accomplished. The retaining walls for the subway had been carried up simultaneously with the elevation of the tracks, so that the work which now remained to be done was the placing of permanent bridges in substitution for the pile trestles across the subway.

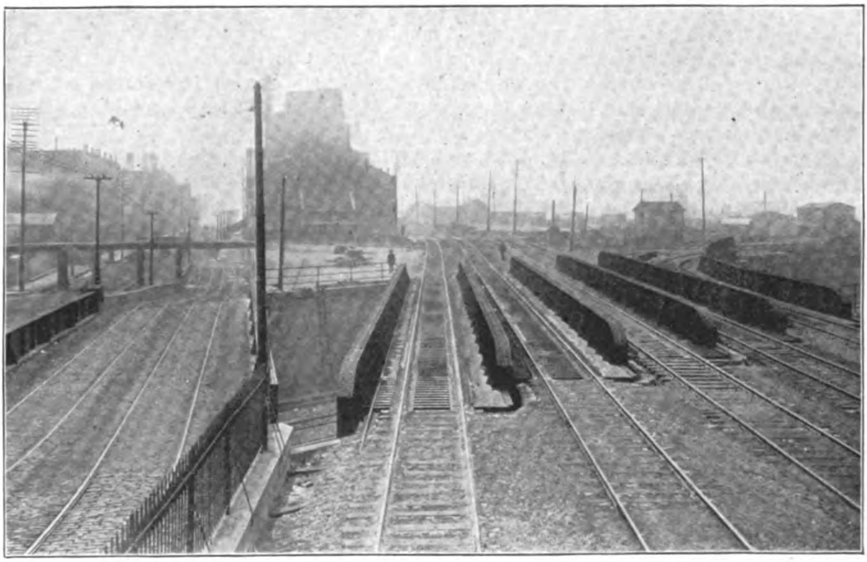

Fig. 515.—Elevated Tracks at Sixteenth Street Crossing and Subway, Chicago.

Figure 512 shows the location of the various tracks of the crossing after the subway was completed. The heavy lines represent plate girders. The tracks through the subway were depressed to an elevation of only 3 ft. above city datum. The other elevations noted in the illustration refer to city datum. Figure 513 is a view looking southwest along the subway while the tracks across it were still on temporary pile supports. The tracks in the foreground are those of the C., R. I. & P. and the L. S. & M. S. roads; those on the pile trestle are the St. Charles Air Line. Figure 514 is a view looking in the opposite direction (northeast) through the subway after the plate-girder bridges had been put in to carry the elevated tracks. The tracks on the lower level are those of the C. & W. I. R. R. The girders supporting the tracks rest upon two lines of columns intermediate between the side walls of the subway, the tracks each side of each line of columns being 16 ft. between centers; otherwise the spacing between the tracks is 12½ ft. The distance from the face of each side wall to the center of the nearest track is 8.3 ft. Later on the column supports for elevated tracks were walled in with concrete piers, as shown in Fig. 445, which is another view of this subway. Figure 515 is a view taken when the work was nearly completed, showing all the lines of railway involved in the elevation and depression of the tracks, but not all of the points of crossing. Beginning at the extreme left of the figure a view is had of Clark street, the portion of the street devoted to vehicular traffic being separated from the portion utilized by the street railway tracks by a girder. The street railway tracks appear next on the right. The street is carried over the A., T. & S. F. and C. & W. I. tracks and under the tracks of the St. Charles Air Line, the latter appearing on a temporary trestle crossing the street-car tracks. Next to the right of the street-car line is seen the four tracks of the L. S. & M. S. and C., R. I. & P. companies, each track running between a pair of girders. The track at the extreme right is a branch line connecting the C. & W. I. and L. S. & M. S. roads.

All of the important details involved in the work are too numerous to receive attention in a volume of this kind, it being sufficient to point out the ruling principle in the plan of the work; which was to first elevate simultaneously the tracks running in all of the three directions, in order to keep the enormous traffic moving unimpeded, when piles could be driven through the sand filling for the support of all the tracks crossing the space to be excavated for the subway, after which the subway could be excavated, first for one track, and gradually widened a sufficient amount for one track at a time, until finally the subway was completed and all of the tracks to be depressed were laid therein. The details of the work are exceedingly interesting to persons wishing to study methods of moving a very large traffic over temporary tracks in the presence of extensive and complicated engineering operations. For a full account of the whole undertaking the reader is referred to the Railway and Engineering Review for May 29, 1897, Nov. 19, 1898, and March 11, 1899; the Railway Age for July 29, Aug. 12, Aug. 26 and Nov. 25, 1898; the Engineering News for July 14, 1898 and Apl. 13, 1899; and the Journal of the Western Society of Engineers for December, 1898. The files of these publications for the years 1895 to 1902, inclusive, and the October and December, 1898, numbers of the Journal of the Western Society of Engineers contain a pretty complete account of all the track elevation work performed in Chicago up to the end of the year 1901.

206. The Training of Roadmasters.—In the introductory section of this volume it is stated that the maintenance of railway track is engineering, from which it may be reasoned inferentially that the man who is master of such work is an engineer. The trend of things late years has been to associate the work of track maintenance more closely with the engineering department of railways, or at any rate more closely with engineering methods, which is, of course, a move in the right direction, being in line with progress both for efficiency and economy. Growing out of this change of affairs there has arisen no little discussion and some question as to which of two classes of men, each alone considered, is better qualified for the position of roadmater—the engineer or the trackman. Most readers are familiar with several definitions for the term engineer, or civil engineer, but as pointed out in this connection we readily understand that reference is had to a man trained in mathematics and in the handling of surveying and drafting instruments, as applied to railway location, construction and measurements. When we speak of a trackman as a competitor with the engineer for the position of roadmaster we are understood to mean a man having at least a good common school education, whose experience has covered all the detail operations of track work, but particularly track maintenance. It goes without saying that he should be competent not only as a section foreman, but be capable of supervising the work of a number of foremen in charge of track. As track maintenance is an important branch of engineering it is worth while to consider the relation of these two classes of men to the work.

Since most engineers in these days are college-trained men it is well to analyze their antecedents, for on the part of the so-called "practical" men there is a good deal of prejudice against college men in general. As usual, enthusiasts on the subject carry matters to extremes in making comparisons. It requires only ordinary powers of observation to discover that there are two types of so-called educated men. There are men of the ornamental variety who apparently never survive the pedantic influences of their college days, and among this class may be found some men who can parade the degree of civil engineer. They are usually much concerned about matters of "esprit de corps," "ethics," etc., and they lament the fact that engineers are not able to maintain a professional standing on a level with lawyers and physicians. By such and other characteristics they are easily recognized, and their attitude undoubtedly has some tendency toward lowering the popular estimation of college men in general. Many who undertake to defend the college standpoint handle the truth too timidly. It is an indisputable fact that many college graduates, in scientific or technical as well as in classical lines, have neither capacity nor disposition for business responsibility. It is needless to remark that there is no demand for men of this type on railroads, where, above all things else, successful men must be practical. But such shortcomings are personal qualities, and they should not operate to prejudice the opportunities of college-bred men as a class, the majority of whom are serious-minded, industrious men, who could succeed in spite of a college education, but to whom such a training has been much of an opportunity and who have been broadened and benefited in many ways. Any man who is worth a college education will always be the better for it. There can be no doubt about that. This type of man is inclined to make the best of any opportunity he can get, he will seek to apply his knowledge to business ends, and in time he will become well acquainted with business affairs and methods. There need be no concern about college-trained men who are the right kind of men to start with.

The roadmaster should be an educated man; at least educated along the lines of his work; not necessarily a man of learning, in a strict sense of the term, but a man who has a trained mind, who reads and thinks, and who can comprehend at least the elementary facts of science; a man who is able from his breadth of view, to seek out knowledge, judge of it fairly, and know just how to apply it to his own ends. In favor of the engineer it may be said that his knowledge of mechanical principles, the resolution of forces, the strength of materials, the location of roads, the elements of curves and their computation, and other kindred information possessed by one worthy to be called an engineer, can be of service to any man having charge of track. While such knowledge is not called upon constantly in discharging the duties which engage the roadmaster's attention for the most part, there are occasions when it is in demand; and it certainly broadens his conception of things and enables him to comprehend all of the principles, calculations and manipulations which enter into roadbed and track construction. The man who has a knowledge of fundamentals is also better able to adapt himself to changing conditions than one not so informed and he is therefore so much the more independent of circumstances. In order to do accurate and reliable engineering work one must be able to check up computations, but a person who cannot comprehend the mathematics involved in engineering formulas or who cannot understand their demonstration, is not generally able to check either himself or his work.

The true engineer is a man trained to think with mathematical precision, who has an instinct for searching out the true relations of things and for properly weighing his facts in making comparisons; who is able to discriminate between cause and effect and able to judge of the proper limits of precision in his computations and in his measurements. If with such a training he has opportunity for combining with it the practical experience of any line of work, it ought to follow that, taking men as they are found, he should develop more rapidly and achieve a higher usefulness in the chosen calling than the man without an engineering training. With his ideas regarding system and his direct processes of thought he ought to be able to grasp readily a great deal of knowledge which the man not so trained is obliged to learn by slower process in the hard school of experience. These after all are the most valuable qualifications of an engineer for the management of track maintenance. While there are some questions of live interest in maintenance of way affairs which any engineer or surveyor ought to comprehend more readily than the trackman who does not possess a knowledge of the application of mathematics, still they are but relatively few in number. The advantage enjoyed by the engineer in respect of his education is derived not so much from his knowledge of technical matters as from his training in accurate and systematic methods of thinking; for no man who is not a careful thinker can expect to solve readily the problems which constantly arise in consequence of the changed conditions of train equipment and the general progress which comes about through modifications in track materials.

Such qualifications are therefore all very good, and undoubtedly essential to the highest usefulness, but by themselves they do not necessarily enable the possessor to assume executive control of parties of laborers on work which involves so many important details as does the maintenance of track. On any well constructed road surveying is, comparatively, but a small part of the maintenance work, and but little knowledge of the work and details of track maintenance can be gained with the transit, or at the drafting board. The cost of hand labor in most lines of engineering work is many times the cost of the head-work, and in track maintenance this is particularly so. The largest item in track maintenance is labor, constituting more than 60 per cent of the entire expense. Therefore, one of the most important things the roadmaster must oversee is labor; and men who have stood toil and exposure are usually considered the most competent in this line. It is natural to infer that the man who has had an outlook upon life from the laborer's point of view would be expected to possess some qualifications for overseeing and instructing laborers which would not ordinarily be found with men who have not had this experience.

It is frequently asserted that engineers as a class are so accustomed to precise figuring and exact methods of work that their training affords but little opportunity to develop capacity for handling men, who are not exact instruments; and it is a standing criticism of engineers that they are lacking in executive ability, and in capacity for handling ordinary business affairs. However this may be there can be scarcely a doubt on one point, and that is that trackmen are in possession of a vast amount of knowledge, gained from experience, which every man ought to have who assumes to take direct charge of the track forces. Some occasions under which a demand for special knowledge of track work is liable to arise are the selection and appointment of competent and reliable section foremen; the selection and purchase of suitable track tools; and in judging as to the progress and results which should be expected of the different foremen. In order to pass upon the matter last named the roadmaster must be able to estimate closely the amount of work a man can accomplish in a given time, at any of the multitudinous kinds of track work, and in this he can hardly succeed unless he is familiar with all kinds of track work. And then, to be fair, he must understand the nature of the difficulties which trackmen sometimes have to encounter in their work. He will also be called upon at times for instructions, which he cannot give intelligently unless he is familiar with track work. The most useful roadmaster is the man who can combine with executive talent the ability, upon occasion, to "set a pattern" for his foremen, or put himself in their place. He then ranks as a teacher, whereas if the case be otherwise he will be regarded merely as a critic, and his men will respect his opinions accordingly. On such considerations as these the experience of the trackman should not be ignored in appointing roadmasters.

In favor of the trackman it may be said that the man who has worked up from the bottom, had charge of a section, and who has been with work trains, is able at the start to take hold of things which he has done himself and of which he ought to have knowledge superior to that of the average of his subordinates; while the man without such experience must necessarily rely largely upon the judgment of his subordinates, until they teach him how to maintain track. He cannot, therefore, take hold at once and "push business" as the trackman can, for it takes some experience to enable one to discriminate wisely in the use of knowledge acquired from others. As between the two men, both being capable in their lines, there can be no doubt but that the trackman is far more competent to assume the duties of roadmaster than the engineer who is inexperienced with track work. The logical conclusion of the whole matter is that men are needed who can combine the training of the engineer with the experience of the trackman.

In justice to many roadmasters who have succeeded well in charge of track —the old school of roadmasters, if you choose—it must be conceded that among their number may be found men of fine judgment, well informed on matters pertaining to their work, men who think and study and who are able to reason straightforward and arrive at conclusions. Still, of these men it should be said that could they have had the advantage of a technical education they would have advanced to higher positions than that of roadmaster. All departments of railway work are progressing along scientific lines and coming roadmasters who hope for the largest success must fall in with the general advance.

Although railway officials are coming to recognize more and more the necessity of employing men of engineering training in the track department, there seems to be no united opinion as to the best course these men can pursue to sufficiently acquaint themselves with the details of track maintenance. One idea which prevails to some extent is that young men of this class, can, after a few years' observation of track work, either as surveyors in the regular corps, or as clerical employees in the maintenance of way department, or as assistants to the roadmasters, in some capacity, qualify for positions in charge of the work of maintenance of way. Another idea is to appoint engineers from the regular corps, with supervisors as assistants, who come in direct charge of the section foremen. The supervisor is supposed to be an expert trackman, so that any man who passes for an engineer may, with the support of one or more supervisors, get along for a time whether he knows anything about track from experience or not. In many cases of this kind the apprenticeship or the arrangement is of the nature of an extra or specially created position, tending toward an overabundance of officials. In course of time some of these men do well, but it costs a railway company something to educate to the duties of roadmaster a man who has not been a practical trackman, and in some cases it costs more than the man's technical education ever amounts to. While it is true that engineers in charge of, or associated with, construction work, such as is found in connection with change of grades and location, and work of this character, where some study must be given to the organization of the working forces, and the devising of plans to avoid delay to the traffic, ought to learn some things of practical value, still they do not come in direct contact with the laborers, and many of the most important lessons for a young roadmaster are absent. It is also too frequently the case that the laborers engaged on such work are unfamiliar with the language of the country, and, possessing no skill in the use of track tools, are driven around like so many cattle, direction as to the work being given in a broken tongue, more or less violently, perhaps, or partly by means of signs, gesticulations and other crude methods of communication. The engineer in contact with such a horde has but little opportunity to learn the character of English-speaking trackmen and how they should be dealt with—which knowledge is of inestimable value to a roadmaster, who must be an executive officer in the highest sense of the term.

It must be admitted that the tendency of the times is to divide up the duties and responsibilities falling to the office commonly known as that of roadmaster. This system is recognized wherever the organization comprises a supervisor of track and a master carpenter reporting to a division engineer who reports to the division superintendent. Where formerly there was a roadmaster and a master carpenter (or superintendent of bridges and buildings) both reporting to the superintendent direct, by the arrangement referred to the engineer now fills an intermediate position, being an "extra official," so to speak. The supervisors are recruited from the most intelligent and most industrious class of section foremen, and the master carpenter likewise from the bridge foremen of carpenters or of erection gangs. So far as the position of either of these is concerned, a technical education is not necessary—the man with the broadest experience in track or bridge work, with a fair common-school education, is, generally speaking, the best fitted. The division engineer to whom they report must be no other than a thoroughly trained engineer, whose duty it is to work out those technical matters which the supervisor and master carpenter are not supposed to be able to do, or, at any rate, are not expected to do. Of course it goes without saying that, according to the theory on which the organization is based, neither (the "practical" men or the engineer) can be dispensed with. Although the practical operation of many of the large railway systems of the country seems to controvert this proposition, the tendency is nevertheless as stated at the outset. An unfavorable aspect of the situation is that the so-called modern tendency presumes upon the necessity for multiplying offices.

Having followed the situation up to this point one is readily led to inquire whether, in this land of opportunities, it is reasonable to expect that men will undertake to acquire a knowledge of both track work and engineering; that is, on any such general scale as will meet the demand for this dual training. So far as opportunity exists there is, of course, every opening possible for any civil engineer who wishes to acquaint himself with methods of track construction and maintenance, and there is no hesitation in saying that the man who aspires to the position of roadmaster could employ his time for a year or two to no better advantage than by willingly engaging in the actual work of handling track tools. The man who will apply himself assiduously in this manner must without doubt become better fitted as a supervisor of track maintenance, in all its particulars, than he could hope to attain in any other manner. But good advice as this may be there are but few engineers who have ever resorted to such a course of preparation. The fact of the matter is that after graduation at college, whence most engineers come, the student of track engineering is beginning rather late to learn methods of work so thoroughly grounded in manual labor. To a person at this period there is a natural dislike to the performance of menial service, notwithstanding the nature of the inducement.

Nevertheless such courses of instruction have been inaugurated on a few roads of the country, notably on the Illinois Central R. R. On this road there is a system of track apprenticeship, introduced in 1897, by Mr. John F. Wallace, later general manager, whereby young civil engineering students and graduates from colleges or technical schools, and others from high schools or manual training schools, are taken into the track service as ordinary section laborers. After a year or two of practice those who show the right kind of ability are advanced to the position of section foreman or are taken into the engineering corps as rodmen, chainmen or transitmen. They then stand in line of promotion for such positions as assistant engineer, supervisor and roadmaster. The position last named is equivalent to that of division engineer or engineer of maintenance of way on other roads, and from it men have been frequently promoted to the grade of division superintendent. On this road track apprenticeship is the "doorway to the engineering department," and success by this route means "the survival of the fittest," for there have been many who have dropped out after beholding the serious aspect of a railroad career. A similar system was inaugurated on the Southern Pacific road, in Texas, by Mr. E. B. Cushing, while resident engineer, some years ago.

In a general sense, this process of "natural selection" has been but little tried, as yet, owing quite likely to the disinclination of both college men and railway officials to try the experiment, and the results have not been numerous enough to warrant any prediction as to the extent to which it may be put in practice in the future. The subject has been discussed a good deal by college professors, solicitous of opportunities for their students, but on their part there seems to be a desire that railroad companies should bind themselves to some agreement promising college students who undertake apprenticeships in track work some desirable position as soon as they have shown their fitness. On the face of things such an agreement could hardly be expected of a railway company. Young men seeking positions in maintenance-of-way work should not expect to be nursed. Men looking for such positions should have stamina enough to go to work with a will and take their chances of promotion with the rest of the employees. It is to be assumed that railway companies will seek the most capable men for promotion to the responsible positions, for where such a policy is not followed any plan will fail.

A plan which I would propose would be for railway companies to pick what material they can from among college men who will demonstrate their fitness by taking hold with their hands, and at the same time give equal opportunity to trackmen to qualify as engineers. If bright young men among the track laborers, possessed of a common-school education, were given opportunity to work with the surveying parties and at various kinds of engineering work they would readily pick up the use of instruments, and a little encouragement might induce many of such men to later pursue a college course in engineering. This seems like hitching the horse at the right end of the cart, for then the college graduate is ready and well able to take hold of any position in maintenance work where he can get the opportunity, and he need not then become the subject of ridicule among track laborers. He would also effect a considerable economy in time, both in and out of college, for, knowing methods of work and the practical limitations which have to be met, he would be less inclined to waste time and energy on so many of the hair-splitting niceties and adjustments which originate with inexperienced trackmen. It is a fault with many young engineers that they attempt an undue refinement in applying mathematics to simple track problems.

Why not such a plan? In the transportation department telegraph operators and station agents, with no better fundamental education than some trackmen, have every opportunity for promotion, and for a common thing such men reach the highest positions possible on railroads. To deny trackmen equal opportunities for promotion is to discourage honest effort and drive capable men from the field. If the line of promotion to positions in charge of track was open to engineers exclusively it would not be long, wherever such a policy should become established, until there would be no trackmen worthy of the name. On the other hand if trackmen were encouraged in some such manner as is here recommended there would be some inducement for young men of ambition and energy to remain with the work. There is no getting around the fact that the best prepared candidate for the position of roadmaster, other qualifications aside, is the man able to qualify at least for the duties of a section foreman. It is from a class of men so qualified that the great majority of roadmasters now holding positions have been selected. The most commendable plan would then seem to be to make it a requisite that candidates for the position of roadmaster should have handled track tools for at least two years and be able to qualify as civil engineers. If such a rule were adhered to as rigidly as possible there can be scarcely any doubt that but little time would elapse before eligible candidates would be forthcoming in sufficient numbers to fill all positions for which openings might exist.

Capacity for the performance of executive duties requires knowledge, judgment and decision. Judgment is proper discrimination in the use of knowledge, and decision is courage. General knowledge without particular application under specific conditions is called theory. Practice is the application of judgment to theory, or to general principles, which is only another name for theory. Now general knowledge or theory or general principles, and judgment are acquired by different processes. Knowledge of things and principles may be acquired without seeing the thing or seeing an application of the principle, but judgment on the application of principles and how to establish things in their right relations is rarely if ever acquired except through experience of some sort. Again, knowledge and judgment are different in another respect, in that the former may be more or less a composite of what different men have made known, and may be acquired by an effort of the mind; while judgment is individual, and is the result of one's own habits of thought; and there is nothing which will clarify one's thinking better than experience. The safest judgment is that which is built on its own foundation. The management of affairs is best learned through the management of lesser affairs; and the study of men, especially as related to business affairs, is not a study of books. Technical learning facilitates, but it does not originate. It sets up a standard of what things ought to be, but it does not always point the way for bringing those things about. It does not make up for defects of ability or for incapacity to move things with the facilities at hand. Technical education aims at the ideal, but it requires judgment to deal successfully with realities. In railroading, no more than elsewhere, are ideal conditions the rule. Generally speaking, the most successful railway officer is he who can combine the education which seeks the ideal with that which enables him in any situation to meet the real conditions at hand—in other words he who can combine a technical education with business experience. This, after all, is but a simple matter, easily accomplished if the right kind of men are appointed to positions where they belong and are advanced on their merits.

207. Limit of Capacity of Single Track.—An important question with heavy-traffic single-track roads is the limit of capacity for economical operation. There are so many varying conditions with different roads that theories of train movements in relation to assumed passing points are of but little value except as a rough guide. Exact rules cannot be laid down that will apply to all cases, for the investigation of the matter is largely a special problem for each individual road. Nevertheless, it is evident that there must be certain principles of construction and operation which have a general bearing on the question. When the management of a single-track line is confronted with a congestion of train movements it is seasonable to enquire into the possibilities of relieving the situation, and some of the lines of improvement which may be considered with a view to increase the traffic capacity of the road and put the question of the construction of a second track farther off, are as follows: More passing sidings; extension of siding capacity; a better distribution of sidings; extension or rearrangement of terminal facilities; installation or extension of interlockings or block signals; power units of larger capacity; a more advantageous system of train loading; a better system of train dispatching; a better arrangement of water supply facilities in relation to stations stops, or the making of such facilities accessible to trains while standing on side-track; more systematic attention to locomotive repairs; better discipline; better management, etc. Such matters and perhaps others are of general application, even though they must be considered from different points of view, and a discussion of the question on these lines should bring out valuable information. The issue of the Railway and Engineering Review for March 15, 1902, contained a lengthy symposium on the limit of capacity of single-track roads, consisting of the opinions of 26 railway officials, and the following are brief extracts from these expressions of opinion:

"The problem concerning the capacity of single-track roads is governed by special conditions rather than general principles. Theoretically, this capacity is reached when every passing track is occupied by a train or trains in one direction, meeting with uniform movement at each of these sidings, trains going in the opposite direction. This, of course, is an imaginary condition, and would never be attained in actual practice. The nearest approach to it, with the number of hours required to make the trip, together with the number of trips times the number of cars or tons per train, are data which give the capacity of the road for each 24 hours.

"The capacity is greater on a level road than on a mountainous one. On the level road trains can generally be depended upon to move at a certain speed. On heavy grades one cannot always tell what speed they will make up hill; consequently there will be more delay to opposing trains, and the more numerous the trains the more delay, and the need of double track becomes apparent. At the same time the greater cost of the improvement on a mountain road confronts the officials and deters the building.

"In a general way, the number of trains has more to do with this question than the freight tonnage. For this reason, a low-grade line can be operated as single track with heavier tonnage than would be possible with a heavy-grade line. Stock, perishable freight and merchandise trains must be hurried forward at greater speed than lower classes of freight, and a road having a big percentage of the former class would require double-tracking sooner than one having the same tonnage but consisting of ore, grain, or similar commodities. The speed of the trains also cuts a considerable figure. A few fast mail trains, the speed of which is very much greater than that of anything else on the road, will hasten the necessity for double track, in order to prevent too much delay to slower trains. The more uniform the speed of all trains the larger the movement that can be handled with a given number of passing tracks. Unbalanced traffic has a bearing on the subject, as this condition increases the number of trains for the same number of tons over what they would be if the traffic was balanced.

"The prime factor in double-tracking railways is to expedite the movement of freight, the railway officials of to-day invariably seeing that passenger trains are kept moving, no matter how great the sacrifice to the freight service. Where competition is so great that the speed of freight trains, and prompt movement thereof, becomes a serious factor in getting and maintaining business, it may be better to double-track a road for much less volume of traffic than would be thought necessary where there was no—or very little—competition. Some roads seem to be able to constantly increase a growing business and yet not make as good time with freight as their competitors. I have in mind one road with heavy grades, fairly good power and facilities, that handles about 1500 trains a month over each division of the line that might be said to have reached the limit of its capacity, because at times the trains get over it only after considerable delay and difficulty; yet it seems possible to further increase the capacity of that line by improving its facilities. The capacity and condition of the power on a railroad must also be considered.

"Whether the traffic is fairly well distributed throughout the day and night, or whether it has to be handled during a short space of time is another phase of the question. On a line where the passenger traffic is light and freight traffic heavy and of such nature that it can be distributed throughout the 24 hours, a greater density of traffic may be handled satisfactorily on a single track than otherwise.

"The fact that a single-track road may be blockaded with traffic is not necessarily an indication that it is being worked up to or beyond the limit of economical capacity. The matter really turns upon the question as to whether proper facilities are at hand, and whether train operation in conjunction with these facilities is being properly directed. Ample terminal facilities are necessary, so that trains can be run in large numbers in one direction, meeting in the opposite direction only passenger and perishable freight trains; and if these trains are late, time orders should be given, and not detain them at telegraph offices to give meeting orders; giving passenger and perishable freight trains the preference to insure their making schedule time, letting opposing trains make where they can for them. With a large number of trains bound in opposite directions delays are unavoidable, whereas if they could be run in groups in one direction there would be no delay. Trains would reach terminals on time, motive power would be ready for other trains on time, less consumption of coal and other supplies, less overtime to trainmen, less liability of accidents, etc.

"On roads having a large number of passenger trains, if it can be arranged to have the movement of freight at the time of day when the least number of passenger trains are moving, it will be found that the necessity for double-track arrangements can be postponed for a considerable length of time.

"Train dispatching has largely to do with the volume of business which can be moved over single-track railroads, and actual experience in the matter of what can be accomplished by one set of dispatchers using certain methods, as compared with another set of dispatchers with other practices, is as day and night when compared with results. If too many miscellaneous duties are required of a dispatcher train movements are more than likely to be slighted. This is no theory. His office should not be public. He should not be required to act as operator and deliver orders to trains. It takes time to fix manifold and carbon sheets as well as to fill in all the notations on the order blanks, to say nothing of leaving his desk to deliver them when other trains out on the line may be demanding attention. Under these conditions he is called upon to answer all sorts of questions and engage in conversation, and these interruptions are many times detrimental to the proper performance of his work.

"Side-tracks four to five miles apart are facilities essential to the development of the full capacity of single track. These side-tracks should be long enough to hold at least two trains, and in connection with this feature it is important to have facilities for taking water while the trains wait on side-track. Another important matter is that sidings should preferably be located where it will not be necessary for trains to cut for crossings, as the necessity to do this is a matter of considerable bother and takes time. Lap sidings, with towermen to throw the switches, are also much in favor. The A., B. & C. Ry., for instance, handles a larger regular tonnage than some of the roads in its territory that have double track; yet it still has considerable single track. They have accomplished this by a system of sidings four and five miles apart constructed on the lap plan, with an operator to throw the switches for incoming trains. At each station there are two sidings, many of them of sufficient length to accommodate three 60-car trains.

"I believe that with lap sidings and interlocking towers at each lap, the sidings being located from three to four miles apart, and trains required in all cases to head up to the tower when using the sidings, a single track could be operated more satisfactorily than a double track without siding facilities and where trains are required to cross over to get out of the way of faster trains following. I also believe that such an arrangement of single track, with an absolute block in both directions, as would be entirely feasible, would be safer to operate than a double track not blocked.

"The distribution of side-tracks is governed by special conditions. It is found that on certain parts of roads trains more frequently meet than on other parts, and the modern method of blocking trains makes the need of frequent sidings felt. Where trains frequently meet they should be close together, serving as a basis for sections of double track in the end by joining them together. For heavy volume of business passing tracks should not be more than five miles apart, and for low-grade lines, where heavy tonnage is being handled in the trains, three to four miles will be found much better.

"I think a passing track, of not less than 150-car capacity, should be located every 5 or 6 miles on single track; and in addition, where the traffic is heavier in one direction than in the other, more passing tracks should be located midway between the regular passing tracks, to accommodate the heaviest traffic. The value of a long passing siding can often be increased by the construction of a crossover track midway between the switches, so that if two trains are headed in they can both pull out, whereas without the crossover one is required to back out. Where there is not room for a long passing siding, a second siding can perhaps be constructed outside of and parallel to the first one.

"In the handling of heavy business I greatly favor the double passing track, i. e., one on each side of main line, or side by side, as the case may be, in preference to the long passing track, even where the latter has intermediate switches.

"Passing sidings where there is no telegraph office are sometimes sources of unexpected and serious delays, and there should, if possible, be a telegraph office at all such sidings. They should be located as near the sidings as it is possible to get them. Where they are at a distance too much time is consumed by conductors getting to the office for orders or by the dispatcher sending the operator out to get the train. Something unforeseen is liable to occur at any time, and if the train is lying at or very near the telegraph office, the dispatcher can very soon get it moved to another meeting or passing point.

"Yards at division termini should have a capacity equal to half the entire capacity both ways of the divisions terminating at the point considered, besides the necessary room for switching. Terminal stations should have a capacity equal to the incoming business multiplied by the average time required to place the cars, discharge, reload and place again. Where the facilities are good this can be done in four days, which would make the capacity four times the incoming business, exclusive of the switching room.

"An arrangement deserving careful attention is the double-tracking of the line for one station interval out from terminals, so as to permit trains made up and ready to start, to leave the terminal without waiting for the arrival of some train which may be delayed just long enough to hold the train about ready to start, but not long enough to permit a meeting at the first siding out on the line. This arrangement also helps out where the capacity of the terminal yard tracks is not sufficient to accommodate all in-bound trains that might seek to enter, before out-bound trains can make ready to leave, in which case the in-bound train must take some outlying side-track and wait for the departure of some of the trains from the yard. Water and fuel stations should be so planned as to enable engines to replenish supplies from either main track or sidings, the water cranes being so placed that passenger trains may take water while making station stops.

"The effect of block signals on single track sometimes expedites and sometimes handicaps traffic; yet on some roads block signals have increased the capacity of short divisions of single-track lines.

"I should say that the capacity of single track would depend on the number of preference or passenger trains; second, the limit of time necessary between passing tracks; third, the question of whether it is necessary to block in one or both directions. For instance: On certain divisions of the D., E. & F. Ry., where we have five important passenger trains each way and where we use located stations wholly for passing tracks, and where heavy tonnage trains are handled, necessitating slow speed and an absolute block maintained in both directions, we have found it difficult to get twelve freight trains each way over the road, in addition to passenger trains, without very serious delay to freight traffic; while it has come under my observation that on roads where block signals are not in use and where passing tracks are located with a view to handling heavy traffic, that more than twice this number of trains are handled without serious delay to freight traffic.

"The influence of block signals on this question can be none other than the best. They go a long way towards making single track both safe and profitable. I cannot conceive how a thoroughly modern, properly installed and properly maintained automatic block signal system, or any other block signal system, for that matter, if properly observed by train men, can operate to the detriment of traffic, either on single or double track.

"Where traffic is heavy on a single-track road there should be a tower block system or an interlocking staff system, in order that it should be impossible for more than one train at a time to be between two stations. Or at points where the traffic is not so heavy, a staff system ought to be used, so that the staff or a ticket must be carried between one station and the other.

"I cannot see how block signals can facilitate train movements, and they will reduce the number of train movements on single track in every instance. I have never been in favor of single-track blocking, as I have always been of the opinion that the proper way is to have a positive telegraph block. With this system any block signals between stations would be useless. By using a permissive block, however, I should think that it would not be safe without block signals between stations. My idea of handling trains on a single-track road is: First a positive telegraph block system with sufficient siding capacity at each station; to have all passenger sidings handled by the operator; to have electric automatic station protective signals to indicate the condition of the main track throughout the station and yard limits, where the view is not good.

"It might be considered necessary to double-track a road when the time of getting freight trains over the line was twice as long—caused by meeting trains and allowing superior ones to pass—as it would be were there no trains to contend with whatever.

"A railroad should not be double-tracked until the grades and curves have been reduced to the lowest practicable limit; the roadbed thoroughly ballasted and equipped with 80 to 100-lb. rails; the limit of weight and capacity of power for economical freight train operation supplied; and passing sidings of sufficient length to accommodate two of the longest trains, which sidings should be placed six or seven miles apart and arranged so that they will form part of the second track. Then when the traffic justifies the running of over eighteen trains in each direction daily, or one train every 90 minutes, the second track should be put in, especially if the heavy traffic is regular throughout the year, or for a period of over four months.

"My opinion would be that 50 trains could be handled each way on a division successfully, not to exceed from 100 to 110 miles, where everything is favorable, such as weather, grades not too heavy and long, engines properly rated and in good condition, track in good shape, water tanks at least every 20 miles, good long side-tracks not over 6 miles apart, capable of holding any two of these trains.

"In a general way, my opinion is that a road having 60 trains within 24 hours, even with ample side-track facilities, and an average number of passenger trains, should be considered as requiring double track. Of course, if there are many fast through passenger trains and fast through freight trains it would likely be found advisable to provide double track when the total number of trains reaches 50.

"I have seen cases where a single-track road was capable of handling, under the best conditions, 70 trains a day, ten being passenger. If 25 or 30 were passenger it would change the situation very materially.

"On a road on which I was once employed as dispatcher, we handled in twelve hours, over 13 miles of single track, 70 local passenger trains and from 10 to 15 extra freights, and yet there was but very little delay. There were six sidings—two, each one mile long, and four, each a half mile long, and train order offices at each siding.

"This company is now building some double track where the train density is from fifty to sixty trains per day both ways, but where the traffic is largely composed of live stock which must have quick movement and must move at a certain time of the day, and where the fast freight in the opposite direction moves over the same district at about the same time of day.

"In commencing to double-track a road the work should begin where the largest amount of traffic is handled, which is usually at one of the terminals of the line. But if the volume of traffic is on the middle of the line the double-track work should be begun at this point.

"I would say, in a general way, that double-tracking ought to be done before the limit of capacity for single track is reached, as the work of double-tracking itself involves a large number of additional trains upon the single track, and the double-tracking can be done only at an enormously increased expense if it is postponed until the full capacity of single track has been reached. I have had as many as five or six trains in a district of 20 or 30 miles, held out all day long without a minute's use of main track, and gangs idle in consequence. I would say that in a stretch of 25 miles an increased expense in train service of $50,000 might be caused by postponing double-tracking until the single track was crowded to its fullest capacity with regular trains. In place of about $1000 per mile train service in double-tracking, we have figures running up to $3000 per mile, or somewhat over, the cause being idle time of trains."

208. Hand Cars of the Manitou & Pike's Peak Ry.—The average grade of the cog road from Manitou, Colo., to the top of Pike's Peak is 844.8 ft. per mile, and in several places it is as steep as 25 per cent, or at the rate of 1,320 ft. per mile. In order to insure traction for the locomotives rack bars are laid in the middle of the track, as seen in the illustration on page 703. For rapid transit down grade the officers and employees of this road use what are known as "slide boards," on which they can coast down the track at great speed. The device consists essentially of a plank 12 ins. wide and 3 ft. in length, along the middle of the under side of which there is a cleat which runs between the rack bars and holds the vehicle thereon. On either side of the middle cleat there are brake shoes, bolted to the plank at one end and bearing against the outside surfaces of the rack bars or cog teeth. These brake shoes are applied by clamps bent over the sides of the plank and operated by a lever which, as appears in the illustration, the rider holds within his grasp. The plank bears upon the upper edges of the cog teeth by steel runners, which consist of two straps bent over the ends of the plank. To hold the device in balance a bar or pole is bolted to the top of the plank, crosswise, extending over the track rail on either side. Across the front end of the plank there is bolted a rest for the rider's feet. The weight of the slide board entire is but 35 lbs. The position of the rider when in motion is clearly apparent in the illustration, and the method of operating the device is simply to place it on the track, sit down and attend to the brake. The speed attainable depends upon the pleasure of the rider. A record of a fraction under a mile a minute has been made, and a ride at this speed over the rack rails is said to be stimulating if not exciting. The entire stretch of track from the top of the peak down to Manitou—9 miles—is used, except at four points where the rack rails diverge at sidings. At these points the rider must come to a stop and carry his board about 40 ft. On one occasion an employee of the company made the trip over the 9 miles in 11 minutes. The friction of the runners on the rack rails causes the former to heat, and on the lighter grades of 8 to 12 per cent the heated runners have been known to adhere to the rack rail and stop the vehicle. For the purpose of lubrication, and to prevent the runners from unduly heating, the rider carries a bar of soap which he applies to the top of the rack teeth by reaching over in front of the board. Even then, the friction is so great that, at very high speed, on the long grades, streams of fire follow the flight of the rider.

EXPLANATION OF TABLES.

Table V.—The sine, cosine, tangent, co-tangent, or external secant of an angle greater than 90 degrees is numerically the sine, cosine, etc. of the difference between that angle and 180 degrees.

The versed sine of an angle greater than 90 degrees is equal to 2 minus the versed sine of the difference between that angle and 180 degrees.

Table XI.—The lower frog numbers are inserted in the table for use on street railways.

Tables XIII and XIV.—These tables have been worked out to give measurements for point switch turnouts, having switch points of various lengths, corresponding to different values of spread at the heel. The turnout curve in every case is tangent to the point rail at the heel, and to the frog at the point of frog. For the change in middle ordinate of outside rail of turnout when the main track is curved, see § 68, chapter VI.

Table XIV.—Measurements for Point-Switch Turnouts.

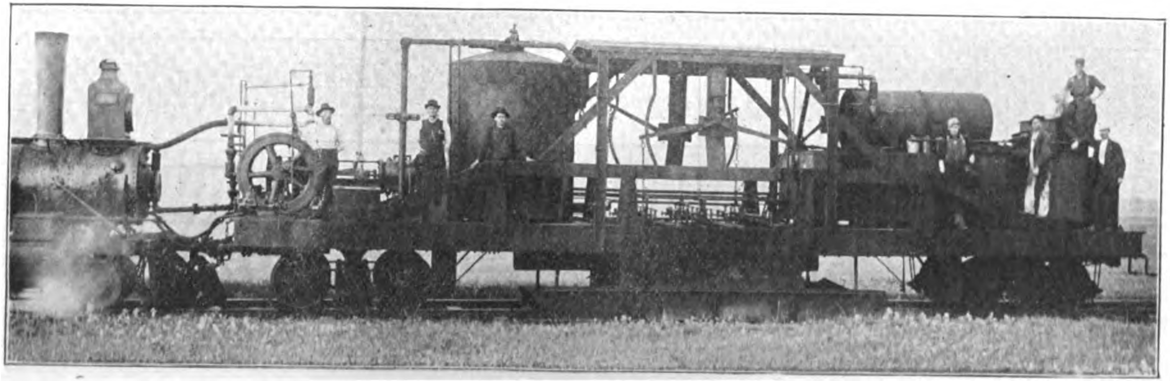

Fig. 537—Weed-Burning Car, Chicago, Milwaukee & St. Paul Ry.

209. Weed-Burning Cars, C., M. & St. P. Ry.—The use of weed-burning machines for destroying vegetation in track is now so well established on roads in the Mississippi Valley that they are no longer regarded as experimental. The Chicago, Milwaukee & St. Paul Ry. is operating machines of more recent design than those described and illustrated in Sec. 90. On the dirt-ballasted track of the various lines of the system in South Dakota, Western Minnesota, and Northwest Iowa, weeds and grass grow all over the roadbed quite vigorously, and the expense of clearing the track by grubbing this vegetation with a shovel or hoe would be a large item.

The car, with all of its appurtenances, is entirely of steel or metal construction. It is 47 ft. long, and the weight, with the tanks empty, is 57½ tons. The "fire pit" is 9 ft. square, reaching 6 ins. beyond the ends of the ties, and is carried under the middle of the car (Fig. 537). Over one of the trucks there is a water tank of 2,500 gals. capacity, surmounted by the main air reservoir, holding air at 70 lbs. pressure. Near the other end of the car there is a cylindrical oil tank with a capacity of 35 bbls., and at the end of the car there is an air compressor taking steam by flexible pipe connection with the locomotive. The water on this car is carried both as a measure

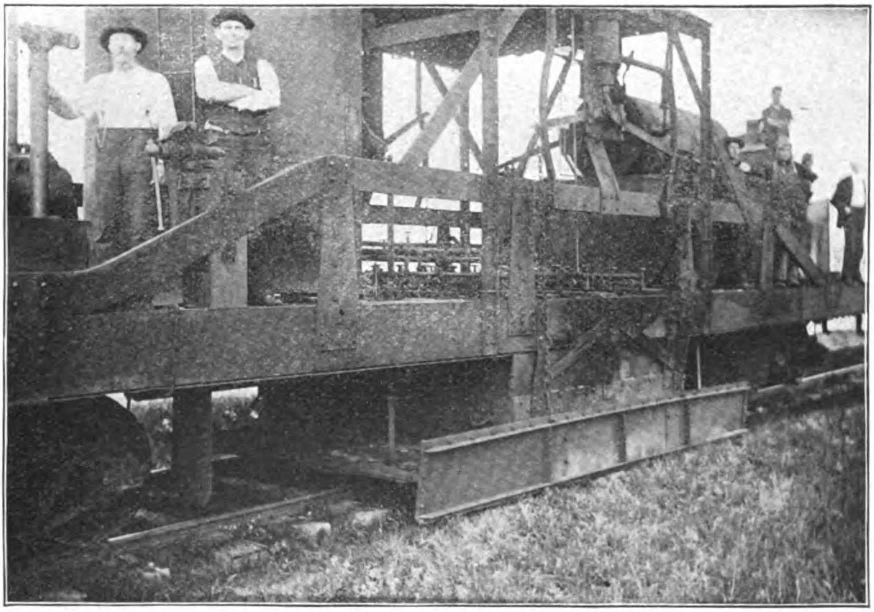

Fig. 538—Near View of Weed-Burning Car, Showing Fire Pit.

of fire protection and for the supply of the locomotive in case the water in the tender should run short. The fire pit consists of a cast iron plate or "floor" 1 in. thick, suspended 17 ins. above the rail, with fire brick 6 ins. thick bolted to its under side, and twenty-five 3-in. combustion chambers or "burners" running vertically through the fire brick and opening downward. The burners are distributed six outside each rail, and 13 between the rails, in rows, staggered. To retain the heat there are side wings (Fig. 538) let down and supported by chains; and there are dampers at each end of the fire pit. The crude petroleum fuel oil is taken from the supply tank and passed through a curled-hair strainer, and then heated to a boiling temperature by coils of steam pipe. It is sprayed into the burners by compressed air at 20 lbs. pressure. To protect the heated fire brick from rain there is a roof over the center of the car. The auxiliary equipment includes a duplex oil pump, for pumping oil out of the supply car hauled with the train. By this means the supply of oil in the service tank can be maintained without interruption while the outfit is in motion. There is also a water pump for fire protection or for filling the water tank through a hose dropped into a stream, as the necessity for taking water in this way frequently arises when the supply runs short and the train is a long distance from a water station. The exhaust from the air compressor is run to the smoke stack of the locomotive and provides sufficient draft without putting on the blower.

When burning weeds, the oil is sprayed into the burners and the flame spreads over the track, underneath the highly heated fire brick. In dry weather the speed of operation is about four miles per hour, but in wet weather the progress is slower. In order to clear the track satisfactorily the car is run over it two trips at each burning. During the first trip the green vegetation is wilted and killed, and after being permitted to dry out for two or three days in the sun the car is again run over the track and the scorched weeds and grass are entirely consumed. There is no trouble from the fire except with rotten or "punky" ties, and as a means of sure protection in this respect a section crew follows the burning outfit to throw dirt upon and extinguish such fires as may become started. The quantity of oil used is about ½ bbl. per mile, and the expense of burning is $1.35 to $1.50 per mile, according to the conditions of vegetable growth and of the weather. These figures cover the entire expense for materials, labor and locomotive attendance. In the part of the country referred to it is necessary to burn over the track three times each season, at intervals of six weeks. The third burning is done partly with a view to kill and consume vegetation which would otherwise catch drifting snow and make trouble in winter.

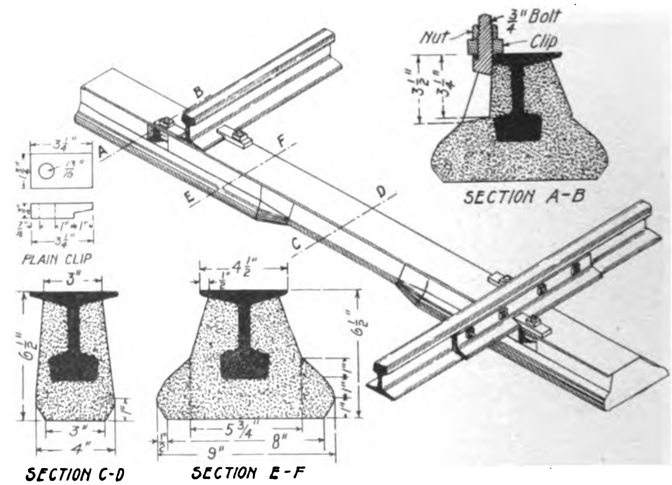

Fig. 539—Construction Details of the Buhrer Concrete-Steel Tie.

The crew required consists of a conductor, who has immediate charge of the machine, two assistants, an engineer and a fireman. The burner car is run either ahead or behind the locomotive, indifferently. When the wind blows lengthwise of the car it is necessary to run water into the axle boxes of the truck in the leeward direction, as otherwise the intense heat blown that way would burn out the journal packing in a short time. The weed-burning train carries, besides the burner car, an oil supply car (usually a stock car loaded with barrels of oil) and a boarding car for the crew. Each of these trains covers 310 to 425 miles of track burned three times each season.

210. Buhrer Concrete-Steel Ties.—In Sec. 169 there is a description of the concrete-steel tie with which Roadmaster C. Buhrer, of the Lake Shore & Michigan Southern Ry., has been experimenting since the spring of 1902. The details of design appear in Fig. 539. The ties are 8 ft. long, and each is reinforced with a piece of rail 7½ ft. long, made by cutting old scrap 60 or 65-lb. rails into four pieces. The concrete body of the tie projects 3 ins. beyond the reinforcement at each end. The metal top face projects ½ in. beyond the concrete body, so as to shed water, and the width of the concrete along the middle portion is 3 to 4 ins., from top to bottom (see Section *C-D*), being narrowed in order to diminish the width of bearing and thus avoid center binding of the track. To provide for the insertion and removal of fastenings there is a recess in the concrete in each side of the tie, under the bolt hole through the top face. The concrete is a mixture of fine gravel and cement, and it is either submerged or frequently sprinkled with water with a hose during 30 days while it is setting.

These ties weigh about 400 lbs. each. It is fully understood that the use of old rails for the reinforcement involves a good deal of metal, undoubtedly in excess of the requirements; but as the principal aim of the experiments was to determine how the concrete would bear up under the traffic and sustain the shock of rolling loads, the excess of metal was of minor importance. The inventor has in view the possible use of various metal shapes for the top face of the tie, such as old rails of lighter weight than the ones used, T-irons, bulb irons, a channel with the flanges downward, and other shapes. Mr. Buhrer is confident that the weight of the necessary metal can be reduced to 80 lbs. or less. The ties are handled by means of tongs made to take hold under the bottom of the tie, and when placed in the track the fastenings are screwed up by means of a socket wrench made by placing a brake wheel on a shaft and forging the bottom thereof to fit the heads of the bolts.

Besides the roads already named as having these ties on trial, the Ann Arbor R. R. (near Durand, Mich.), and the Pennsylvania Lines West (at Toledo, O., and at Allegheny, Pa.) are making tests of experimental sections of main track laid with them. The experiment at Danbury, O., on the Lakeside & Mar-

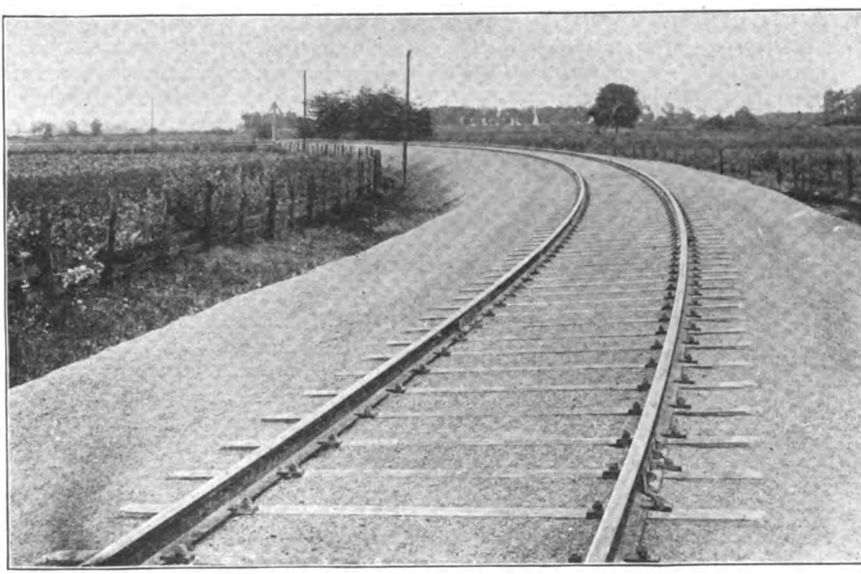

Fig. 540—Track Laid with Buhrer Concrete Steel Ties, L. & M. R. R.

blehead R. R., was started in July, 1903, on a compound curve of 12-deg., 9-deg. and 6-deg. parts, about 1200 ft. long, laid with 17 ties to the 30-ft. rail. Part of the curve is shown in Fig. 540. Over this curve there is a traffic of six passenger trains each day, and a very heavy freight tonnage. Before the concrete ties were laid the wear to the outer rail had been excessive, there had been difficulty in maintaining the rails in gage, and the services of the section men had been frequently called upon to adz the ties in order to return the inner rail from a canted position. When the new ties were placed the track was relaid with new 75-lb. rails, to a gage of 4 ft. 8¾ ins., and ballasted with limestone screenings. On this trial section there is a turnout, and, to demonstrate the feasibility of using these ties in any place where wooden ties can do service, this turnout was laid with concrete ties. Not only the ties under the lead rails, but the headblock for the switch stand is reinforced concrete, made up generally on the same design as that of the ties of standard length.

At latest reports the track at Danbury had remained in good surface, line and gage at practically no expense for repairs or attention, and the service of the ties had been highly satisfactory On the various roads mentioned these ties have been laid in both gravel and broken stone ballast.

It is interesting to state further that in some cases these ties are being used in the track circuits of automatic electric block signals, on both the L.

S. & M. S. Ry. and the Pennsylvania Lines West. The means of insulation consists of oak shims ¼ in. thick., in some cases, and fiber shims in others, placed under the rails, with fiber bushings and washers for the fastening bolts and clips. In some of these trials only one rail (that is, only one side of the track) is insulated from the metal top face of the tie.

211. The Ware Pneumatic Rail Unloader.—Section 146 covers the use of machines and appliances for unloading rails from cars where access to the rails can be had at the end of the car without lifting the rails, as with gondolas with removable ends and box cars with end doors, but rails are frequently shipped from the mills in gondola or deep steel cars with permanent ends. Mr. Henry Ware, roadmaster with the Buffalo, Rochester & Pittsburg Ry., has designed and used apparatus for handling rails out of such cars. The machinery (Fig. 541) consists of two skids or incline troughs, over which the rails slide from the rear of the car, with pneumatic hoisting apparatus for lifting the rails from the pile in the car to the level of the skids. On each side of the car there is an upright, which is secured to the side of the car by means of an adjustable stake pocket and two adjustable brace rods. It can be placed on any kind of a car having open sides. On the inside of each upright a roller is permanently secured at an elevation about 10 ins. above the level of the top of the car, and there is also a roller at the top end of each skid or incline, which is hooked over the end of the car in line with the roller on the upright. The trailing ends of the skids are supported by a 5x5-in. piece of timber crosswise the rails, carried upon two small wheels. All parts of the machinery are detachable and can

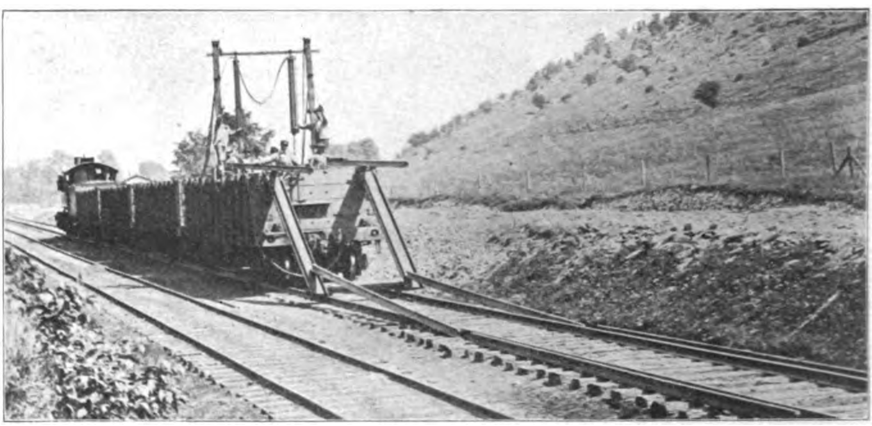

Fig. 541—Ware Pneumatic Rail Unloader, B., R. & P. Ry.

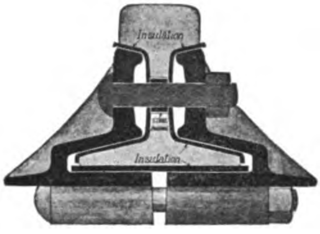
be removed or attached without the aid of tools, except in the case of the stake pocket, which requires the use of a spike maul to drive the wedge which makes the adjustment of the pocket to the various widths of the car sides. The pneumatic hoists are suspended from a cross bar supported by the two uprights. The compressed air used is taken from the train brake line through a flexible hose. In unloading rails three men are required to handle the rail and tongs, and one to manipulate the working of the air for the cylinder, on each side of the car, or eight men to unload and distribute rails from both sides of the car at the same time.

In operation the suspended tongs are attached to either the head or base of the rail, whichever is most convenient for grappling, and the rail is raised to a sufficient hight to guide it onto the rollers. The air is then released, the tongs detached and the men push the rail over the rollers. When the center of the rail reaches the roller on the skid the rail tips up, the end of the rail slides to the ground, and, as the train moves ahead, the upper end of the rail gradually slides down and is landed on the ends of the ties, just outside of, and clear of, the service rails, without further attention after they enter the skids. Each car, as it is unloaded, is cut off from the train and allowed to stand on the track while other cars are being unloaded, or until it is pushed to a siding by the regular traffic, when all the empty cars can be left on the siding or coupled in next to the engine and hauled along with the train. On some roads rails are unloaded with steam derricks or wrecking cars. In such cases the train is obliged to return to a siding after unloading each car, in order to make a shift



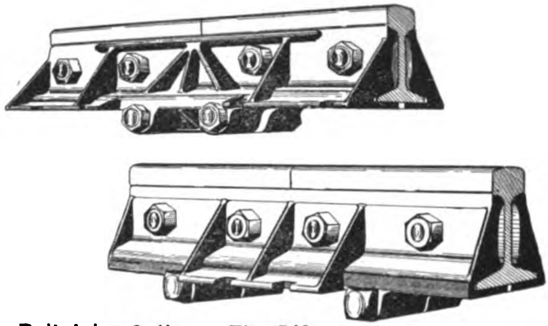


Fig. 542—Atlas Rail Joint Splices—Fig. 543.

of cars to get the next car of rails to be unloaded ahead of the derrick. This machinery obviates the necessity of running to sidings to shift cars.

212. Rail Joint Splices.—The Atlas joint splice consists of two malleable iron or cast steel bars, grooved to fish with both the bottom and top of the rail flange, as well as with the under side of the head. The sides of the bars are gusseted or ribbed transversely (Fig. 543), and there are depending lugs with two bolts, under the rails, to draw the bars securely together at the bottom. The style of bar for supported joints is shown by the bottom drawing, and that for suspended joints by the upper drawing. The Atlas insulated joint splice is of the same pattern, being fitted with fiber sheet insulation under the base and at the fishing surfaces of the rail (Fig. 542), with fiber bushings for the splice bolts where they pass through the rail web. To relieve these bushings from wear they are protected with a metal washer where contact comes with the web of the rail.

The Wolhaupter joint splice consists of two grooved base-griping angle bars, with a separate corrugated base plate fishing into the bars. In Fig. 544 the lower half-tone view shows the outside bar, the upper view the inside bar, and the right-hand view a section of the splice at the middle. The base plate is shouldered along one edge to take the abutment or outward thrust of the rail flange, and on the gage side of the rail the base plate and the bottom part of the inside splice bar interlock, the horizontal leg of the splice bar being cut away at both ends and the base plate cut out at the middle. The inside spikes are driven in holes punched through the base plate, and bear against the edge of the rail flange where the ends of the splice bar are cut away. As the base plate is shouldered against the outer edge of the rail flange these inside spikes are as effective in holding the gage against lateral stress as the outside ones, and they hold the gage and alignment of the rails independently of the adjustment of the splice bolts.

Step Splices.—Mention may be made here of certain step or compromise joint splices not covered in Sec. 95. As the Atlas joint splice is shaped by molding and casting, it is readily made for step joints, and is much used for a compromise splice. The Vulcan step joint is made without splicing bars, merely by fitting and bolting the two rails together (Fig. 545). The rail of larger section is bent to a small angle and the head of the lighter rail is planed off to make a

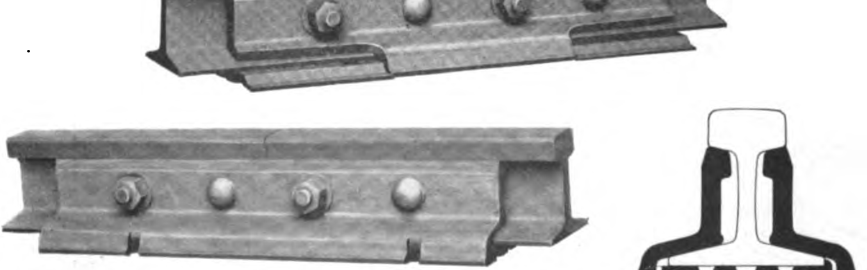

Fig. 544—Wolhaupter Rail Joint Splice.

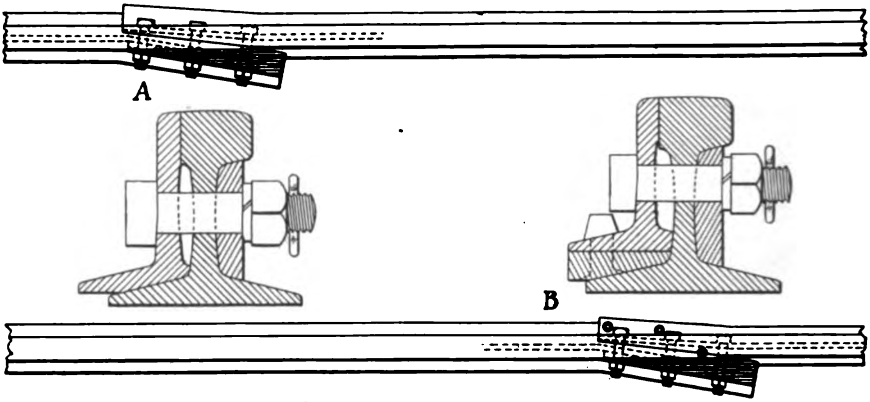

Fig. 545—Vulcan Step Joint.

miter joint with it, fitting against a shoulder at the bend, as shown. The base of the lighter rail is planed to rest upon the top of base of the heavier rail. Where the variability of the hight of the sections is great a metal shim is riveted to the base of the smaller rail, as shown by engraving *B*. The two are then bolted through and through horizontally with three bolts. The ends of the two rails lap about 12 ins., and outside of the rail head line the bent end is planed down on a bevel to put it out of reach of the false flanges of guttered wheel treads. This step joint is standard on the Atchison, Topeka & Santa Fe Ry., and is used on a large number of other roads.

213. **Mansfield Semaphore Switch Stand.**—In the development of railway signaling the semaphore has been gradually gaining ground as the standard and most satisfactory type of signal. Where a high signal is used at switches thrown by hand the semaphore has been widely adopted in preference to the revolving target. For a good many years the idea of working a semaphore signal in connection with ordinary hand-throwing switch stands has been in the minds of a few railroad men, and at one time a semaphore switch stand with the arm standing about 18 ft. high was used to some extent on the Pennsylvania R. R. The Chicago & Alton Ry. has adopted a semaphore signal and stand for switches thrown by hand. It was designed by Mr. Geo. L. Mansfield, assistant engineer with that road. The stand is also widely used on other roads. As seen in Fig. 546, the stand is thrown by means of a weighted ground lever operating a bevel gear in the column or base, which turns a revolving shaft passing up through a 1½-in. pipe tube screwed into the top table of the stand. At the top of this tube the shaft operates another set of bevel gears which actuates the semaphore 8 ft. high.

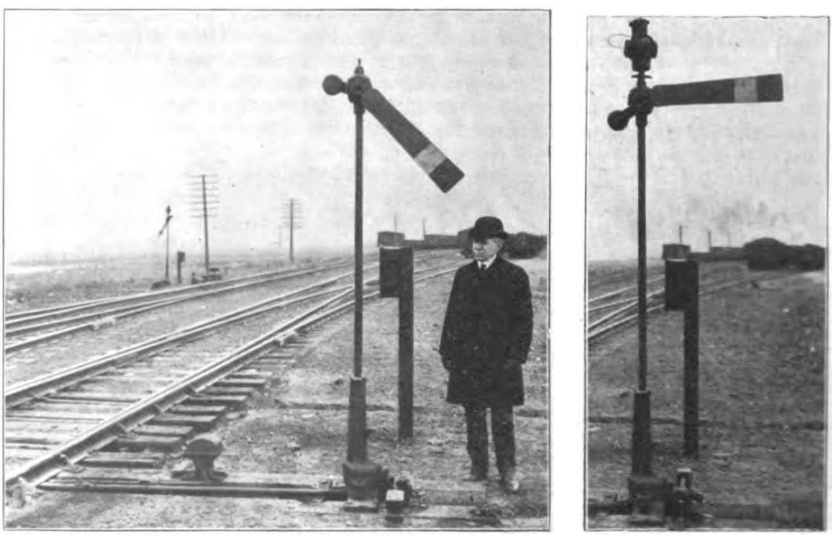

Fig. 546—Mansfield Semaphore Switch Stand, Chicago & Alton Ry.

As applied on this road, the stand was specially constructed throughout, but the design of the upper part, including the hollow mast, or tube, the gear mechanism and the semaphore, is such that it is adaptive to existing stands of the revolving type, of almost any pattern. When thus applied the top table of the stand is tapped out to receive the tubular mast supporting the semaphore, and the shaft operating the semaphore is jointed up with the shaft already in service. For a night signal the ordinary switch lamp is used on top of the revolving shaft, as seen in the picture at the right.

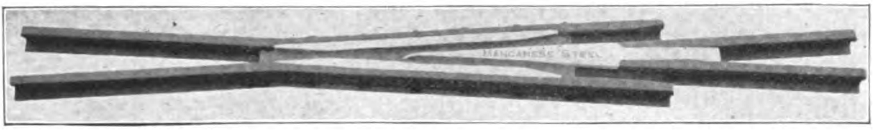

Fig. 547—Manganese Steel Frog Construction.

There is one difficulty with single-arm semaphore switch stands for single track, which does not arise with a signal of the revolving target type. In practice semaphore signals are supposed to govern the movement of trains only when approached in the direction from which the arm is seen at the right of the pole. As engineers are accustomed to regard semaphore signals only in this manner, it is clear that a single arm used on single track would govern trains running only in one direction. It is therefore the practice on some of the roads using this stand to equip it with a double arm. An extra arm is attached in place of the counterbalance shown, and in this way the stand governs trains running in both directions.

214. Manganese Steel Frogs.—An idea on improving the wearing qualities of frogs, which has been receiving considerable attention for some years, is the use of hardened steel for the parts which take the bearing of the wheels opposite the point piece and in the throat. One method of constructing frogs with such hardened parts is to bolt up pieces of rail in the ordinary manner of frog construction, with the wing rails bent around the hardened bearing pieces, all being bolted through and through, as in Fig. 91, Sec. 58. Another method is to cast the point and wearing parts of the wings in one solid piece, and then fit the legs of the frog to it. Such is the manner of constructing the Manganese steel frog (Fig. 547). The bearing parts on either side of the point and in the throat are one solid casting of manganese steel, which is made very hard. The wing parts of the casting afford a good width of bearing for the wheel tread. The bent wing rails of ordinary steel are then planed out to fit in with this part of the frog. The point rails are bolted on to either side of the heel casting in a manner to have the latter take part of the bearing. The wing rails are bolted on with reinforcing straps outside. These frogs have been in use on the Pennsylvania R. R. and some other roads in large numbers. One of them was laid in one of the main tracks of the Pennsylvania R. R., west of the Broad Street station, in Philadelphia, where the wear and tear from the very heavy traffic is so great that no frog of ordinary carbon steel was ever able to last longer than three months. At the end of 37 months this frog was still in use, and in fair condition, with prospects for a further service of many months.

215. The Oscillating Cattle Guard.—As animals are afraid of an insecure surface under their feet, the principle has been applied in the construction of a cattle guard that will swing so easily that stock will not obtain a sufficient foothold to encourage them to attempt to walk over it. The Oscillating cattle guard consists of a wooden slat device built 9 ft. long, with slats spaced ¾ in. apart and spiked to wooden bolsters, in three sections. The bolsters rest upon steel cross bars, being fastened by saddle clips to which the bolsters are bolted.

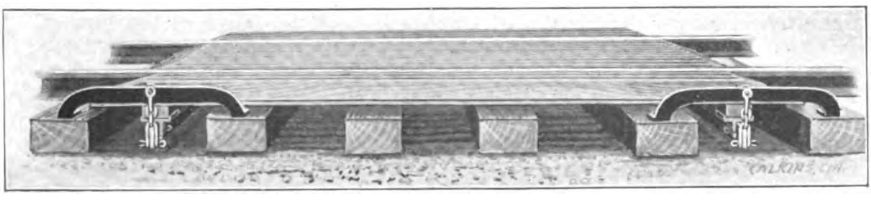

Fig. 548— The Oscillating Cattle Guard.

These saddle clips project down on either side of the cross bar in a manner to hold the bolster closely to the bar. Each cross bar hangs under, and 1 in. clear of, the track rail, in a space between ties, and is supported at each end by a chain hung upon an arched bracket resting upon, and bridging the interval between, two ties, as shown by Fig. 548. The bottoms of the slats clear the tops of the ties by an inch, and no part of the guard extends above top of rail, so that it cannot interfere in any way with the operation of snow plows. If desired, the two slats next the rails can be removed to permit unobstructed operation of snow flangers. The removal of the guard in whole or in part, as to make more room for tamping ties or for shimming the rails, is conveniently and quickly done, as it is only necessary to take out the cotter pins which secure the saddle clips holding sections of the guard to the cross bars.

216. Tie Plates.—The features of the Hart tie plate, shown at the right in Fig. 549, are described in Sec. 11. The Chicago tie plate, shown at the left in this illustration, has a side sloping top, with four rows of raised bosses to take the bearing of the rail, as shown in elevation by the upper engraving. The sloping top is intended to drain off water, brine, sand or grit. The Federal tie plate, shown as the central engraving of the illustration, has a top sloping from

Fig. 549—Various Tie Plates.

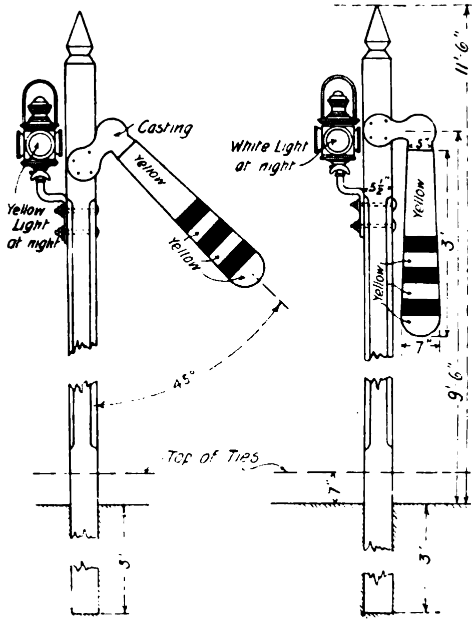
center, with raised boss bearings for the rail, but only one under flange to hold it to the tie. This flange is central with the plate, is thin and has parallel sides. This plate is made by rerolling the base and web of old rails.

217. Speed Regulation Signals for Curves, P. L. W.—On the Pittsburg, Ft. Wayne & Chicago and the Pittsburg, Cincinnati, Chicago & St. Louis (Panhandle) systems of the Pennsylvania Lines West a signal is used to regulate the speed of trains at sharp curves. It consists of a post standing 11½ ft. high above the ground and 7 ft. from the gage line of the rail, with a semaphore arm in a fixed position, as shown in Fig. 550. The semaphore arm is attached to a casting which is spiked to the post. The face of the arm is painted yellow, with black bars, the appearance suggesting the local name of "coon tail" signal. The back is painted white. At sharp curves, where it is considered necessary to reduce speed, the slow-up signal arm stands at an angle of 45 deg. with the post, which is placed 1000 ft. in advance of the point of curve. The signal for resuming speed is a semaphore arm hanging vertically, or parallel with the post, and the signal is placed at the end of the curve. The drawing shows a lamp attached to the post. It was originally intended to use lights on these posts at night—a white light with the signal permitting full speed, and a yellow light with the slow-up signal, but this plan was not put into practice at the start.

218. American Rail Loader.—The American rail loader is quite similar in construction to the Laas pneumatic machine, described in Sec. 146 and illustrated by Fig. 369. The principal difference is that the former is made to run on the top edges of the sides of a gondola car, and hence can be used on such cars when the ends are closed. The truck wheels are adjustably attached to their axles, and by this means their gage is readily changed to the requirements.

219. Hedge Snow Fence.—On some of its divisions the Intercolonial Ry. has pursued the plan of cultivating hedge snow fence wherever the trees will grow, and many examples of thriving trees on the line of the snow fences may be seen. Fir and spruce are set out on the track side of the fence, and by the time the fence decays the growth of trees will take the place of the lumber fence. Trees 10 to 12 years old attain a hight of 8 to 12 ft., growing bushy near the ground and standing close enough together to serve the purpose of a snow fence excellently. In order to maintain a bushy growth the trees are trimmed to a hight of 12 ft. and are not permitted to permanently exceed this hight. At many points on the Northern Pacific Ry., in North Dakota, rows of cottonwood and willow trees have been set out back of the board snow fences, and have thriven well.

220. Nickel Steel Rails.—Experimental use of nickel steel rails for six years seems to indicate that rails of such material will outwear three or four



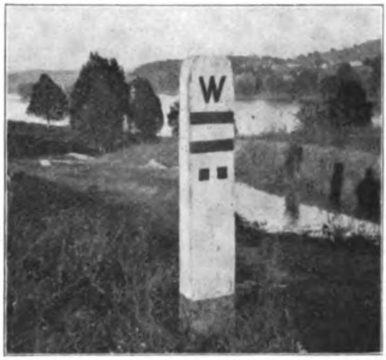


Fig. 550—Speed Regulation Signals for Curves, Pennsylvania Lines.

Fig. 551—Whistling Post, Southern Ry.

sets of carbon-steel rails. Nickel-steel rails laid in a freight track of the Pennsylvania R. R., at Kittanning, Pa., lasted three years, as against 10 months for rails of ordinary steel.

In addition to the roads mentioned in Sec. 197 the following others are experimenting with nickel-steel rails: Bessemer & Lake Erie R. R., the Union R. R., and the New York Central & Hudson River R. R. At the West Albany Hill on the road last named 204 tons of nickel steel rails were laid in 1903, in sections adjacent to, and opposite, sections of ordinary steel rails in the same track. The chemical composition, besides the iron, was found to be: carbon, .418 per cent; silicon, .102 per cent; manganese, .79 per cent; phosphorus, .094 per cent and nickel, 3.38 per cent. Some frogs made of the same steel are also under trial.

221. Coughlin-Sanford Switch Point Lock.—The Coughlin-Sanford swing-rail frog (Sec. 58, Fig. 95) is now worked in connection with a switch point lock. The target is on a separate stand from that which throws the switch and is worked by the lever of the switch point lock. The point lock consists of a plunger rod working through a slotted casting, with connections to the switch points so arranged that the plunger is blocked until the switch points have been thrown fully up to the stock rail. Should a lump of coal, an icicle or other obstruction fall behind the switch rail, or the switch point get out of adjustment, it is impossible to move the lock lever or give a clear signal. The lock lever is the one to which the switch padlock is applied, and when thrown to the locking position it lies directly over the ground lever of the duplex stand which throws the switch and frog. It is therefore impossible to open the switch without first moving the signal and lock lever, withdrawing the lock plunger and setting the signal in the danger position.
