them, principally because one not conversant with such books in their entire scope is liable to mistrust his ability to pick out those parts which he might comprehend. For the benefit of persons seeking familiarity with easement curves, some of the problems involved have been demonstrated, as in a text-book, one object in view being to show that the use of such curves, in all ordinary cases, is not so complicated with mathematics as some may have supposed.

A considerable volume of descriptive matter that is used largely in illustration of practice or of principles discussed has been arranged in the form of supplementary notes. While most of this matter is regarded as essential to a comprehensive treatment of the various subjects to which it relates, and therefore exceptional to the class of matter customarily reserved for use in an appended form, there were two reasons for the arrangement. In the first place, it serves the convenience of the general reader, who may wish to omit extended reference or numerous concrete applications; and, secondly, it gave opportunity to make use of a smaller size of type than seemed appropriate for the purpose of a general treatment, thereby effecting some economy in space. In this edition certain new devices and developments, brought out since the publication of the first edition, or within recent time, are considered in this supplementary chapter.

A constant aim has been to follow practice up to date, and give reference to all new improvements which seemed likely to assume future importance. One particular object in view has been to cover as widely as possible the development of labor-saving machinery. In this line there has been much improvement within the past few years, and this phase of the subject is destined to be one of increasing interest.

I shall appreciate the kindness of any reader who will notify me of typographical or other imperfections discovered, or who will give me the benefit of his criticism upon any statement or matter of opinion in which he may find interest, or send me data or records of work to compare with similar data herein contained. Having treated of many questions on which there are conflicting opinions among expert trackmen and engineers, I could not resist the temptation to now and then venture my own opinion on such matters. I am very sure, therefore, that certain opinions herein expressed are contrary to the views of some maintenance-of-way men. To a very large extent, however, I have accorded questions of this character full discussion, presenting the views of both sides, believing that those interested in a work of this kind would appreciate the enumeration of established opinions fully as well as, and perhaps better than, the conclusions which any one person may have drawn from the same. It is needless to here dwell upon the advantages of discussion, for much benefit is sometimes derived in the way of suggestion, even though the result may fall short of definite conclusions. In this light it is sometimes profitable to launch an opinion, notwithstanding that opposition to the same can readily be anticipated. A writer on track who would confine his remarks to matters of settled opinion would necessarily have to omit many interesting features of practice.

NOTES ON TRACK.

CHAPTER I.

TRACK FOUNDATION.

1. **Introduction.**—The proper construction of railroad track and the efficient and economical maintenance of the same involve the science of engineering. There are so many definitions of the term "engineering" that a new one will not be attempted here, for almost any of them apply. One which fits the case very well may be comprehended by saying that to properly construct or maintain track is to know how to "make a dollar go the farthest." Of the three recognized stages having to do with track in service, either construction or maintenance is a field of engineering of no less importance than that of track location. Considering the specializing tendency of the times, which has created such professions as bridge engineering, hydraulic engineering, sanitary engineering, and other departments included within the scope of civil engineering, why should there not be recognized a distinct class of work known as "track engineering?" Track and roadbed represent a much larger investment than do bridges, waterworks, or sewers, or more than all combined, and the problems which have to be studied and solved in relation to track are about as difficult as one will find in any line of engineering work.

Track engineering begins with the reconnoissance or preliminary surveying and must be followed through the location and the construction of the roadbed, the building of the track proper, and continue with the maintenance and repairs ever afterward; for in no sense can it be excluded during the progress of any of these steps. In locating the line for a railroad track, it may often happen that a choice may be had between soils or substrata of different kinds, without sacrificing anything in matters pertaining to right of way, grades or curvature; or the local conditions peculiar to one side of a valley may differ so widely from those of the opposite side, in such respects, for instance, as exposure to wind and drifting snow, slides, falling rocks, surface drainage, springs of water, stream encroachments on the roadbed, the shading of the right of way by steep hills or by forest, as to materially affect the cost of maintenance. Although the relation of such matters to the work and expense of track maintenace is apparent yet it has not always been considered during that part of the work so often regarded as preliminary in a too strict sense. If things are allowed to shift too much for themselves during construction it will usually be found that methods of work will be permitted which will result in inferior service. In these days when so much of industry is dependent upon the activities of corporations, and when labor is becoming more and more divided, men in general will take less and less interest in that which they engage to do, except in what may appear to promise them more or less direct returns in higher compensation or in reputation. Obviously, then, there will be a larger demand for men whose occupation it shall be to maintain a close watch on details, with a view to turn aside all the undirected and misdirected tendencies which might lead to extravagance, inefficiency, or whatever in the end might operate depressingly upon dividends, which constitute the ultimate aim of the projectors of railroads.

Now, it does not matter by what name we choose to call this occupation—whether it be intelligent foremanship, good railroading or engineering—there is room for it; but if any system of work or management which can be applied to track supervision in a manner to make track more durable, safer, or less expensive to maintain, be not engineering, then I know of no appropriate term to apply to it. In almost all industrial lines, particularly those identified with mechanical or electrical engineering, it is the chief consideration of the science that questions of economy in maintenance or running expenses shall not only share equally with the attention usually given by the engineer to construction in general, but that they must be entertained by him particularly and studiously in coexistence with his plans of construction. Already a great deal more study is being devoted to track engineering than was the case when 60-ton locomotives and 20-ton freight cars were typical of rolling stock, and the tendencies indicate a still larger application of engineering principles to this line of work.

It is not difficult to explain the situation in the past. Track is so extended over distance, when compared with other works or structures; the roadbed, the ballast and the materials of which the track is constructed are subject to such inequalities and irregularities; the track structure is so simple and deteriorates by such insensible degrees; and the wide-spread but mistaken idea that "main strength and awkwardness" are as efficient in its service as intelligence and skill, has so prevailed, that, in the very nature of things, the officials not directly responsible for the condition of the track were slow to grasp the idea that track should be studied as thoroughly as other engineering structures. The simplicity of the track structure is the deceptive element in questions relating to maintenance economy, for ideas concerning the stability of track are too frequently confined merely to the question of approved qualities of rails, ties and ballast. The fact that the track structure lies upon the surface, exposed to the extreme action of the natural elements, is a very important consideration in track engineering.

One of the most expedient resources available for moving people out of a rut is to make them feel the disadvantages of their position from a financial point of view. Opportunities for applying this principle to railroad track are easy to find. For the sake of illustration, let us for a moment contrast the track with some other engineering structure in use on railroads—say an iron or steel bridge. Now the average bridge is considered a costly structure, and much care is taken with every detail which goes into its make-up. The foundation upon which it rests is usually built to stand; all materials going into it are of the most substantial quality; all the pieces going into the superstructure are not only carefully made and inspected but are carefully handled when being put together; connections or joints between pieces are made stronger than the pieces themselves; every piece in the whole system is carefully adjusted to its place, so as to bear its proper stress, and that before any load is allowed to come upon the bridge. The structure is supposed to be kept well painted; it is watched and inspected frequently; and should there be found deflections much exceeding those calculated upon, or any behavior tending to show the least weakness, the whole thing is counted a failure. Such is engineering, and such is what makes weak railroad bridges scarce and bridge accidents of seldom occurrence. All the care exercised costs, but everybody knows that it is money saved and that it is good economy. As for the track, who does not know that ten miles of average track costs more than the average bridge of several hundred feet length, foundation and all? Yet who does not know that when put together the work has too frequently been done with a rush and that reckless work due to this cause has been too frequently overlooked? In how many instances has one not seen the work improperly finished, as, for instance, when ditching and such necessary work was left to be completed at a time when its cost must necessarily amount to much more than what it would have been in the first place? How many have been the cases where costly materials are worn out or rendered useless through lack of attention, or through ignorant supervision, long before they should be? Now all this costs money and it is known to be false economy, yet it has not been so generally conceded as have like mistakes in some other lines of engineering. What then is needed? I maintain that the same strict and intelligent engineering is needed that is usually applied to some other railway affairs.

It is supposed by not a few trackmen that the term "engineering" relates to matters in which they are not concerned; while on the other hand, to some railroad surveyor or draftsman the employment of the word in connection with trackmen's work is to disparage his occupation and its relative importance to the occupation of a trackman. Where such is the presumption both parties have a mistaken conception of the word engineering. I consider that there are many roadmasters and section foremen who have more to do with track engineering than some men commonly known as civil engineers, yet whose experience has been nothing more than surveying or drafting, no matter how extended their experience within such limits may have been. Really, surveying and mathematical calculations cut but a small figure in track maintenance. It is true that in some respects track location can be fairly well learned from books, drawings and office work, but how to build and maintain track to best meet diverse conditions cannot be learned between covers or in an office. The experience necessary to teach such knowledge must be had by actual contact with the work. According to some men's ideas track engineering is largely a matter of surveying and the ability to select good materials, but in the following pages it is attempted to show that it also requires intelligent manipulation and an adjustment of parts involving no mean order of skilled labor.

There can be no question but that some prestige is lost to the engineering profession from the fact that so many men who have a general knowledge of engineering principles attempt to make their applications too specific, without having acquired that view of things which comes only by patient and earnest devotion to the particular line of duty, with some responsibility therein; and so it is with track engineering. There are men who have never so much as sweat a drop in any kind of service calculated to impart a knowledge of track work, or lost a moment's sleep caring for the safety of track, who, nevertheless, are ever eager to propose what they think to be some track improvement; and as a rule their ideas on improvements amount to about as much as their services have. And so, many practical railway men who, in reality, do most of the thinking and perform most of the work that is worthy to be called engineering, hold in a sort of contempt the very term which best describes the results of their own efforts. Between these two classes there has existed to no small extent an attitude which has tended to discourage practical men in what they ought to seek after more than they do; and as a partial result of this there is, at least, a misconception of terms.

Almost everywhere one hears it said: "Theory is not practice," "Theory will not work in practice," etc. The term theory is too often used with that looseness of expression synonymous with inference, guesswork, speculation, etc.; whereas in its proper sense it applies only to those ideas which have not been known to fail under any reasonable test, and for which there are, therefore, good grounds for putting them to further test wherever they can reasonably be applied. Again, what would be theory in a sense pure and simple might not be theory as applicable to every case where one might wish to make it hold; example: One may find tables giving the outside rail on curves as much as 14 ins. elevation, for a certain degree of curve and a certain speed not uncommonly made. Now, as for some specially built vehicle running upon some specially built track, this application may be theory; but it is not theory which has to do with the conditions which obtain in railroading; when applied to such it is not theory but nonsense, because no account is taken of circumstances which might be known. Some man's ideas about the application of some mathematical formula or scientific principle does not necessarily constitute a theory.

The fact of the matter is that all competent men, commonly called "practical" men, use more theory than they may think they do; it guides them in much or all of their work, although they may never have thought to express it in so many words, perhaps. What men need to have in order to accomplish the highest results in any line of work is a clear understanding of the principles they are using. And then, too, unless men understand such principles, or the theory of their own work, they are unable to apply themselves to such changing conditions as may arise in any business experience of a few years. Practice without some knowledge of the principles involved is like working blindfolded, while, on the other hand, a knowledge of principles without some practical ideas of applying them is useless. And then, in order to get a proper conception of the principles underlying a case it is essential that right premises be taken. Theory cannot be formed upon faulty observation, neither is it derived by defective reasoning, nor does it necessarily follow from hit or miss speculations. Correct theory (meaning theory correctly applied) and good practice are always in strict accord; and where they apparently are not, an investigation will always lead to some interesting disclosure; generally showing that there was either a misconception of principles or an attempt to make a wrong application of them. Or, in every case where an idea is said to work well in practice it is needless to say that it conforms to principle; and if seemingly not, then the legitimate principles involved are not well understood. The only essential difference between correct theory and good practice, in one way of expressing it, is that practice so called, must employ a knowledge of details, while theory, in distinction therefrom, may stand entirely upon a knowledge of principles—which, of course, must be learned from details, although not necessarily from the details of the thing or practice to which the application is made. Hence it is that a knowledge of principles, as applying to some particular practice, sometimes precedes a knowledge of its details and sometimes vice versa. Good practice is theory rightly applied; or theory may be called the explanation of, or the reason for, the practice. They both represent truth, when rightly comprehended; and how to comprehend the two in their right relations and to carry them out in application is engineering.

2. Meaning of Terms.—A railroad is made up essentially of three parts: the foundation, the ballast and the track. The foundation is the earth support, the upper surface of which is usually brought to an established line known as sub-grade. In the case of an embankment or a fill the foundation is the earthwork; in a cut it is the lower limit of the earthwork. Ballast may be considered to be some kind of material placed upon the foundation to put track in surface and afford drainage, and perhaps also to hold the track in alignment. In the case of dirt or "mud" ballast the foundation might be considered as extending to the track, the ballast being in that case only that portion of the material which lies between the ties; and the drainage, so far as accomplished, taking place on the surface. The track is the rails, with their fastenings, and the ties. While, as regards only the path of the wheels, the rails alone might be considered as constituting the track, the fact that the tie serves as a means of holding the rails to proper gage, as well as serving for a support, and that the whole is a separate, distinct structure, would make it seem that the tie ought to be considered an integral part of the track. For purposes of general description it is also more convenient not to subdivide the portions of the road further.

As names for these parts several terms have grown out of practice, some of which do not express the real meaning, and as a result there is more or less interchange in their application, and, consequent confusion. For instance, the term "grade" is in common usage among contractors and track-layers to denote the upper surface of the foundation, when, as all know, the same term is the universally accepted expression for rate of ascent or descent with respect to level. The term "roadbed" is sometimes used to denote the foundation, sometimes the ballast, and sometimes the surface of contact of the ballast with the ties; that is, in the last case it is used in the same sense as when the bottom of a river is spoken of as its "bed." The term "track" is sometimes used to denote both the superstructure and the ballast. In imitation of the English, some members of the engineering profession choose to call the combined track, ballast and foundation "the permanent way," which, by the way, is something of a misnomer. There is nothing about American railroad track that is particularly permanent, except, perhaps, the line establishing the location; but to maintain the track to this requires constant or continued labor; while the materials in track and ballast (and foundation, too, sometimes) require, in course of time, more or less frequently, either changing or replenishing. Even stone arch bridges, on some of our roads, have failed after less than fifty years of service.

In the present connection it is instructive to enquire into the significance of the term "permanent way" as it is used in England. In that country the application of the term arises from the manner in which track is constructed. After the roadbed is completed a stretch of "temporary" track is laid with old materials, and after the ballast is hauled in this track is lifted approximately to the final grade and ballasted. The ballast is then leveled to the bottoms of the ties, the new rails and ties are strung out along each side of the track, the temporary track torn up, the ballast dressed off to a smooth surface, the new or "permanent" track is laid and thoroughly tamped and the ballast filled in and dressed off to standard section. Thus the road is extended by first laying temporary track, a section at a time, and repeating the process just described, using the old materials over and over. By such practice the lifting of new track through any considerable hight is avoided and trains are not permitted to run upon the same until it is put into final condition. The term "permanent way" is thus used in a comparative sense, to distinguish the road, as completed for traffic, from the temporary track laid down for the purpose of forwarding materials and placing the ballast. As applied to American roads, however, the term loses its English significance, for we do not build track in the manner described. As the term is also without application in a literal sense it is both un-American and in bad taste to speak of American railroad track as "permanent way."

In view of possible misunderstanding, some of the terms used in this book are here defined as follows: Track foundation is called the roadbed, and its upper surface, sub-grade. The material between the ties, and between the ties and the sub-grade line constitutes the ballast. The rails and ties, when united, are called track. The combination of these three parts, the roadbed, the ballast and the track, is known as a railroad or railway; or, simply, the road. The term "rail," or "the rail," is sometimes used to denote a piece of rail of standard length, say 30 ft., and sometimes to denote all such pieces on one side of the track taken collectively, the same as though the rails were jointless. The term "steel" and "the steel" have the same significance. A "piece of rail" refers to a piece shorter than standard length, or shorter than 30 ft. Maintenance of way is commonly understood to mean or include the maintenance of all the fixed property of a railroad, as track, bridges, buildings, signals and water supply. Where nothing is said to the contrary, the gage of all track herein considered is understood to be standard, or 4 ft. 8½ ins. The word "ton" without qualification means the American ton of 2000 lbs. Wherever locomotive weights are referred to the weight of the tender is not included. The term "ends of the ties" is commonly used to refer to that part of the ties which extends outside the rails.

3. The Roadbed.—It is not the purpose to deal here with those problems of locating the roadbed which belong properly to surveying, treatment of which can be found in the many books on field engineering. Neither can there be included the discussion of a subject of such scope as the more intricate engineering problem known as the economic theory of roadbed location, where the topography of the country gives rise to such questions as compensation between distance, grades and curvature. The object is to take up only those features of the roadbed which may in some way affect the condition of the track built upon it, either during the construction of the track or after it is put to its use.

Unlike almost all other foundations prepared to sustain a great weight, the roadbed of railroad track is largely of an unstable nature. Instead of seeking for a solid substratum, as is done when laying the walls of a building or when constructing a pier or abutment for a bridge, it is found expedient to take the surface of the ground pretty much as it is and, in excavation, go only so far as a predetermined grade line has been established, without reference to the nature or depth of the yielding soil; while, when this same established grade line lies above the ground there is added to the top surface such material of the same yielding nature as lies most conveniently for movement. Such, at its best, is the roadbed. This, with a comparatively thin layer of ballast material of such quality as the available expenditure will admit of (and, often, no better than common soil itself), must not only bear up a ponderous load, but bear it intermittently, and under conditions which increase the effects to a degree not possible with the same burden imposed as a stationary object. How, then, to construct, with such material, a formation extending over long distances, in a manner to endure not only the weight above but also the natural forces expending themselves around it, is the work of building a roadbed.

Roadbed Cross Sections.—Almost every railway has a standard cross section for roadbed, at least on paper, and among different roads these so-called "standards" vary considerably in form and in dimensions. So far as fills are concerned the width of the roadbed at sub-grade should afford at least a sufficient base for the ballast. Taking the depth of the ballast not to exceed 8 ins. below the bottoms of the ties, and allowing for a narrow shoulder of ballast against the ends of the ties, the ballast will overspread a strip of roadway about 14 ft. wide. The least permissible width for single-track roadbed at sub-grade is then about 14 ft., after shrinkage; and since the top width of an embankment should increase with hight it might be well to settle upon 16 ft., after shrinkage, as the least permissible width of roadbed at sub-grade on embankments exceeding, say, 10 ft. in hight. A width of 14 ft. allows for no shoulder on the roadbed outside the ballast; and although good track can be maintained upon roadbed without such shoulders, the conditions are by no means ideal, and the highest efficiency of support cannot be looked for on these dimensions. As for economy of maintenance, however, that is a matter having to do with the amount of surface repairs, which, of course, depend mostly upon the volume of the traffic. The situation with many railroads in this country is such that it would hardly be found economical to adopt such dimensions for roadbed as might, from the standpoint of efficiency alone, measure closely up to the ideal. For roads having but few trains daily it is a question whether the minimum widths of roadbed here given may be exceeded with any economy. On roads carrying heavy traffic 18 ft. is usually considered the least advisable width of roadbed for fills, and a maintained width of 20 ft. is sometimes found to be standard. On the Southern Ry. the standard permanent width of single-track roadbed on embankments, at sub-grade, is 14 ft.; on the Great Northern Ry. it is 14 ft. on tangents and 16 ft. on curves; on the Southern Pacific (existing high embankments) and Atchison, Topeka & Santa Fe (branch lines) roads, it is 15 ft.; on the Atchison, Topeka & Santa Fe (main line), Baltimore & Ohio, New York Central & Hudson River, Northern Pacific, Southern Pacific (for construction of new lines) and Louisville & Nashville roads it is 16 ft.; on the Chicago, Burlington & Quincy Ry. it is 17 ft.; on the Burlington, Cedar Rapids & Northern and Cincinnati, New Orleans & Texas Pacific roads it is 18 ft.; on the Philadelphia & Reading Ry. it is 18½ ft.; on the Pennsylvania R. R. it is 19 ft. 2 ins.; on the Illinois Central and Union Pacific roads it is 20 ft.; while on some cheaply built roads it is only 12 ft. The width of roadbed for double track exceeds the width for single track by the distance between track centers. Since in excavations the roadbed must be made wide enough to afford room for proper drainage parallel with the track, the width of roadbed in cuts is considered in connection with the subject of ditches.

The advantage of increasing the width of roadbed with depth of fill is that after the embankment has settled it can be built up to grade again by dumping material on top without having to replenish the slopes in order to get the necessary width of base. This principle of construction is adhered to on a number of roads. On the Chicago, Milwaukee & St. Paul Ry. the standard maintained width of roadbed, at sub-grade, on embankments is 18 ft., but on branch lines, a narrower roadbed has sometimes been constructed. In construction of new lines, however, it is the practice of this company to increase the width of roadbed at sub-grade 2 ft. for each 10 ft. in hight of the embankment. On the Michigan Central R. R. the roadbed is made 1 ft. wider for each 5 ft. increase in hight of embankment. The standard width of embankments on the Kansas City, Pittsburg & Gulf R. R. is 16 ft. for fills up to 15 ft. in hight and 18 ft. for embankments higher than 15 ft.

It is poor economy to make a fill so narrow that it must be widened while the work of ballasting is in progress, in order to keep the ends of the ties from overhanging the ballast, which has slidden down the bank. It is poor economy for two reasons: first, ballast, be it gravel or other material, is rather too expensive to use for widening embankments, if it must be hauled some distance; and secondly, gravel deposited upon a hard slope will slide off. The slope of an embankment cannot therefore be maintained in a manner to sustain the weight above, by depositing loose gravel upon a firmer substratum, without using a quantity of it which is entirely out of proportion to the quantity of filling required. Trackmen can recall the familiar spectacle of having seen half the ballast, which had been hauled for the purpose of ballasting and surfacing the track, lying either at the foot of the embankment slope or along its sides, to be crowded farther down by every workman stepping out of the way of a passing train, thus weakening the support which the ends of the ties ought to have. Insufficient support for the retention of the ballast is the most frequent cause of center-bound track. The first cost of extra material required to make the fill of proper width at sub-grade, which such materials as will lie stably along the slope, is small in comparison with the cost of afterwards wasting a large amount of more costly material which is not so well suited for the purpose of an embankment.

The roadbed should be brought to full width and completed before track-laying begins. Cuts and fills are often left to be widened after the track is laid, but it is nearly always one of those mistakes which cost. Engineers usually aim to have the cuttings make the fills, without hauling farther than can be done to advantage with teams. But in rare instances, where fills cannot be finished out from borrow pits, and material must be hauled a long distance, it is advisable sometimes to leave the widening of a cut, now and then, to be done with the work train rather than to waste it at the first. In such cases, however, it should be done as soon as a work train can be put on after the track is laid. Where some exceptional case of this kind is calculated upon and the practice does not become general for the whole line, there may be found a saving; but in the main, where the road is rushed through with earthwork only partly completed there usually follows much waste of ballast, which is lost by sliding off the narrow shoulder, and the track is flooded in cuts for want of proper ditches. In attempting to widen an old embankment having hard slopes, stones and lumps dumped from the top will roll to the bottom and out of the fill; and, when lying upon a harder surface, the quantity of material of any kind which must be used is disproportionate to the quantity which would be needed, during construction, just as in the case with gravel, above explained, because the weight from above will push the bottom of the slope out and the earth will not then stand at the same slope as when the fill is made with loose material all at one time. Work trains being always more or less hindered in their work by regular trains, it is well to do all that can be done on the roadbed before the track is laid, for it is nearly always the cheapest, the most economical, and by far the best plan. Where an embankment is deficient in width it is hardly worth while to raise the track to grade in ballasting, because track boosted upon a narrow heap of material obtained by robbing the side slopes will quickly settle, from want of lateral support to retain the ballast. It is just as well, and indeed better, in such cases, to permit the track to remain at such hight as is consistent with the width of the supporting base, even though there may be local depressions below the established grade line. In widening out an embankment on which ballast has already been deposited, the material added to extend the shoulders, unless it be the same material as the ballast itself, should never be built up higher than the bottom of the ballast, as to do so will obstruct the drainage.

For drainage purposes the roadbed ought to be somewhat higher in the middle than at the sides. Unless such is the case the water which settles through the ballast will find its way into the roadbed, soften the material and cause it to settle under the pressure of the traffic and heave during freezing weather. On standard cross sections it is customary to show the roadbed crowned 3 to 6 ins. in the middle, but the scheme is seldom carried into practice. Such negligence is one of the worst mistakes that is made in railroad construction. In cuttings it is an easy matter to crown the roadbed at the center, without extra expense, and on the natural earth the material is usually firm enough to preserve the sloped surfaces permanently. On embankments filled from trestles and in filling up ravines by dumping over the slopes it is impracticable to do this, but in filling an embankment by working from the bottom with teams the material can be so placed that the top of the roadbed will shed water fairly well. The standard roadbed of the Missouri, Kansas & Texas Ry., which is 16 ft. wide on embankments and 18 ft. wide in cuts, is flat for a distance of 4 ft. each side of the center line—that is, over a width corresponding to the length of the ties—but from a line directly under the ends of the ties there is a slope of 6 to 1 out over the shoulder. On curves the surface of the roadbed may be made flat and inclined to the same slant as that to which the track is to be elevated. This arrangement allows of an equal depth of ballast under both sides of the track and, therefore, an equal settlement for both sides, because all kinds of ballast in new track will settle some. It also effects an economy in the use of ballast. Roadbed which is not made to slope in this manner on curves should be widened on the outer side of the curve to provide the extra width of shoulder required for the higher and longer slope of the ballast on that side. Such extra width is especially needed where the roadbed is narrow or of minimum allowable width.

Grading.—The manner in which a fill is made has much to do with the efficiency with which it will support the track. The most solidly compacted work is had when horses are driven continually over the fill during the progress of its construction, as when hauling in carts, wagons or scrapers. Earthwork constructed by such means will usually settle but very little afterward. Shrinkage is greatest on embankments formed by dumpings from wheelbarrows, by machine graders or by casting the material by hand from side ditches. The method of depositing the material in roadbed construction, affecting so largely as it does the question of shrinkage, is a matter of no small importance; for when a fill settles, the track must be put again to surface with ballast. By providing against future settlement as far as possible there is curtailed an item of considerable expense. In the present connection, therefore, it may not be amiss to consider briefly some of the methods and means employed in roadbed construction.

Wheelbarrows and plank runways are used where the material to be moved must be taken across a ravine, or across a track, as at a side-hill cut in filling for a second track; or in moving material from borrow pits across ground that is too rough for team work; or in short hauls where the material is broken rock or is too largely intermixed with large stones or boulders, or where the ground is too thickly set with stumps to be easily taken up with plow and scrapers. Speaking generally of team work, drag scrapers or slips are considered the best vehicles for hauls up to about 90 ft.; wheel scrapers for hauls between 90 and 300 ft. in length; and dump carts or dump wagons where the material is to be moved more than 300 ft. The capacity of drag scrapers is 4½ to 5½ cu. ft., and on a short haul, like 25 or 30 ft., a team will move in one day about 70 cu. yds. of earth or other material that can be loosened up with a plow and readily picked up by the scraper. On a haul of 90 ft., a team and drag scraper will move about 50 cu. yds. in a day, and on a haul of 125 ft. about 40 cu. yds. The capacity of wheel scrapers is 9 to 12 cu. ft., where an extra team is not required for filling, and 12 to 16 cu. ft. where an extra or "snatch" team is generally used in filling. In ordinary material and under ordinary conditions a team and wheel scraper will move 50 to 55 cu. yds. of earth per day, on a haul of 90 ft.; about 40 cu. yds. on a haul of 300 ft., and about 30 cu. yds. on a haul of 450 to 500 ft. On the longer hauls, it pays, of course, to use the large-size scrapers. The capacity of a two-wheel cart hauled by one horse is ¼ to ⅓ cu. yd., according to the character of the roadway, and this vehicle is economical on hauls up to 1500 or 1800 ft. The capacity of four-wheel wagons hauled by two horses is generally about 1 cu. yd. and these are generally economical on hauls up to about 3500 ft. Where a large quantity of material is moved into one embankment a temporary track and dump cars is a very common arrangement. Over moderate distances the dump cars can be hauled to advantage with horses, but for distances exceeding 2000 ft. a small locomotive is generally more speedy and economical. Where the fill is to be made from a temporary trestle the use of dump cars is necessary. They are also generally used where the excavation is made with a steam shovel, although teams and wagons are occasionally employed in hauling from a steam shovel.

In districts where the ground can be plowed and the surface is not badly broken up grading machines are much used in railroad earthwork. The New Era grader consists of a strong vehicular frame mounted upon low wheels with wide tires. Suspended from the frame and connected to the front axle is a plow, with hand wheel and chains for regulating the depth of furrow. Running from the moldboard of the plow there is a side belt conveyor which moves at right angles with the course of the machine. The hight of delivery from this conveyor is regulated by hand wheel and chains, and the conveyor may be extended in sections to deliver the material as far as 22 ft. from the plow. The machine is drawn by eight or twelve horses hitched four abreast, or by a traction engine. On prairies, or on comparatively even ground, embankments 4 ft. high and full width for single track may be built up from the sides by deposits direct from the machine, or the machine may deliver into wagons driven alongside, as in making fills from cuts or wherever it is desired to deposit the material beyond the reach of the conveyor. A driver and two attendants are required for the operation of the machine and it is said that under favorable conditions 1000 to 1500 cu. yds. of earth can be handled in 10 hours. The handling of filling material with trains is treated at length in Chapter X, §148.

The amount of shrinkage or settlement of embankments, in hight, after completion depends upon the character of the material, the method of placing it and the weather conditions during construction. Embankments made of rock either loosely thrown down or deposited in any other way consolidate rapidly and do not shrink appreciably after completion. Among earth materials sand and gravel shrink least of all, and next in order come clay, loam and loose vegetable mould or surface soil, the last named shrinking or settling the most. As for methods of handling, the results are about in the following order: Embankments built with (1) drag scrapers are tramped most thoroughly by the teams and settle the least; and next in order come (2) wheel scrapers and carts; (3) wagons, when the material is deposited in horizontal layers; (4) cars unloaded from trestles; (5) carts, wagons or cars dumped over the side or end of the embankment; and (6) wheelbarrows and hand casting with shovels. The condition of the material when it is put into the embankment may depend largely upon the weather conditions, and this is another factor of the shrinkage. An embankment put up during wet weather will stand better than one of the same material made in the same way during dry weather; in fact many embankments constructed during very wet weather settle but little after completion. Frozen material deposited in any manner will always settle a great deal when it thaws out. Embankments made of any dry material except rock, by any of the methods, will not shrink to their final volume until after they have been pretty thoroughly soaked with rain water.

Practically all of the shrinkage in earthwork takes place vertically, and in railroad construction it is customary to build the embankments high enough above the permanent grade line to allow for settlement. In consideration of the several varying factors as above explained, it is readily seen that the amount of shrinkage to allow in any particular case must be determined largely in the judgment of the engineer acquainted with the conditions. This explains why different persons of limited experience who have sought to reduce such problems to set rule have produced widely varying or conflicting figures. All rules on shrinkage of earthwork must be construed liberally and in light of the attending conditions. With this understanding the following allowances may be considered approximate guides in general cases under normal conditions: for sand and gravel embankments put up with drag scrapers, 1 to 3 per cent; for clay and loam handled in the same way, 3 to 5 per cent; for wheel scraper, cart and wagon work in horizontal layers, 2 to 7 per cent, according to the character of the material; for material dumped from cars on trestles, 6 to 8 per cent; for embankments extended by dumping over the end, from grade, out of carts, wagons or cars, 6 to 10 per cent., according to the character of the material; for wheelbarrow work or hand casting, 12 to 25 per cent. Embankments made with grading machines are at first fluffy and covered with lumps, but it is customary to follow up such work with a harrow and a road roller, to even up and compact the surface. There is some disagreement as to whether or not the percentage of settlement with high embankments is greater than with low ones, after completion, and data have been produced to prove either view. It is quite probable that here again the method of construction, and also the time factor, may have much to do with the question. For instance, the comparison of high and low embankments built up by team work in horizontal layers might not be the same as with embankments of corresponding hights built with material dumped over the end, from grade. In the one case the material throughout the embankment becomes quite solidly compacted as the earthwork rises, while in the other the compression of the material in the bottom of the bank depends entirely upon the weight of material above, which, of course, is greater the greater the hight of the embankment. It seems reasonable to suppose that, ultimately, the percentage of settlement must increase with hight of embankment, but it might not occur in every case that the disproportion would be discoverable after the completion of the work. The time consumed in constructing the higher of two embankments might also be so long that much of the material would find its bearing in considerable measure before the completion of the work. Another matter to consider in this connection is the character of the bottom on which the embankment is built. On a yielding bottom the settlement of the natural surface under the weight of the embankment may be very considerable or even exceed the shrinkage of the material of which the embankment is composed. Such effects, of course, increase with hight of embankment.

The allowance for shrinkage of embankments has frequently been a source of trouble between contractors and the parties for whom the work was done, but if the plan is followed of paying for earthwork in the excavation the shrinkage is not then a matter of live concern with the contractor. In relocating parts of the line on its Wyoming division the Union Pacific R. R. built a number of very high embankments, and on these allowance was made for shrinkage without carrying the earthwork above the established sub-grade. The plan followed in this case was to estimate the probable shrinkage or settlement and then make the top width, at sub-grade, equivalent to what the width of the embankment would be at this level if the earthwork was built up sufficiently high to allow for the estimated shrinkage and made standard width at that level. This provided an embankment which would be wide enough after settlement to hold the filling material required to raise it again to the established sub-grade. The extra width of the top of the embankment, as constructed, was provided for by making the slopes steeper than the standard inclination, which was 1½ to 1. This scheme in no case increased the slope beyond 1.4 to 1, and as these slopes flattened as the embankments settled there was no trouble in maintaining them. The idea in this plan of work was to avoid the possibility of getting the embankments permanently too high by overestimating the shrinkage, and also to avoid widening the base of embankments to provide for shrinkage, which, from the fact that shrinkage is vertical in every case, is not necessary.

Embankments built up in layers extending the full width of the cross section shed water much better than those made by dumping over the end or side; and if these layers are crowned at the middle the embankment will drain out better than it will if the layers are horizontal or dishing. It is well, in any method of building an embankment, to keep the middle of the filling all the while somewhat higher than the sides, so that any tendency to the formation of layers will result in lines or courses which slope toward the exterior. This matter may be placed in charge of the man who trims out the fill and, by a little attention, is easily looked after at no additional expense. It helps toward the regularity of the layers to roughly level down the peaks of heaps of material dumped, although no considerable amount of time need be spent at it. The filling in rear of abutments and retaining walls should be deposited in layers generally not to exceed 1 ft. thick, well compacted and inclined away from the masonry.

Particular care should be exercised to avoid the formation of hard, steep slopes or cleavage planes within an embankment. Such faulty construction is most likely to occur where different kinds of materials, or materials from different sources, are used for filling at various stages of the work. A brief account of an interesting experience in this line on the Minneapolis & St. Louis R. R. will serve to illustrate the practical workings of a case in point. The facts were kindly supplied me by Mr. H. G. Kelly, chief engineer of the road. An embankment about 1000 ft. long and 25 ft. high, constructed less than four years, began to give trouble by sliding, and in attempting to remedy the matter by dumping more material upon the slidden portions of the embankment something like

$10,000 was expended without accomplishing the purpose sought. Investigation disclosed that the embankment had been formed of light clayey loam hauled from cuttings and deposited upon a substratum of heavy blue clay scraped up from borrow pits. The seat of all the trouble was found by excavating into the bank, when it was discovered that a well defined plane of cleavage existed between the two materials, coinciding with the inclined runway of the scrapers used during construction. The sliding of the embankment had taken place upon this inclined plane. The trouble was permanently cured by heroic treatment, at a total cost of $1200, in the following manner: During dry weather longitudinal trenches were excavated on the side slopes, near the foot of the embankment, on either side, and between these two trenches cross trenches 2 ft. wide and 10 ft. apart were cut through the embankment and carried down below the so-called plane of cleavage. Meanwhile the track found support upon an improvised trestle formed by placing long stringers upon two-pile bents which had been driven when the sliding became serious, prior to the excavation work, resort to this means of support being taken to carry the trains. The trenches were then filled with pile heads and old ties and covered over with the clay excavated from them. This mass was then fired, more clay being added as the burning material in the trenches settled down. The embankment smoldered away like a charcoal pit for six weeks and the bank was burned into a solid mass of brick, never to slide again. Following the result of this experiment the same method of treatment has been applied to other embankments on this road containing clay, with uniformly successful results. Where filling is to be done on a steep, hard slope, as on side hill, it is well to break up the cleavage plane by cutting lines of steps in the slope, to bind the new material. In most cases this may be done sufficiently well by plowing deep furrows several feet apart. To prevent the slopes of filling material from sliding it is sometimes the practice to dig a trench just inside each toe line of the embankment, but with material of approved quality such precaution is not necessary.

Large stones should not be placed in shallow fills, and when such are found above the surface, on location, within 2 ft. below sub-grade, they should be broken up, rolled into pits or rolled outside the slope stakes. Stumps should be cut off at least 2 ft. below sub-grade, but wood which rots quickly should not be permitted to remain in a fill at all, except, perhaps, in the case of an embankment formed upon a steep hillside—where the trunks of all large trees which stand within the slope stakes should remain standing, to assist in retaining the earth and prevent sliding. Just before the embankment is completed or at that time the trees may be cut off at proper distance under sub-grade, or even with the slope. It is usually required that large trees shall be cut so that the tops of the stumps shall not be more than 3 ft. above the ground, and that where embankments are less than 3 ft. in hight all trees and stumps shall be cut close to the ground. The surface of ground to be excavated and where embankments less than 2 ft. in hight are to be built should be grubbed free from stumps, roots and other perishable material, and all brush should be cleared away. In some cases where the materials vary considerably it is advisable to reserve the best of them for finishing and dressing the surface. In a wooded country, where grading is done by contractors, especially when sublet to numerous subcontractors, it is well to keep close watch to see that logs are not rolled in and covered up. One is justified in being suspicious of all filling done at night or not during regular working hours. Aside from rotting and weakening the fill years afterward, or burning, in case the ends get uncovered, a fill containing many logs, especially where several are rolled together in a heap, or are near the top in any shape, will be springy or humpy and a positive hindrance to good surface for a long time.

The top surface of roadbed should be graded off smoothly, filling up all pockets or depressions which would otherwise remain to collect and hold the water which sinks through the ballast, where it can freeze in in winter time and heave the track. For this reason ruts from wagon wheels driven over the roadbed should be filled and the material compacted before the track is laid or the ballast deposited. The practice of running material trains over newly laid track before it is surfaced or ballasted also requires that the roadbed surface be made smooth, to afford an even embedment of the ties and thus avoid kinking the rails.

As far as possible, embankments or other made ground should be completed early, so as to have time to settle before the track is laid. Embankments seldom settle evenly, and track laid thereon before settlement does take place is sure to require considerable labor to keep it in fair surface soon after the trains begin running. Where a short fill comes between two cuts or next to a bridge it should be put high enough to allow for settlement. If not, the fill will settle below the established grade, while the roadbed in the cuts or the track on the bridge will not, and there will then result an ugly sag.

The slope of railway embankments varies from 1 to 1 for rock fills to 1½ to 1 for ordinary earth, and easier slopes for soft material like clayey soil, when such must be used. By building up a rough dry wall on the exterior of a rock fill it may be made to stand at a slope somewhat steeper than 1 to 1. Ordinary earth will stand for a time at a slope steeper than 1½ (horizontal) to 1 (vertical), but under the action of the rains, the winds and frost it will gradually wear down to about 1½ to 1. In excavations, solid rock which will not disintegrate by exposure will stand to a vertical face. Firm dry earth well protected from water seepage is sometimes sloped 1 to 1 in cuttings, but under less favorable conditions it will not always stand at even 1½ to 1. Under ordinary conditions, however, 1½ to 1 is considered safe. Where excavation is made through rock overlaid with earth, the earth slope should be cut back to leave a berm of 3 to 4 ft. from the brink of the rock slope, to retain loose material which slides or rolls down in moderate quantities. The slope of earth in such places should be made easier, if anything, than elsewhere, because rock cuts are usually made so narrow that only a relatively small amount of material sliding into the same is liable to fill the ditch and obstruct the rail.

Sub-Drainage.—A question which has received but little attention from American railway engineers as yet is the sub-drainage of roadbed. Although the value of sub-drainage in wet cuts is recognized, and in comparatively few cases something has been done to put the principle into practice, but little or nothing has been done to carry the water from embankments by under drains. In selecting material for ballast the drainage feature is considered one of the most important properties, but it should be understood that drainage as applying to ballast refers to the drainage of water from the ties *to the roadbed.* Through stone ballast, for example, water sinks to the roadbed as through a sieve, and in gravel ballast the same thing occurs after the material becomes thoroughly soaked. The sand contained in gravel has, of course, some capacity for holding the water back. Such being the case the roadbed under most of the track which is considered well ballasted must receive a good deal of water. So far as ballast is concerned it reaches its limit of settlement within a comparatively short time, and those who will investigate matters closely will find that rough surface in old track is caused largely by settlement of the roadbed or settlement below sub-grade. One very responsible cause for this condition is the seepage of water through the ballast and into the roadbed. While much of this might be drained off on the top surface of the roadbed, if the same was properly crowned, it is known, nevertheless, that only a comparatively small amount of roadbed construction is brought to such a top surface and compacted sufficiently to hold its slope until the ballast is placed upon it; and in many cases, as already shown, it is impracticable to do this. As a rule, then, a good deal of water must find its way into the interior of the roadbed to soften the material and keep it continually settling, and, in cold weather, to freeze and heave the track. Moreover, as most double-tracking is done by building a second track beside the old one, it is impracticable to crown the roadbed midway between the tracks and slope it to either side, since the roadbed at subgrade under the old track, if properly formed, is highest underneath the center of the track and, in any case, it is not accessible. Such being the case one has good reason to think that most of the water which finds its way through the ballast on double track percolates through the roadbed material to considerable depth.

The value of tile drainage being well understood, there would seem to be no difficulty in keeping the interior of the roadbed reasonably dry by resorting to the usual methods of sub-drainage. It would certainly be worth the cost of thorough trial, on any railroad where the annual rainfall is considerable, to see if a longitudinal tile drain laid a few inches under sub-grade, with cross drains leading to the surface at frequent intervals, would not intercept the larger portion of the water which ordinarily sinks through the roadbed. On single track such a drain might be laid under the center of the track, preferably in sections draining into the cross drains at a considerable fall rather than in a continuous line laid to the grade of the track, except perhaps on the steepest grades. On double track, where the roadbed is constructed before either track is laid, and properly crowned in the middle, a line of tile might be laid under the center of each track, but otherwise, as in the case where the two sides of the embankment or cut were formed at different times, only one drain would likely be used, and that could be placed to best advantage midway between the tracks, or about on the dividing line between the old and new embankments. On the double-track lines of the Baltimore & Ohio R. R., where stone ballast is used, an 8-in. tile drain is laid upon the roadbed midway between the tracks and the ballast is filled in level with the tops of the ties. The roadbed is crowned 6 ins. in the middle and the depth of ballast at this point is 12 ins. below the bottoms of the ties.

Sodding and Seeding.—Still another line in which the maintenance of earthwork is open to improvement is the protection of slopes against washing or sliding, by the growth of vegetation. Barren embankment slopes are continually eroded by rains, and ditches at the bottom of bare slopes in cuts become obstructed by sediment washed down by the rains or which rolls or slides down when loosened by the thawing of the ground. On English railways the sodding of slopes is a feature of general practice, but in this country it has been considered too expensive to have succeeded to anything like extensive trial. Here and there the slopes of a cut will be found sodded, but in general practice the natural growth of weeds or grass, without any attempt at encouragement or cultivation, is all that can be found on either cuts or fills. A healthy growth of grass on slopes requires nourishment by a coating of soil. In cuts this may sometimes be obtained by stripping the top surface some distance back from the cut. The best opportunity to obtain the material on the right of way, however, is before the cut is excavated. The top soil is scraped back beyond the slope stakes into heaps and after the excavation has been completed it can then be spread over the slopes that are to be sodded or seeded. On embankments the strippings from gravel pits, material cleaned from ditches, the bedding from stock cars, and other fertile material which must be hauled off for disposal may be utilized to encourage the growth of vegetation. Sweepings from streets are also good material for this purpose, as they contain a large percentage of fertilizing matter and a considerable mixture of seeds of various kinds.

Before sodding or seeding is begun the slopes should be dressed off reasonably smooth and angular shoulders and intersections at the top and toe of slopes should be rounded off to a natural contour. Sods about five years old are the most vigorous for transplanting, and those from high, well drained ground are, from previous condition of growth, better able to thrive on dry slopes than sods from swampy or wet localities. As a means of assisting the sod in getting started some recommend sowing a mixture of timothy seed and oats over it the first year. These will quickly spring up and form strong roots to help hold the sod in place. To strengthen the growth later on, Kentucky blue grass, white clover, perennial rye, red fesco and red top, in the proportions of 8, 4, 9, 3 and 8, respectively, are considered a good mixture for supplemental seeding. In the South the slopes of embankments are frequently set with tufts of Bermuda grass in rows 1½ to 2 ft. apart, as referred to in §148. This grass will thrive in sand, and in a short time it forms a thick sod entirely covering the ground. Its characteristics are described in §12, in connection with sand ballast. Where sod is placed on steep slopes it is customary to drive stakes, in rows, staggered, to hold it in place until the roots take firm hold. The stakes are usually driven flush with the surface of the sod and permitted to remain. Seeding is, of course, cheaper than sodding, but some time is required for the growth to form a sod. The variety of seed best suited to the climate and soil is perhaps best ascertained by observation of the natural growth or of the grasses grown under cultivation in the locality. Willows and scrub brush indigenous to the locality are also planted on slopes to check the tendency to slide or wash away. An advantage in a growth of willows is that their great vitality permits close trimming, forming in time heavy stumps and strong roots to permeate the ground and hold it in place, without the presence of an excessive or troublesome growth above the surface.

Borrow Pits.—A matter which ought to receive more attention than it sometimes does with fills made from borrow pits, is the nearness of the pit to the foot of slope. At the foot of slope of shallow embankments, say up to 3 ft. in hight, there should be a berm at least 4 ft. wide; and for higher embankments the berm should be wider. The removal of earth in nearness to the foot of slope increases the hight of the embankment by the depth of the pit excavated, and if the pit is too near it of course weakens the embankment. It is also to be considered that with a narrow berm ties and other materials thrown off the cars will slide or roll out of reach; and besides, if the embankment must ever be widened, a pit at the foot of slope must first be filled before an addition can be made. In improving the grades of a line it is not unusual to raise the track as high as 4 ft., increasing the hight of the embankment that much, which means a widening at the foot of slope of about 6 ft. It would seem like good policy, therefore, to be mindful of a good factor of safety in establishing the width of berm, making it at least 8 or 10 ft., wherever practicable, and always leaving room for a double track on one side. The standard cross section of the Union Pacific R. R. provides for a berm 6 ft. wide on one side and 18 ft. wide on the other side, as the probable base for a widened embankment for a second track. The standard plans of the Kansas City, Pittsburg & Gulf R. R. require berms 6 ft. wide for banks 15 ft. high or less and 12 ft. wide for banks higher than 15 ft. The standard berm of the New York Central & Hudson River R. R. is not less than 6 ft. wide in any case, nor less than double the depth of the pit or ditch, always leaving room for double track on one side. On the above-mentioned considerations it is just as important that the berm should be guarded against depletion as that it should be established at proper width in the beginning—which is to say that the berm should not be cut away to "build up" the bank.

Borrow pits, or ditches from which material is taken for shaping up banks, are frequently left by the construction forces in an unsightly condition, being excavated on irregular lines and to irregular depths, and without sloping the sides. Properly, the sides of borrow pits should be trimmed up parallel with the alignment, and the side next the track should be given a natural slope, according to the character of the material, never steeper than 1 to 1 for earth, and usually 1½ to 1 or the same as the slope of the embankment. The drainage of borrow pits close to embankments should also be looked after, and the proper time to do this is, of course, when the pit is being excavated. In most instances the pit may be so located that the excavation of the same will provide an outlet, or the excavation for an outlet to the pit may be made to supply part of the borrowed material. Water standing in a borrow pit at a higher elevation than the surface of the right of way on the opposite side of the embankment will naturally seep strongest in that direction, thus tending to soften the earthwork foundation.

Roadbed over Marsh Land.—Aside from the nature of the fill itself the ground upon which it is made is sometimes so unstable that proper support for the track cannot be easily obtained. Such is frequently the case in swampy or boggy land and on quicksand. On an easily yielding surface a shallow fill will roll up ahead of a train and give way underneath it, without remedy. Under such circumstances it becomes a difficult matter to maintain the track in fair surface, and the rails will creep badly. There are several measures which may be taken to overcome difficulties or improve the conditions in a situation of this kind. In the first place, before attempting to fill across a swamp or bog the region should be drained as thoroughly as may be feasible, and in order to accomplish this it is sometimes necessary to undertake the drainage of a large area, by extensive excavation distant from the right of way. The hope of accomplishing results on this line of operations lies, of course, in the amount of fall obtainable. It is then important to look carefully to the drainage near the track, usually by cutting ditches of good depth as near the embankment as the conditions of stability will allow. The Galway & Clifden Ry., in Ireland, runs through long stretches of bog land and the matter of drainage and types of roadbed construction have been closely studied. On this road the standard arrangement for drainage consists of two longitudinal ditches 22 ft. apart on each side of the track. The inner ditch on each side is 4 ft. wide at the top and 3 ft. deep, and is cut at a distance of 6 ft. from the toe of the embankment. The outer ditch is 6 ft. wide at the top and 5 ft. deep. The side slope of these ditches is 1 in 3, and the two are connected by cross drains every 100 ft.

In filling over boggy land it will usually pay better to haul the filling material some distance than to use the top surface of the swamp, as it is seldom fit for constructing embankments. The best results are obtained by leaving the top surface under the roadbed undisturbed, as it usually consists of matted vegetable matter which will carry a considerable weight without breaking. To secure a proper distribution of the weight the filling material for the embankment is sometimes deposited upon a corduroy foundation, but more frequently upon a brush mattress. In making embankments over marshy land in Holland it is quite commonly the practice to first lay a mattress of willow boughs, 2 to 4 ft. thick, extending from toe to toe of the embankment slopes, before the earth filling is begun. On the Galway and Clifden Ry. a layer of brushwood and poles 3 ft. thick has been used as a foundation for embankments on bog land, with satisfactory results; but the most successful construction in this line is reported to have been obtained by building the embankment with turf, without brushwood, and then covering it with an 18-in. layer of stiff, marly clay, which hardens upon exposure to the air and becomes water proof. A source of trouble to be guarded against with embankments made by filling over a peat bog is fire. In extremely dry weather peat, especially in a bog which has been drained out, will sometimes take fire and burn over large areas, smoldering away for weeks. It is something of a task to extinguish such a fire, as it will burn on in spite of light rains, and if not stopped in some way will burn right under an embankment and let it down. About the only way to fight it is to dig a trench across its path.

Where the yielding material in marshy land is shallow or extends but a few feet below the surface, the stability of an embankment constructed thereon improves with increase in hight; but if the yielding material extends to considerable depth any increase to the hight of an embankment only makes matters worse. In the latter case the weight of the superimposed embankment causes it to sink into the mass of yielding material, the displacement of which usually takes an upward course, bulging the ground on either side of the embankment. Not infrequently a large mound will be formed at either side of an embankment which has settled in this manner, sometimes overthrowing right-of-way fence and telegraph poles or carrying them out of line. A remedy sometimes applied is to drive a row of piles a few feet apart along the foot of each slope of the embankment. As a better means of preventing settlement it has been proposed to construct a sort of pier as a foundation for the embankment, by driving a row of piles outside each line of slope stakes and placing a line of timber inside each row of piles as backing for a row of sheet piling. It is proposed to then tie the two rows of piling together with rods and in this way prevent the mucky material underneath from getting away. The practicability of this scheme would, of course, depend a good deal upon the depth of the marsh. On ground of this nature, however, it is sometimes better not to fill at all but to build the track on piling.

Where the track must run but a few feet above the surface of a marsh, and piling, for some special reason, is impracticable, a substructure which will bear up evenly under the track may be made in the following manner: Grade off the top surface just enough to get a fair bearing, and upon it lay closely, thick, wide cross ties 12 or 15 ft. long. Upon these place deep stringers of good length and lay them to break joints. Use about as many as would be required to support the track on piling. Upon the stringers place sawed cross ties and drift-bolt them, and lay the track about as it would be laid on a bridge floor. Each bottom tie should be made to lie in as good a bed in the mud as may be, without special reference to the other ties each side of it. The stringers can be evenly supported by spiking shims of proper thickness to the tops of such ties as are not touched by the stringers after they are put to place and leveled up. In this manner the stringers transmit the weight over a larger surface than a shallow earth fill can and, when properly made, will maintain track in quite even surface. The stringers should be braced to a portion of the ties underneath them to keep the track in alignment. The structure is simply a track built with a double course of cross ties with stringers between the two courses. It is to be expected that there will be more spring in such a structure than in track supported on piles.

Before roadbed construction through marshy land is undertaken soundings should be made by a portable pile driver, or other means, to ascertain the conditions underneath. If the material underneath is found to be extremely soft or readily yielding to a considerable depth, it is well worth while to consider the alternative of either abandoning the location or resorting to pile construction. The sinking of embankments into marshy ground is not of unusual occurrence. It has frequently happened that fills made through swamps or bog land or over strata of quicksands have displaced the underlying materials and entirely disappeared. Difficulties of this kind have sometimes been met by continuing to deposit filling material until equilibrium was obtained between it and the material which it displaced, but in numerous instances large sums of money have been expended in this way only to abandon the work in the end. In cases of this kind the most serious trouble has not usually developed until after the roadbed was subjected to the weight and jar of passing trains, but proper examination beforehand, at nominal expense, might have disclosed the exact nature of the conditions. The perplexity of dealing with such conditions has, in a large number of instances, convinced maintenance of way men that the most satisfactory practice lay in the permanent use of piling and in foregoing any attempt at earthwork. It will be interesting to give here the particulars in a case or two of the kind under consideration.

In the summer of 1897 the Chicago, Indianapolis & Louisville ("Monon") Ry. made extensive changes in the location of its line in the vicinity of Cedar Lake, Ind. A stretch of track about 300 ft. long, on the old location, crossed the eastern side of a marshy basin, generally circular in shape and about 1,000 ft. across. In eliminating a curve the track at this point was relocated farther over, so as to cross about 800 ft. of the marsh, on a line running 125 to 200 ft. distant from the old location. Filling material was obtained from a heavy cutting to the south and work had progressed on the construction of an embankment, with teams, for a period exceeding a month, during which time a fill about 7 ft. in hight had been extended nearly half way across the marsh. No unusual settlement had apparently taken place, when, upon taking up the work one morning, it was found that 150 ft. of the fill had sunk about 16 ft. and disappeared under a depth of 7 ft. of water. This, the first subsidence, is shown in Fig. 1, the bottom picture being a nearer view looking down into the depression. The track appearing in the background of this view was the old main track, about 125 ft. distant, which had carried traffic for years without extraordinary settlement. The work of filling was next taken up from the north side of the basin, the material being hauled out on cars which were unloaded from a temporary trestle. After considerable progress had been made this embankment also disappeared, carrying the trestle and track with it so suddenly that a train of cars which was being unloaded at the time was barely saved from sinking with the track. This part of the fill also sank beneath the water and no trace of the track was afterward discovered. The sinking of the embankment caused the surrounding surface to bulge upward, and large cracks 6 or 7 ft. deep were opened up along the lines where the top stratum was sharply broken off and deflected downward by the sinking of the earthwork. These cracks revealed a bed of peat extending the whole depth and below. The surface of the water which covered the sunken embankment was 2 or 3 ft. below the general surface of the marsh. Moisture was absent on the top surface, as may be surmised from the fact that at the time the photographs were taken the peaty surface was afire and was burning over a considerable area. The hazy appearance in the background of the illustrations is due to smoke arising from this burning peat. There was no water in sight at any point on the marsh and the land was enclosed and used for pasture. Judging of the nature of the deeper earth structure from the foregoing suggestions of instability it was decided to abandon the project of filling and carry the track across on piling. Something of the nature of the underground support may be inferred from the fact that the piles had to be driven to depths varying from 75 to 150 ft. in order to secure bearing of sufficient supporting power. The piles used were of oak in 25-ft. lengths, spliced by cutting off squarely and joining end to end, using a drift bolt, and two iron straps bolted through and through at each joint. The pile driver which appears in the illustrations had progressed with the work of bridging across about one-half of the affected territory.

A most remarkable and strange circumstance associated with the sinking of this earthwork was that immediately following the first subsidence the water covering the sunken embankment was thickly populated with

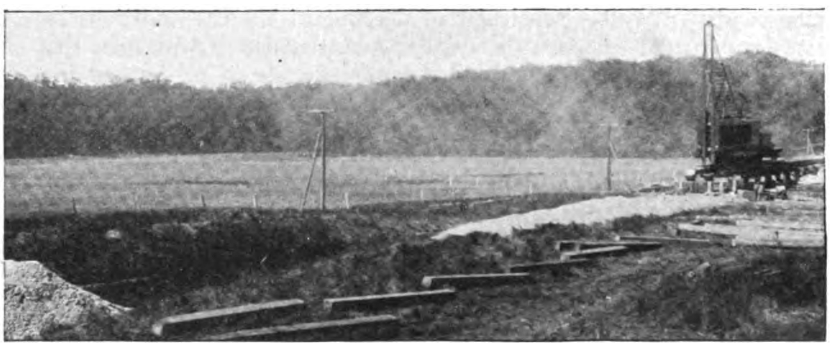

Fig. 1.—Sunken Embankment, C. I. & L. Ry.

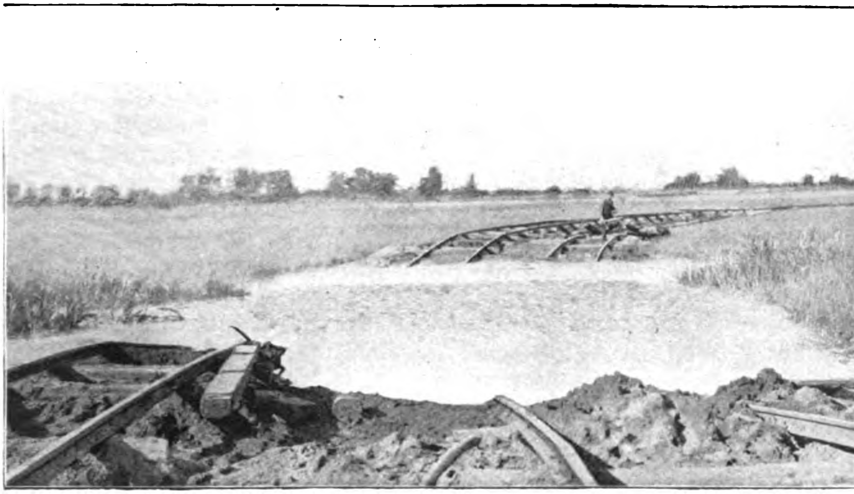

Fig. 2.—Sink Hole, Grand Rapids, Holland & Lake Michigan Ry.

fish and frogs. The fish were of all sizes, from minnows to fish 6 or 8 ins. in length, and there was no peculiarity of eye structure such as is commonly found with subterranean varieties. There was apparently no grounds for explaining the presence of these aquatic inhabitants on the theory of an underground passage, for there was no near body of water on the same level containing fish. The surface of the water in Cedar Lake, one mile distant, is 28 ft. below the water level at the point of subsidence, as determined by the railroad surveys, and the track between the two points is on a grade of 26 ft. per mile. The only satisfactory explanation is that at one time an open body of water existed in this basin, and that within a comparatively recent period it was gradually overgrown with a thick bed of peat moss, the surface of which, over the whole area, is now found in the decomposed state, or in the form of peat. The looseness of structure in places would admit sufficient air to maintain the life of fish descended from the earlier inhabitants of the open water, and enable frogs, by burrowing, to exist on water which did not appear at the upper surface. There are lakes in this country where growths of this kind may now be seen in progress. Beds of moss of astonishing depth have become extended from the shores and are slowly spreading over the surface of deep water. In some cases these floating beds are so firm and their buoyancy so great that one might readily mistake them for the real shore of the lake. This fact explains why railway embankments sometimes sink so suddenly. So long as the floating crust can bear up the material filled upon it, the settlement may not be excessive, but when the conditions of support or the increase of load become such that the crust breaks through, the sinking of the embankment then takes place suddenly.

A case similar to the foregoing, but more nearly in line with ordinary experience, occurred some miles west of Chicago, on the Chicago, Burlington & Quincy Ry., in 1890. In making a fill for an additional track beside an old embankment the earthwork settled 1 to 3 ft. per day. By persistently filling, however, until the track had settled altogether about 40 ft. and 95,000 cu. yds. of gravel and dirt had been dumped into an embankment 1000 ft. long, the settlement finally ceased. The earth on each side of the embankment was crowded outward and rolled upward in a ridge 10 ft. high, and the telegraph poles were moved 12 ft. farther from the track. It is probable that the settlement did not cease until the new embankment found bottom on bed rock or upon a hard stratum. In filling for an embankment on similar ground at Barclay, Ontario, on the Canadian Pacific Ry., it was estimated, from the amount of material required, that the depth of the "muskeg" must have been 200 ft. Figure 2 shows a sink hole on the Grand Rapids, Holland and Lake Michigan Ry., near the city limits of Holland, Mich. Only a short time after the tracks had been laid the entire roadbed sank completely out of sight in the marsh, only a pond of water remaining visible at the surface. The distance across this sink hole was 700 ft., and an attempt was made to fill it with sand and gravel, but seemingly there was no bottom, and this method had to be abandoned. Support for the track was finally provided by building a pile trestle with 30-ft. piles spliced together.

Instances of extraordinary settlement or sinking of roadbed in marshes have been numerous. An account of several occurrences of this kind in Pennsylvania, New Jersey and New York may be found in the Railway Review for Nov. 21, 1891. The usual remedy is either a pile trestle or filling material in sufficient quantity to "strike bottom." A plan followed on the Detroit & Milwaukee R. R. in crossing a sink hole 2600 ft. long and 60 ft. deep, 6 miles east of Grand Rapids, Mich., was to make a slab raft 10 ft. thick and fill on top of this with sand. There was some difficulty from the tipping of the raft in sinking, but in the end the work was successful.

4. Ditches.—By proper drainage of the roadbed and track much expense which otherwise might be incurred in keeping the track to surface can be saved. Water must be kept out of, or drained away from, the ballast as much as possible, to keep it from softening and settling or to prevent it from freezing and heaving in winter; the roadbed must, for the same reasons, be protected. The proper form, depth and size of a ditch and its distance from the ties depend a good deal upon surrounding conditions. First of all, most of the ditches that are needed are located in or around cuts. A very important ditch at a cut, if it be a sidehill cut or wherever the general surface of the ground slopes toward the cut, is the surface ditch, along the upper side, the purpose of which is to intercept surface water and divert it from the cut. The size of a surface ditch must depend upon the amount of land to be drained. Ditches of this kind must sometimes be made as deep as 5 or 6 ft., and correspondingly broad, in order to afford sufficient capacity for the large amount of water which comes in torrents during hard rain storms. The ditch should stand a good distance back from the top of slope, say 10 or 15 ft., and the dirt taken out of it should be heaped up on the side toward the cut. Where such ditches are too close there is danger that the seepage of water from the bottom of the ditch will soften the earth and cause slides. Spoil banks or material wasted in the excavation of cuts should be a good distance clear of the slope stakes, say at least 15 ft. In matters of this kind it is well to have in view a safe margin to cover possible improvements, such as the widening of cuts for more ditch room or for laying a second track or to obtain easier slopes. The surface or "top" ditch should be run each way from the lateral watershed to the nearest culvert or other opening under the track; or, at all events, the ditch should be so diverted that the water discharged will not find its way into the roadbed. Where the slopes of a cut are springy it is sometimes the practice to cut diagonal ditches down the slopes, at easy grades, to prevent excessive wash. Where springs of considerable size gush out of the slope the best way to take care of them is to lay lines of drain tile to conduct the water directly or diagonally down the slope and into the ditch or under drain. If the slope of the hillside is a long one it is well to have a second surface ditch farther up the hill, to catch the larger part of the flow during heavy storms. By properly ditching the region above the track much water which would not appear upon the surface directly above the cut, but which, nevertheless, would find its way out at the face of the cut, can be turned aside. Cases of this kind are on record where cuts, which beforehand had been wet and bothersome, have, by surface ditching, been made nearly or quite dry.

Drainage Conditions as Affecting Land-Slides.—Roadbed in side-hill cuttings through clay sometimes gives way and slides down the hill, carrying the track along; likewise slides from above become troublesome when water gets between the strata underneath the surface. In cases of this kind it is well to keep water out of the cut, as far as possible, and make search to see if by draining out some pond or swamp at a higher level the water can be prevented from soaking through the ground toward the cut. Clay, if kept dry, is tough and will sustain pressure very well, but when wet it becomes plastic and will slide down the slightest grade if not confined in some way. Much of the region surrounding the Puget sound is of clay formation and has presented special difficulties to many kinds of engineering work requiring good foundations; all the more so, too, because of the large and long continued rainfall in that region. Railroad ditching properly done means the draining of a large area, sometimes.

A good illustration of the influence of seepage on earth movements is to be seen on the Canadian Pacific Ry., along the Thompson river, about 200 miles east of Vancouver, B. C. Owing to the irrigation of terrace lands some remarkably large land-slides were developed in this locality before the railroad was built. One of the slides was about ½ mile wide and ¾ mile long, back from the river, and covered an area of 155 acres. This enormous mass of earth dropped vertically, in one movement, to a depth exceeding 400 ft. at the back edge, and the lower portion was pushed ahead until it came to rest against a steep bluff on the opposite side of the river, damming the river to a hight of 160 ft. and forming a lake 12 miles long. As soon as the river rose above this dam the water cut its way through and the loose material was all swept away. About a mile distant another slide occurred having a width of 1880 ft., a length back from the river of 1575 ft. and covering an area of 66 acres. Within a distance of 6 miles there were four other large slides, across all of which the road had to be constructed, following closely the contour of the river bank at an elevation of 50 to 80 ft. above low-water level. The material composing these slides consists of soil overlying strata of sandy loam and clear sand, below which the material is stratified gravel and boulders. The whole rests upon a stratum of clay silt, and it was upon this material that the sliding took place. The slide at each point occurred between three and six years after irrigation began. The largest slide above referred to was hastened by the bursting of a reservoir two miles distant in the hills, which poured a flood of water upon fields that had already become well soaked. As all the arable land at this point was carried down with the slide the irrigation was stopped and in the course of a few years the water drained out so completely that movement ceased and no trouble with the track has occurred. At the other slide, however, there has been continued application of large quantities of irrigation water upon the cultivated fields above the slide and in consequence the track has been continually pushed toward the river, sometimes at the rate of 8 ft. in one night, the roadbed sinking at the same time as much as 4 ft. As the material has been forced forward the river has washed it away, and from time to time a new roadbed has been built further back and the track moved over to it. This portion of the road has had to be carefully watched, and in order to maintain a safe passage across the line dividing the stable from the moving material the track has had to be continually shifted.

Track Ditches.—The office of a ditch near the track, sometimes called the "track ditch," is to drain off the water which falls upon the track and that which runs toward it from the side. As the roadbed is subject to seepage from the water collected the drainage conditions naturally improve with increase of distance between the ditch and the track. Reference is limited to comparatively near distances, of course, and, standing in some relation to depth of cut, there is a limit of excavation to be calculated upon, at which the interest on extra capital invested to save repairs will balance with the saving so made. Beyond this limit engineers are not supposed to go, unless the extra material excavated can be disposed of to advantage. An important study in problems of track engineering is to find the proper balance between efficiency and economy. Thus, under certain circumstances, it might pay better to leave some cuts at a minimum allowable width and, with the saving in expense so effected, widen others out to exceed standard dimensions, possibly, than to make all of the cuts the same width merely for the sake of appearance or of conforming to some adopted standard. To put upon paper the form and dimensions of a ditch, called a "standard" ditch, and to suppose that it will meet all the conditions economically, may be landscape gardening but it may or may not be good engineering. The idea of standardizing is a valuable one if it goes far enough to provide a standard for each of the several conditions requiring different methods of treatment.

Forms of Ditches.—In a general way ditches take two forms, according as the roadbed is shouldered or not. Where the roadbed is not shouldered the ditch is formed by sloping the roadbed at the sides to meet the toe of the slope of the cut. At the ditch it is usual to increase somewhat the general side slope of the roadbed due to the crowned center, so as to gain depth for the ditch. Ditches of this form are most commonly found in narrow cuts, where there is not room to shoulder the roadbed and cut a ditch beyond the same. On some roads, however, this form of ditch is preferred for any width of cut, the advantage claimed being that such is the natural form; and that if a shoulder is interposed between the track and the ditch it will eventually become rounded off or worn down to a common slope from the track to the back side of the ditch. The following are some of the roads on which this form of ditch is standard, the width of single-track roadbed, from toe to toe of slope, and the depth of ballast under the bottom of the tie being given in each case: Southern Pacific, roadbed 16 ft. (18 ft. in regions where rainfall is heavy) ballast 8 ins.; Erie, roadbed 18 ft. 8½ ins., ballast 12 ins.; Atchison, Topeka & Santa Fe, roadbed 26 ft., ballast 10 ins.; Cincinnati, New Orleans & Texas Pacific and Baltimore & Ohio roads, roadbed 18 ft., ballast 12 ins.; Pennsylvania (light-traffic lines), roadbed 19 ft. 2 ins., ballast 8 ins.; Philadelphia & Reading (in dry cuts), roadbed 18½ ft., ballast 8 ins.; Southern Ry., roadbed 18 ft., ballast 6 ins.; Missouri, Kansas & Texas, roadbed 18 ft., ballast 6 ins. On this road a middle strip of the roadbed 8 ft. wide is flat, the slope into the ditch (6 to 1) starting under the ends of the ties. On each of these roads except the Southern Pacific the ballast is either shouldered out beyond the ends of the ties or at least filled in against the ends. On that road broken rock ballast is dressed in this way but gravel ballast is not.

The other of the two forms of ditches here considered is made by constructing a roadbed of ordinary width, at sub-grade, as on embankment, and then excavating the ditch beyond the shoulder. The idea in constructing a ditch in this manner is to remove the water as far as possible from the ballast. Ditches of this form are either V-shaped or trough-shaped, the latter having a flat bottom. As between two ditches with the same side slopes the flat-bottomed one will, of course, carry more water for the same depth than the one that is V-shaped. Some prefer the V-shaped ditch, however, because it takes up less room and so concentrates the flow of water that it is more likely to keep itself clear, especially where the flow is small. On different roads the width of single-track roadbed with V-shaped ditches varies from about 19 ft. to 28 ft. from toe to toe of slope, although in some cases it is less than 19 ft. The toe-to-toe width of roadbed with trough-shaped ditches varies from about 22 to 28 ft., for single-track roads, although both wider and narrower measurements may be found, in cases.

Size of Ditches.—The width of roadbed in cuts and the size of ditch should be governed to some extent by the depth of the cut, because a long slope brings more water to the ditch than a short one, and consequently more sediment; hence the larger the ditch the less will be the trouble to keep it clear. In cuts of extensive length it may also be found advisable to increase the capacity of the ditches toward the outlet. All things considered, 18 ft. should be about the least allowable width of roadbed in cuts, and then the conditions must be favorable. A width of 18 ft. gives a space of 5 ft. each side, clear of the ties, to include the ditch; and it is about the least room that will allow for taking out ties in renewals, after assuming that the bank slopes well away from the ditch and that the track will be raised above sub-grade when ballasted. Under less favorable conditions, as when, for instance, the cut is deep and long and much water is to be carried in the ditch, or when the cut is through wet material or material of the nature of clay, 18 ft. is entirely too narrow. As far as I am able to discover, the largest practice with trackmen, wherever the ballast does not exceed 12 ins. in depth under the ties, seems to be to maintain ditches at a distance of 7 ft. from the rail to the foot of slope at the back side of the ditch. This measurement gives a roadbed about 19 ft. wide; and right here it should be explained that the roadbed constructed or maintained by trackmen does not always measure fully up to the blue-print drawings in the chief engineer's office. In order to treat the subject comprehensively one should not fail to investigate the least width of roadbed upon which good track can be maintained, because it is upon roads of small earning capacity that questions of this kind must receive the most studious consideration. On roads with large earnings at disposal the question of the most economical width of roadbed largely disappears, and a width may be selected which is known to be sufficient to afford desirable conditions. I have therefore outlined, in a general way, what I consider to be typical conditions or situations to be met in ditching and the least width of roadbed which may apply to each case.

In a dry gravel cut there is seldom need for a ditch, because ordinary rainfall does not, on such ground, run off on the surface. As, however, the material ought to be removed far enough back from the ends of the ties to make room for taking them out without too much digging during renewals, or without having to raise the rail, it is well to slope it away gradually somewhat lower than the bottoms of the ties, as far as there is room. This will provide for those extraordinary rainfalls when water comes in quantities faster than it can soak away, and also for winter, when snow melts on frozen ground. Six inches is far enough to go below the level of the bottoms of the ties in this instance. Of course it improves appearances to make the ditch deeper, but as the whole foundation is porous this is a case where the requirements for ditches under almost all other conditions do not arise. Engraving *A*, Fig. 3, is an illustration of this ditch.

In all other cases the ditch ought to fulfill the following requirements: it ought to carry the water away below the level of the bottom line of the ballast, because all ballast except common dirt is porous, and if the ditch be not lower than the bottom line of the ballast the latter will be soaked with water whenever there is any in the ditch; the ditch should also have at least a slight grade, which can be maintained, even on level ground, by

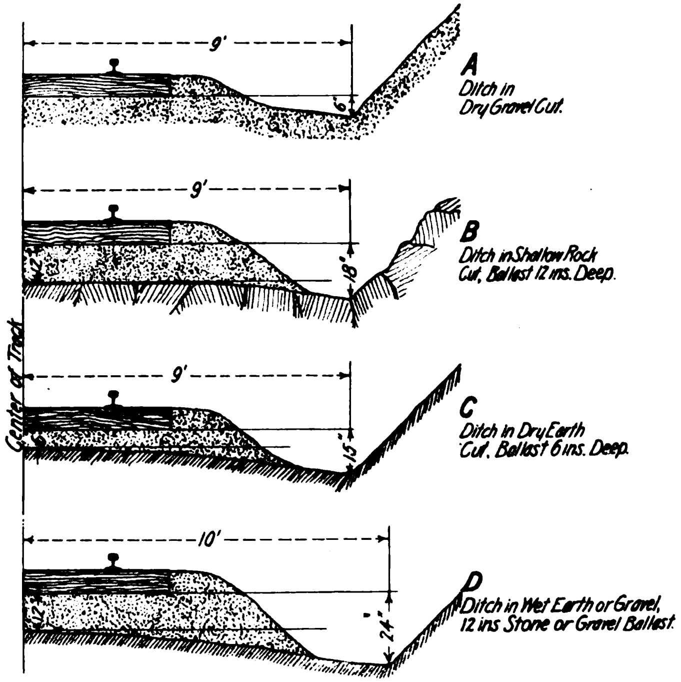

Fig. 3.—Half Sections of Roadbed and Ballast.

making the ditch deeper at one end than at the other. In such a ditch the water has a chance to run off; whereas, in a level ditch water is liable to be dammed and held to soak through the roadbed, causing the track to heave in winter time and require shimming.

In rock cuts the bottom of the ditch need not be more than 6 ins. below sub-grade unless the quantity of water to be carried off cannot be accommodated by such shallow depth. In shallow rock cuts the toe-to-toe width of roadbed should, for convenience of tie renewals, be at least 18 ft. Engraving *B*, Fig. 3, shows the amount of ditch room available in such a cut where 12 ins. of ballast is used. In deep rock cuts the expense of excavation becomes a paramount consideration, and in such places 16 ft. is a very common width of roadbed.

In a dry cut the only water to be carried out of it is that which falls between the slopes, and under ordinary conditions a ditch 9 ins. deep below sub-grade will answer. In such a cut the quantity of ballast required does not exceed that required for fills. For a depth of ballast not exceeding 6 ins. below the ties a toe-to-toe width of 18 ft. will answer. Engraving *C*, Fig. 3, shows such a roadbed for dry earth cuts, the term "earth" in this connection meaning common loam or sand in distinction from gravel and unmixed clay. If, however, there is more or less water in the cut coming from springs which flow out of its slopes the ballast and the ditch should both be deeper than in the case just referred to, and the cut must therefore be wider. The ditch should be at least a foot lower than sub-grade and the ballast a foot deep above sub-grade. Twenty feet between the slopes, toe to toe, will give ditch room for single track, as shown by Engraving *D*, Fig. 3. Where springs come up through the roadbed there is usually much difficulty in keeping the ballast dry and the track to surface. The only remedy lies in widening out the cut to make room for a ditch which slopes away from the track gradually, and in putting in a good depth of ballast,

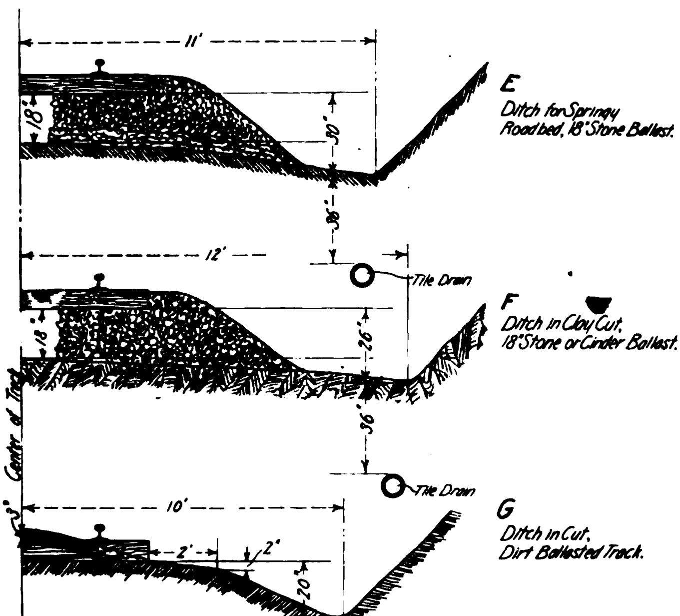

Fig. 4.—Half Sections of Roadbed and Ballast.

the bottom course of which is rather coarse rock. About 18 ins. of ballast should be used and the cut should be at least 22 ft. wide at sub-grade, as shown in Fig 4, Engraving *E*.

In a clay cut a deep ditch cannot be maintained, for the reason that when the top of the roadbed becomes wet it will slide laterally, under the weight and shock of passing trains, and fill the ditch, if there be much of a slope toward the same. Mistakes are often made in cases of this kind. When the track is found to be settling and the ditch filling up, in such cuts, some trackmen will deepen the ditch accordingly, making allowance in depth for the plastic clay which they evidently think cannot be kept out. Such treatment only makes matters worse, for it weakens the roadbed by taking away its lateral support, and the material under the track will keep pushing into the ditch and the track will continue to settle. The proper thing to do is to widen out the cut to make room for a roadbed which slopes so gradually that it will not slide out—a flat roadbed, comparatively speak-

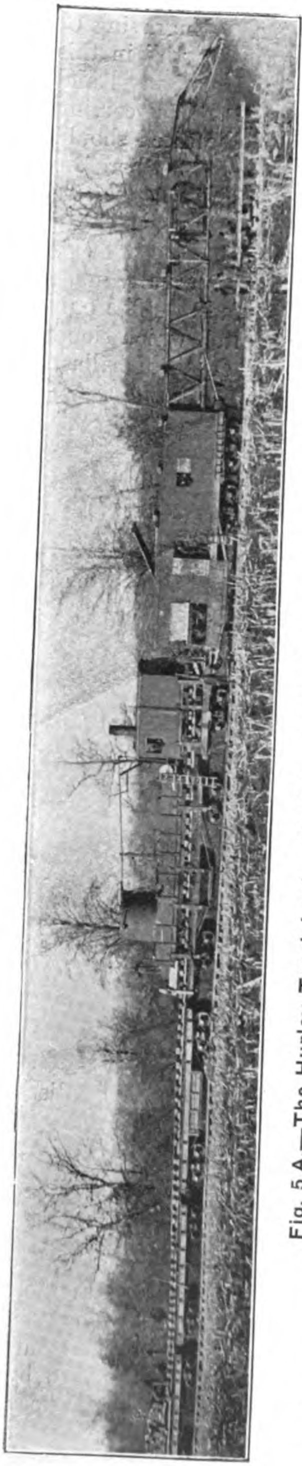

Fig. 5 A.—The Hurley Track-Laying Machine, in Use on the Bessemer & Lake Erie R. R.

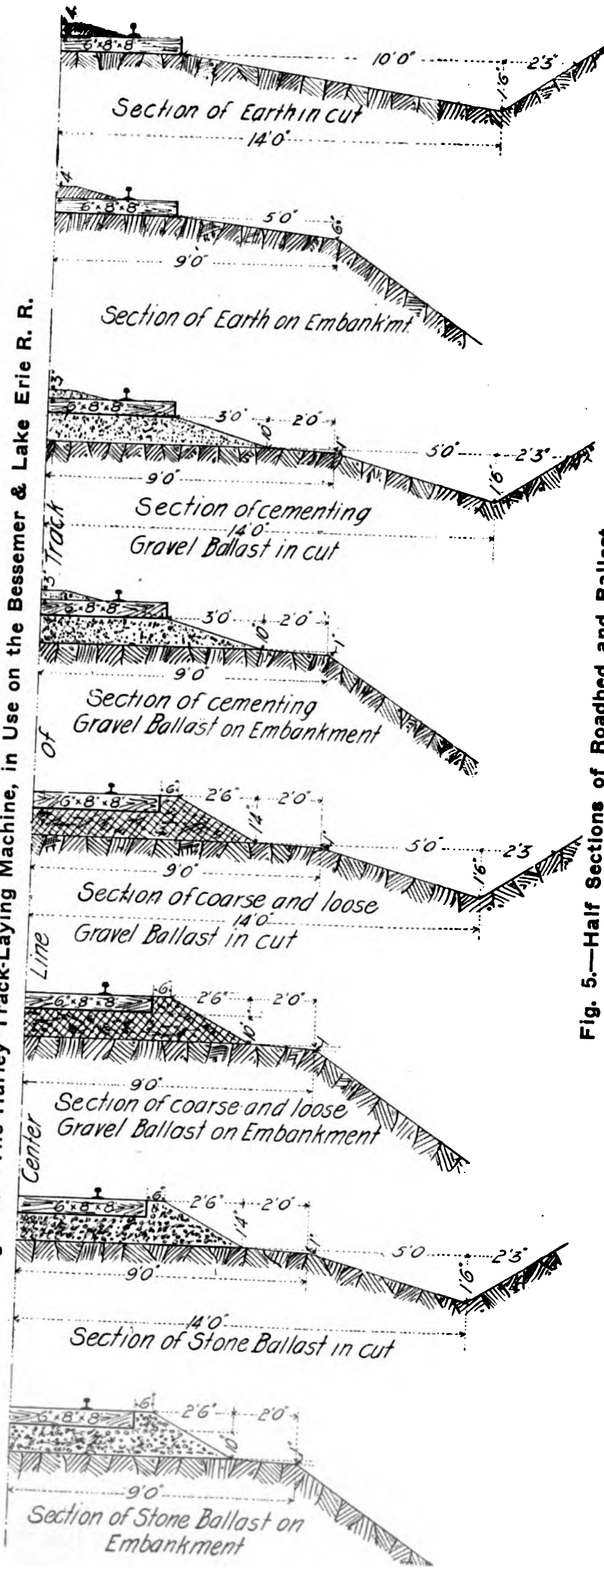

Fig. 5.—Half Sections of Roadbed and Ballast.

ing, or one which crowns just enough to drain the water into a broad, shallow ditch next to the slope. In clay cuts ditches should never be formed by shouldering the roadbed. Eight inches below sub-grade provides depth sufficient to carry off the water, and the toe of the slope,—that is the far side of the ditch—should be at least 12 ft. from the center of the track. Engraving *F,* Fig. 4, illustrates this arrangement. The depth and nature of the ballast required are discussed in §12.

One more case invites consideration, namely the ditch for dirt-ballasted track. Of course it goes without saying that such is not suitable ballast where there are springs under the track, but a ditch can be made which can drain the track of water coming from the side. A cut of 20 ft. width, for single track, will allow a shoulder about 2 ft. wide outside the tie ends, sloping away 2 ins., and a ditch about 18 ins. deeper, at an ordinary slope of 8 to 3, as illustrated by Engraving *G,* Fig. 4.

The foregoing seven conditions cover perhaps all the general problems which arise in ditch construction, or those which call for different methods of treatment. The depth of ballast needed and depth of ditch should, after the nature of the cut is known, determine largely the width of cut, and not the width of cut the depth of ballast and depth and slope of ditch. Bearing in mind that the variety of roadbed and ditch measurements here presented is due to a close study of conditions, to ascertain what might be considered the least measurements applicable to conditions which obtain in common practice, it may be explained that it is not usual to find so many standards in practice with one company. It is more frequently the case that a single set of measurements, large enough to answer the requirements of the worst supposable conditions, is made standard. The roadbed sections shown in Fig. 5 are an illustration of such practice, there being but one width (18 ft.) for roadbed at sub-grade, both on embankments and in cuts, and but one toe-to-toe width of roadbed in cuts (28 ft.). These sections represent liberal roadbed measurements in cuts. The standards of the Illinois Central R. R., even though more liberal, are yet quite similar, the only differences being in width of roadbed at sub-grade, which is 20 ft. both for embankments and in cuts, making the width of ditch 6 ft. 3 ins. instead of 7 ft. 3 ins., as shown in the illustrations. The gravel ballast is shouldered out 18 ins. beyond the ends of the ties, instead of 6 ins., and stone ballast is shouldered out to 12 ins., instead of 6 ins.

In excavating ditches the angular form of the standard cross section at the meeting lines of slopes (drawn that way for convenience of indicating dimensions clearly), should not be followed. The various slopes forming the outlines of the ditch should meet by curved surfaces; as, for instance, the bottom of a V-shaped ditch should be rounded out and not brought to a sharp corner. The rounded corner is the shape which results from the forces of nature and it applies to the edges of embankment slopes and the top edges of slopes in cuts as well as to ditches.

Where it can be done the ditch should be given grade sufficient to carry off the water with some rapidity; a fall of at least 4 ins. per 100 ft. is desirable, and 6 ins. per 100 ft. is a common specification. The dimensions of ditches shown on the standard drawings of railroads are usually supposed to represent the cross section of the ditch at the highest point. In case it becomes necessary to deepen the ditch to obtain a grade, as on level ground, the standard dimensions must then be exceeded. The standards of the Louisville & Nashville R. R., are different in this respect. On this road the ditches are made with a flat bottom and the width of roadbed between ditches is 16 ft. The grade of the bottom of the ditch must not be less than 6 ins. per 100 ft., wherever such is practicable. In summit cuts the ditches are 3 ins. deep at the summit and in level cuts they are 3 ins. deep at the middle of the cut, increasing to the standard depth of 12 ins. toward the ends. In cuts where the grades are steeper than ½ per cent the grade of the ditch is made parallel with the grade of the track and 12 ins. deep. This practice seems proper, because at a summit in a cut or at the middle of a level cut from which the ditches slope either way, there should be but little water in the ditches, and in long level cuts they must be made shallow at this point in order to avoid running too deep in obtaining the necessary grade. Deep ditches in soft material are objectionable, as already explained, and in any material the deepening of ditches in deep cuts requires the removal of large quantities of material in making the slopes.

Ditches should be made regular in width, and smooth, so that puddles of water will not stand in them, to afford a source for seepage. If, owing to the shape of the cut or for any other reason, a ditch cannot be made regular in width it is well to make the track side of it straight and parallel with the rails. Where there is an embankment or fill adjoining a cut the offtake ditch or ditches should be diverted from the made ground and carried around on solid material. Neglect of such precautions has been the cause of many a bad washout during times of excessive rainfall or sudden thawing. The track ditch may be turned into the surface ditch and the channel formed by the two combined may be run to the nearest culvert or stream. If the ditch must be carried over or near made ground the embankment may be protected against scour by paving or riprapping. Another arrangement having the same purpose in view is to conduct the water from the end of the cut through a line of large drain tile or sewer pipe laid to a good grade. Tile as large as 15 ins. in diameter has been used in cases of this kind. In long side-hill cuts it is seldom necessary to carry the water the entire length of the cut, as the ditch may be turned under the track at intervals, through box drains or culverts. In through cuts the ditches should be of the same depth on both sides of the track, on curves as well as tangents.

Tile Drains.—Valuable assistance to the drainage can be obtained by laying drains of farm tile under the ditches (Engravings *E* and *F*, Fig. 4). Especially is this the case in wet cuts or in cuts where there is not room for a ditch of proper width and depth, and in cuts where there is trouble in keeping the ditch clear of sliding material. The utility of tile drains or "blind ditches" has long been demonstrated by farmers, and the use of tile in railway work is increasing. The ditch serves to carry off water when it comes in quantities, as during storms or thawing weather, and seepage into the tile drain prevents water from standing in the ditch at ordinary times and also drains out the roadbed to the level of the tile. Where under drains are used the ditches may be made shallower than otherwise, and in some kinds of material this is a considerable advantage. To put the tile below frost, or at least below the action of hard frost, it is laid 2½ to 4 ft. deep. Water running continually in a tile drain will compromise the action of frost to some extent. In tile-draining a through cut it is usual to lay drains under both ditches. If practicable the drain should have some fall, 3 ins. per 100 ft. or ⅓ in. per rod, being desirable. Tile is made in 1-ft. and 2-ft. lengths, but the 1-ft. lengths are preferable for the sizes up to 12 ins. in diameter. Round tile at least 5 ins. in diameter is preferred for railroad service. It is frequently used in sizes up to 8 ins. in diameter, where the quantity of water so requires, and 6-in. tile is commonly in use. In very long cuts it may be necessary to increase the size of the tile toward the end of the cut or to lay two lines of tile in the same trench, but resort to either plan is unusual in practice. Glazed tile is stronger than the unglazed article for the same thickness, but if the unglazed tile is properly burned it is considered quite strong enough for practical purposes, and just as durable. Water enters a tile drain through the joints. Water under pressure will percolate through the wall of the tile in some quantity, but in ordinary drainage all that gets through in this manner amounts to but very little, and cuts no figure in drainage. Unglazed tile will absorb water until the pores become filled, but without some force behind it there is but little tendency to pass through.

Experts in tile drainage work have special tools for digging the trench and laying the tile. For excavating the top portion and body of the trench a long and narrow shovel or post-hole spade (Engraving *B*, Fig. 6) is used. The blade measures 5½ ins. wide at the step, 6 ins. at the cutting edge and is 18 or 20 ins. long. For sticky soil the skeleton ditching spade shown as Engraving *A*, with a blade 18 or 20 ins. long and 6½ ins. wide, is preferred. For taking out the bottom spading a round-pointed spade (Engraving *D*) with a blade 18 ins. to 22 ins. long, 5½ ins. wide at the step and about 4½ ins. wide at the cutting edge, is used for ordinary soil, and for sticky soil the round-pointed skeleton spade shown as Engraving *C*, with a blade 18 or 20 ins. long and 4½ ins. wide, is used. These tools enable the excavation of a narrow trench but little wider than the tile, if desired, thus

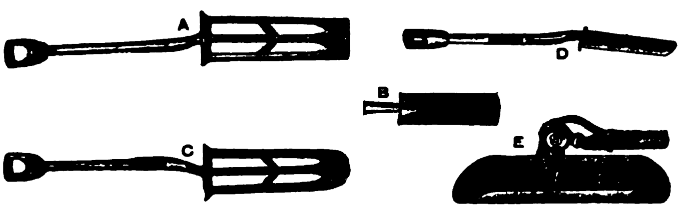

Fig. 6.—Tools for Tile Drainage.

saving something in material handled and expediting the work. To clean up the bottom of the trench for laying the tile a drain cleaner (Engraving *E*), consisting of a scoop with a long handle, arranged to draw toward the user, is employed. The blade is made of shovel steel, 15 ins. long and 4 to 6 ins. wide, according to the size of the tile. The handle can be adjusted to any angle convenient to the user, by raising the spring, and when the spring is in position the blade is locked against rocking. As a guide for dressing the bottom of the trench to a uniform grade it is customary to set grade stakes at intervals of about 30 ft. alongside the line of the trench, using an engineer's level. A ditch line is then tightly stretched from stake to stake, to the grade for the tile, and after the trench has been nearly completed in depth measurements are taken from this line for dressing up the bottom. A measuring instrument commonly used consists of a vertical staff graduated to feet and inches, with a horizontal sliding arm made fast by means of a thumb-screw. The arm carries a spirit level and is long enough (about 2 ft.) to reach the ditch line when the staff is stood in the trench. In railroad work where the track is in good surface the rail might be used as a reference for the grade of the trench. In order to have the trench in smooth condition for laying the tile, the workmen dress it to grade without stepping on the bottom. The sections of tile are laid to place with a hook on the end of a long handle. For laying tile through quicksand a sheet iron box, open top, bottom and rear, and commonly known as a "coffin," is used. This box, and the use of the same are described in §196, in Supplementary Notes.

The tile should be laid to a straight line and uniform grade, with the joints fitting closely. Some use a pole of round or square timber somewhat smaller than the inside diameter of the tile, to keep the tile properly lined up while it is being tamped and covered over. Each advance section of tile is strung upon the pole as it is pulled ahead one section at a time, the rear end of the pole remaining continually within the covered tile. When laying tile on very soft ground the precaution is sometimes taken to lay a narrow board in the bottom of the trench, to prevent displacement of the tile sections. When filling in the trench with loose material it is the practice with some to cover the tiling with inverted sods, moss, slough grass, hay, straw or some such material, to exclude fine particles of filling which might be washed into the tile through the joints. As a means of aiding seepage toward the drain some recommend filling the trench with coarse gravel or cinders, but not with loam or sand; while others of long experience claim that the water will readily find its way into the drain through any material, however compact, and for filling in the trench such men prefer to use only the material excavated, without straw or other screening material. The bottom spading is considered the best material to place directly upon and surrounding the sides of the tile. Stiff blue clay is considered excellent material for covering over tile. In cuts with wet slopes, where the bank is liable to slide, it is sometimes the practice to cut ditches diagonally down the slope to ease the grade for the running water. A better plan, where there is tile sub-drainage for the ditch, is to conduct the water down the slope through covered diagonal branch drains leading into the main line of tiling. A pile of loose stones or wire netting should be placed over the outlet of a tile drain to keep out muskrats and other small animals. To lay drain tile properly requires experience, and some railway companies find it cheaper and productive of better results to employ experts who have worked among the farmers, to do this work. Twenty-three cents per rod for the work of digging the trenches ($3\frac{1}{2}$ ft. deep) and laying the tile is a price that has been paid by the Chicago, Burlington & Quincy Ry. to contractors. Mr. Alexander Birss, Prairie, Wash., who was formerly engaged for a great many years as a tile-drainage contractor, in Iowa, has kindly favored me with some interesting information on tile drains and the work of laying them, which may be found in §196, Supplementary Notes, in the back part of this book.

As a substitute for tiling a continuous bundle of poles, trimmed of their branches and placed butts and tops, is sometimes laid in the bottom of the trench and covered over. Blind ditching may also be done by partly filling the trench with broken stones, preferably placing a plank in the bottom of the trench. A form of blind ditch much used by farmers in the eastern states is laid with flat field stones as a bottom paving, and on top of these, flat stones are stood edgewise leaning toward the middle of the trench from both sides, to form an inverted V-shaped opening 2 or 3 ins. wide at the bottom. Over these stones other stones are thrown in loosely and covered with the soil.

The most desirable way to ditch yards is by sub-drainage with tiling or, if the area to be covered is extensive, with branch drains of tile feeding into sewer pipe mains. Catch basins at points where water is liable to collect are desirable, as they prevent the formation of puddles of water between the tracks, which get covered with ice during freezing weather. The work of switching may be considerably expedited by maintaining the footing in good condition in all kinds of weather.

Ditch Paving.—The paving of ditches with cobble stones is practiced to some extent. Where coarse gravel is on hand the paving material is easily obtained and the work of laying it is not very expensive. Paved ditches retain their shape better than unpaved ones, because they are flushed by heavy rains, and if filled by sliding material or sediment washed down there is a good bed to shovel upon when cleaning out the ditch. To improve the appearance of ditches in the vicinity of stations the paving is sometimes whitewashed. Whitewash will keep the paving clear of grass, and if salt is mixed with the lime the whitewash will adhere better to the stones. Concrete paving or lining is also applied to ditches on a number of roads. Brick, cement and asphalt are materials used for paving some of the ditches on the Pennsylvania R. R. In ditches through soft material on steep grades some kind of paving is necessary to prevent gullying in time of hard rain storms. On some roads old ties have been used to good advantage in ditches where such protection is necessary.

Retaining Walls for Ditches.—Various means, some of which are mentioned in § 160, are resorted to for maintaining open ditches along sliding banks. A common method of securing the foot of a sliding bank is to build a thick masonry retaining wall and lay tile drains at the back side, under back filling of coarse gravel or broken stone. Such walls are usually built to a heavy batter, like ¼ to 1, and topped out with heavy coping stones. The bank is then sloped from the top of the wall, reducing the general slope and lessening the tendency to slide. In order to make sure provision for drainage, weep holes through the wall with a ditch in front of it are recommended. An interesting piece of work that may properly be referred to in the present connection is a concrete slope facing constructed at Chestnut street, St. Paul, Minn., to protect the tracks of the Chicago, Milwaukee & St. Paul Ry. from falling rock and other material. At this point there is a side-hill cut through soft sandstone for several hundred feet, the sandstone being overlaid with a limestone ledge and the latter surmounted by a glacial drift formation of sand, gravel, boulders, etc. The bank rests at a slope of about 1 horizontal to 2 vertical, and a cut-stone masonry retaining wall had been built along part of the distance to support the limestone ledge, which was constantly being undermined by the disintegration of the sandstone. As a means of cheapening the construction, a concrete facing wall, with brick pilasters at intervals to support the limestone ledge, was substituted for the remainder of the distance, it being assumed that if the sandstone could be protected against rain and frost its stability would be secured. The foundation for the facing wall and pilasters was put into the sandstone 4 ft. below rail level. The facing is 256 ft. long and 56 ft. high, and was built up by depositing concrete behind a wooden form built from the foot of the slope by stages and supported on bolts anchored to the standstone. These bolts were jointed about the middle of their length, and after the concrete had hardened the outer half of the bolt was withdrawn, the hole filled with cement mortar, the concrete facing thus remaining bolted to the sandstone bluff. The average thickness of the concrete facing below the ledge is 2 ft. 5 ins., and above the ledge, 3 ft. 2 ins.

5. Culverts.—The drainage of roadbed comprises ditches and culverts, the purpose of the latter being to convey ditch water or small streams underneath the track or to permit the escape of rain water, melted snow or springs draining toward an embankment. To be serviceable under all conditions a culvert must answer the requirements of size, and be secure in foundation and end construction against washing out. Respecting the first essential, engineers when laying out culverts should exhaust every resource available for estimating the quantity of water liable to flow along the streams crossed, especially those which are found dry at times. Where opportunities are at hand, as in settled districts or where roads or railways traverse the country, the most satisfactory way to estimate the size of culvert openings is by observation of the volume of flow during high water, either at the time or by high-water marks. To find the latter, observation may be made of existing openings on the stream or by examination of the banks, preferably where the stream is contracted; or by inquiry of parties familiar with the locality. Along with every party doing the preliminary surveying for a railroad there should be some man experienced in exploring or "cruising," who should scour the country surrounding for such information regarding the rainfall and the streams as will be of benefit to the company in the proper construction of its bridges and culverts. In placing culverts on an old road the determination of the sizes of the openings is less problematical, because exact records of high water should then be obtainable. In constructing railways in this country, and particularly in the West, it is extensively the practice to bridge the water courses with timber trestles, so that the construction of permanent works at the drainage openings is usually postponed until the wooden structures need renewing. This gives a period of some eight or ten years, during which time it is customary for both the bridge and track departments to keep record of high water at the various openings, as reported by the bridge inspectors and the section foremen. In a large proportion of the cases, therefore, there need be no uncertainty regarding the capacity of culvert openings. The contingency does sometimes arise, however, that the capacity of culvert openings must be determined upon where reliable information concerning the streams cannot be had. Under such a circumstance the engineer is compelled to resort to some basis for estimating the maximum rate of discharge through each opening. The investigation of such problems proceeds so largely upon matters of judgment that many are disposed to regard the accepted methods of calculation as in large degree conjectural, or as processes more or less entangled with guesswork. While it is true that much of the data made use of in such cases are necessarily assumed, or even guessed at, it is also true that some determination is compulsory, and guessing by method is certainly preferable to guessing at random. The amount of confidence to be reposed in calculations of this kind depends, of course, upon the experience and observing capacity of the engineer in charge.

Calculation of Maximum Flow.—Where reliable information cannot be obtained regarding the maximum flow of the streams the size of opening or, what leads to the same end, the maximum flow through the opening, is determined by some empirical rule or method of calculation. One of the simplest rules is to base the unit of opening area upon acreage. For instance, it is commonly the practice to allow a square foot of culvert opening for some certain number of acres drained, the relation of drainage area to the unit size of opening being ascertained from experience with the topographical conditions and rainfall of the particular section of country. To give one or two illustrations of such practice, the Chicago, Rock Island & Pacific Ry. allows for drainage, in Nebraska, Kansas and eastern Colorado, as follows, a single line of cast iron pipe being referred to each case: 16-in. pipe for 20 to 40 acres; 20-in. pipe for 30 to 60 acres; 24-in. pipe for 45 to 90 acres; 30-in. pipe for 70 to 140 acres; 36-in. pipe for 110 to 220 acres; 48-in. pipe for 180 to 360 acres. These allowances are based upon 14.3 to 28.6 acres per square foot of opening, or an average of about 21½ acres per square foot of opening. The wide latitude left to the discretion of the party in charge of construction enables him to take into account the variability of the topographical features, such as the slope of the ground, the state of the soil (whether cultivated or not), and the shape of the drainage basin; as, other features being similar, water draining out of a circular valley will flow off more rapidly than from a long, narrow valley of the same area. The rules in force on the New York Central & Hudson River R. R. when reliable records of the flow of water to be taken care of at any new culvert cannot be had, are similar. For 5 acres of steep land or 10 acres of flat land, 10-in. pipe is used; 12-in. pipe for 10 acres; 16-in. pipe for 20 acres, and so on up to 36-in. pipe for 110 acres. Compared with rules in force on some other roads for small culverts these openings seem small. On the Missouri Pacific Ry. it has been the practice to allow one square foot of opening to drain four acres of steep or mountainous land or six acres of flat or rolling land.

Another way of determining the area of culvert openings is by the use of an empirical formula, in which the factors are the drainage area and a variable coefficient to suit the conditions of the locality. The best known formula of this class, or the one which has been most extensively used in American railway practice, is the Myers formula, proposed many years ago by Mr. E. T. D. Myers, since then president of the Richmond, Fredericksburg & Potomac R. R., by which

$$\textit{Area culvert opening in sq. ft.} = C \times \sqrt{(\textit{Drainage area in acres})}$$

The values usually given to C are: for flat or slightly rolling ground, 1; for hilly ground, about 1.5; and for mountainous and rocky ground, 4. The important respect in which this formula differs from the foregoing rules is that the size of opening varies as the square root of the drainage area instead of by a straight proportion; which would make it appear that the so-called "rules" require an opening too large for the larger drainage areas. Such is probably the case, for it is well established that the rate of flood discharge from a large area compared with the rate from a small area for the same rainfall and same duration, is not as great as the ratio of the two catchment areas. In the Talbot formula the size of opening is made to vary as the fourth root of the cube of the drainage area, thus:

$$\textit{Area culvert opening in sq. ft.} = C \times \sqrt[4]{(\textit{Drainage area in acres})^3}$$

In this formula the coefficient C takes a value varying from $\frac{2}{3}$ to 1 for steep and rocky ground; and $\frac{1}{3}$ for rolling agricultural country subject to floods at times when snow melts, where the valley is three or four times as long as it is wide; if the valley is longer in proportion to width the value of C is decreased still further. In districts where snow does not accumulate, C is taken at $\frac{1}{5}$ or $\frac{1}{6}$, or even less, for oblong valleys. In the case of either of these two formulas it is quite apparent that experience and good judgment are essential to a proper choice of coefficients. In any case of uncertainty in this respect the opening should be given the benefit of the doubt.

The most thorough way of getting at the proper size of waterway, where authentic report concerning the maximum flow of the stream is not procurable, is by a survey of the drainage basin and the various conditions which affect the situation. Such work is sometimes undertaken for openings of considerable importance. On the Atchison, Topeka & Santa Fe Ry. it is the practice when constructing new culverts to send an engineering party around the watershed and have a rough survey made of the drainage basin. Although there are numerous formulas which may be applied to some of the elements concerned in an investigation of this kind, I think I can do no better than follow the sense of a paper on this subject presented before the Institution of Civil Engineers by Mr. George Chamier, in 1898. The elements which must be taken into account as a basis for calculating the maximum discharge are (1) drainage area, (2) rainfall, (3) amount of surface discharge and (4) the diminution in proportionate flood discharge due to area. Regarding the drainage area the form and greatest length of the catchment basin are all important, as well as the extent, for upon these features depends the time required for the flood water to reach the outlet from all parts of the drainage basin. Thus, with surrounding ridges of the same elevation, in either case, the discharge of flood water from a circular basin takes place more rapidly than from an oblong basin, for the reason that the distances traversed by the various streams are shorter and the declivities greater. The general slope of the ground over the catchment area and the outlines of the valley traversed by the main stream are also important, as affecting the velocities of the streams. The estimation of the time required for the flood water to reach the outlet from the farthest point of the basin calls, of course, for the judgment of the investigator. The velocity of the water increases as it collects into well defined channels. The time required for rain water to flow off the surface into the brooks is rather conjectural, in any case, but the rate of flow over grassy surface may be taken at ½ mile per hour for moderate slopes, and 1 mile per hour for steep side-hill. Under average conditions the velocities of streams range from 2 to 4 miles per hour, but in mountain torrents and rapid rivers much higher velocities have to be considered. The velocity in any case can be ascertained approximately from the dimensions and inclination of the channel, with some assumption as to the probable volume of flow at times of flood. The reliability of all such estimates depends, of course, upon the experience and judgment of the calculator.

As to rainfall it is desired to know the maximum downpour during a period corresponding to the size of the drainage area—that is, for such a time as is required for the flood water to reach the outlet from the farthest extremities of the basin. The maximum rate of precipitation occurs only during short periods, of an hour, or a few hours, at most, so that, for the smaller drainage areas, for which the duration of fall to be considered is necessarily short, it would be incorrect to estimate the maximum fall in proportion to the maximum daily fall. Thus, for instance, it is not uncommonly the case that 25 per cent of the maximum daily fall is registered in an hour. In order to get at flood discharge it is, of course, essential to have some record of the rainfall for the section of country, and in order to anticipate the greatest rainfall for short periods with a reasonable degree of assurance it is necessary to have approximate data as to the diminution of the rate of fall with the duration.

As to surface discharge, it is known that, owing to absorption of the soil, evaporation and percolation into subterranean passages, only a portion of the rainfall need be taken into account. The ratio of the water which flows off the surface (and finds its way into streams) to the total amount of rainfall is known as the "coefficient of surface discharge." For countries where heavy rains are liable to occur when the ground is frozen this coefficient is usually assumed at ⅔, while for rocky mountain slopes without fissures, very steep ground, or paved streets the assumed value may exceed 0.80. As a general rule the coefficient of surface discharge is taken at some value between ⅓ and ⅔. Mr. Chamier's estimates are as follows: For flat country, sandy soil or cultivated land the coeff. disch. is taken at 0.25 to 0.35; for meadows and gentle declivities, absorbent ground, 0.35 to 0.45; for wooded slopes and compact or stony ground, 0.45 to 0.55; for mountainous and rocky country or non-absorbent surfaces, 0.55 to 0.65. It is clear, of course, that the maximum ratio of surface discharge to rainfall does not obtain until the ground has become thoroughly saturated.

Aside from the diminution of the discharge due to the above causes there is also a diminution due to causes which act upon the water after it has collected into streams, such as evaporation, which in hot climates is great; and absorption by overflowed lands or by irrigation; or percolation through the banks. In limestone countries streams of considerable size sometimes entirely disappear into underground channels. And then the flow of some streams is impeded, and the rate of discharge diminished, by obstructions in the form of dams or accumulations of flood debris, while lakes and swamps are well known regulators of flood discharge. For average cases Mr. Chamier gives $(\sqrt[4]{M^3}) \div M$ as the ratio of decrease of flood discharge due to area, where M denotes the area of the drainage basin in square miles. Observation of, and experience with, the conditions in particular localities would quite likely find different powers of M suitable to the various conditions obtaining. Thus it appears that in determining upon the data for the solution of the problem the judgment of the investigator is called into service at every step.

Having considered the various elements of the problem in some detail the formula for flood discharge at the outlet follows by the simplest logical process, being

$$Q = A \times R \times C,$$

where Q denotes the maximum discharge in cubic feet per second; A, the number of acres; R, the average rate of greatest rainfall anticipated, in inches per hour, for such duration as will bring flood water to the outlet from the most distant point of the drainage basin; and C, the coefficient of surface discharge. If the drainage area exceeds 1 square mile, the formula must include the factor for diminution of discharge according to area, and it then becomes

$$Q = A \times R \times C \times (\sqrt[4]{M^3}) \div M;$$

or, substituting for A in terms of square miles, the factor $(A \div M)$ disappears and we have

$$Q = 640 \times R \times C \times \sqrt[4]{M^3}$$

One inch of rainfall per hour over a surface of 1 acre is at the rate of 1 cu. ft. of water falling per second, which is the rate of discharge, supposing all the water to flow off. Having ascertained the maximum discharge to be anticipated at the outlet, the area of the opening will depend, of course, upon the velocity of flow, which is frequently assumed at 10 ft. per second. In the case of mountain torrents and rapid streams, where the velocity exceeds this figure, the error is on the safe side; and if the natural velocity is less than the figure assumed the amount of head necessary to produce a velocity equivalent to the difference is but small, and if the foundation of the structure is secure against scour there need be no concern if discharge occurs under moderate pressure.

Before dismissing the subject of calculating culvert openings it should be borne in mind that rainfall is not always the only source of flood water to be taken into account. In regions where snow accumulates or falls to considerable depth the highest floods may occur when the snow melts, as then the flow of water may be due to heavy rainfall and melting snow combined. Thus, for instance, in some parts of the State of Washington, on the western slope of the Cascade mountains, the most troublesome freshets occur late in the fall, when heavy rains, accompanied by a "Chinook" wind, fall upon heavy accumulations of October snow. To know the extent to which melting snow contributes to the volume of flood water requires special knowledge of the climatic conditions obtaining in particular sections of country, and the matter is so important that it should never be lost sight of in fixing upon culvert areas. In building a road through a wooded country waterways should be made about double the size found necessary for use at the time they are built, so as to allow for the increased rate of drainage after forests are cleared away, swamps drained, etc.

Open Culverts.—Where the track crosses small rapid streams which wash down large quantities of drift, and the track is close to the bed of the stream, it is sometimes necessary to construct an open culvert, in order that the opening may be accessible for cleaning out when it becomes filled or obstructed. Formerly it was much the practice to construct such culverts by merely laying two stringers across walls of masonry or heavy sills, to carry the rails. In some sections such is known as a "beam" culvert. Such openings in the track are not to be advised, as in the case of a derailed car or truck running into the same there is certainty of wreck to the train. Where an open culvert is unavoidable a standard bridge floor should be built over the opening. When it becomes necessary to clean out such an opening it is an easy matter to remove some of the ties or spread them apart. Another occasion for shallow openings under the track arises in irrigation districts, where the right of way is crossed by ditches or canals in which the water level is but slightly lower than the track. On the El Paso division of the Southern Pacific road trough stringers have been used for the support of the track rails over irrigation ditches. This stringer is formed by riveting two 12-in. channels (placed back to back) to a third channel of same width placed open side downward between them. The rail rests upon 4x12x12-in. creosoted blocks placed in the trough, the depth of which is such as to bring the top of rail flush with the top of the stringer. The fastening for the rail consists of clips, with bolts passing through block and bottom channel. For 15-ft. spans the sides of the trough are formed of channels each weighing 50 lbs. per foot, and for 12-ft. spans the channels weigh 30 lbs. per foot; the bottom channel used in either case weighs 30 lbs. per foot. At the ends the stringers are anchor-bolted to 12x12-in. caps with bearing plates 1 in. thick between the two. On the Pacific system of the same road a similar method of support is employed in crossing irrigation ditches, the stringer supporting each rail in this case consisting of two pieces of T-rail 5 ft. long, spaced just far enough apart to permit the flange of the track rail to lie in the opening between their webs. The flange of the track rail fits closely under the heads of the two stringer rails and is supported upon bolts passing through the webs of the stringer rails at intervals of 18 ins. In some places there are as many as three consecutive spans of these T-rail stringers.

Wooden Box Drains.—Box drains made of plank of durable lumber, like cedar, are admissible for small cross drains where the depth under the track is not sufficient for masonry or pipe culverts. Such a box may be made by spiking together four 3x12-in. planks, standing the side planks within the edges of the bottom and cover planks. It should be made 15 or 16 ft. long for single track roadbed, or long enough to reach to the ditch line. The ends may be sloped to conform to the side of the ditch or slope of the shoulder. When placed between the ties such boxes are usually left open on top, the sides being held apart by flat strips nailed across the top edges. If there is much fall in the water directly upon leaving the box the ground should be paved with stones for a safe distance, or, if the quantity of water amounts to nothing more than a trickling stream, as from a permanent spring, it may be conducted away by a V-shaped trough made by nailing together two 1x6-in. boards. Where one box of this kind is not large enough to carry all the water which may come at times, and the track is not high enough above the stream to admit of a deeper closed culvert, a partitioned box may be used, spacing the partition planks, say, 12 or 15 ins. apart, the number of partitions made depending upon the width of opening desired. In this case the bottom and cover planks should be spiked on crosswise the box. All such small passageways should be at least 6 ins. below the bottoms of the ties. The use of a box drain is superior to the practice of leading small streams or springs under the track by an open ditch and placing the track upon stringers thrown across the ditch. These stringers will continually settle and give trouble. For unimportant side-tracks such a makeshift may answer well enough, using ordinary 8-ft. ties for stringers. To prevent the track ties from slewing out of their proper positions they may be drift-bolted to the stringers, or cleats may be nailed to the stringers between the ties, or a board may be laid outside each rail, parallel to the same, and nailed to the ties. A substitute for a box drain is sometimes made by building a walled trench about 12 ins. wide in the clear and paved on the bottom. The trench opening comes in the space between two ties, and, being open, can readily be cleaned out when clogged with mud or ice. To prevent people from stepping into such openings in the dark they should be provided with a removable plank cover.

Along side-hill cuts it is a good plan to carry springs (where there are but a few of them some distance apart) directly across the track at the point where each comes out, instead of allowing two or more to flow together before leading them across. In long through cuts where the track is curved and water runs continually, it should be carried under the track from the ditch on the outside of the curve to the ditch on the inside of the curve, at frequent intervals, so that it may run against the bank; if it was to run altogether in the ditch on the outside of the curve it might cut into the roadbed or into the ballast on the shoulder.

Timber Culverts.—In districts where timber has been plentiful it has been used in culverts a great deal, especially where difficulties have stood in the way of delivering permanent materials at the site of the culvert in time for the graders. In timber countries such culverts can be quickly and cheaply built, and under certain circumstances such construction is undoubtedly economical. As most kinds of wood placed in the ground will rot out in 8 or 10 years the larger number of timber culverts have been built only with the idea of temporary construction. In such cases it is intended to make ample allowance in size for reconstructing the culvert at some future time with durable materials, as of masonry or pipe, placing the new structure inside the old one without disturbing the embankment, which, during the life of the wooden culvert, should become well settled. Where durable timber, such as cedar, is obtainable, however, wooden culverts are sometimes built with a view to permanency. On the Canadian Pacific Ry. cedar timber is used in small culverts quite extensively and in the western parts of Washington and Oregon, where such timber is abundant, it is largely used for railway culverts. The estimated life of such timber is 150 to 200 years, as determined by the fact that almost everywhere in the cedar forests trees may be found lying in the ground partially or wholly covered, in perfectly sound condition, with other trees growing on top of them as old as the age stated. Some consider that timber of this quality will outlast many kinds of stone, where the masonry is exposed to moisture and freezing. On the Southern Pacific road timber barrel culverts built of creosoted staves are used to some extent. The material for the culvert, including the portals, is cut according to plan before creosoting. Culverts of this material are built in sizes of 24 ins., 36 ins., 48 ins., 66 ins. and 72 ins. diameter, the cost, for material and labor, not including the portals, ranging from $1.06 to $4.90 per lineal foot of pipe. There are also some locations where timber culverts are applicable to better satisfaction than others, owing to the difficulty of obtaining suitable foundations. Such is the case on marshy ground, where, in considerable depth of peat, the cost for masonry foundations would be heavy. Furthermore, peat is said to have a preserving effect on timber, while in some cases bog water has been found to act injuriously on cement and concrete.

Timber culverts of large size, or when placed under high embankments, are usually built on a flooring of 6x8-in. or 6x12-in. timbers laid on flat, and in contact, crosswise the channel. These floor timbers usually project some distance beyond the sides of the culvert—all the more so if the foundation is soft or yielding. The side walls or partitions (if any) are formed of 8x8-in., 10x10-in. or 12x12-in. timbers laid on top of one another and drift-bolted together and to the floor. In some cases the floor timbers are gained out for the side-wall timbers about 1 in., forming a shoulder to prevent the side wall from being crowded in by earth pressure. The thickness of the cover timbers may vary from 6 ins., under the outer portions of the slope, where the depth of filling is shallow, to 8 ins. farther in, and to 10 or 12 ins. under the central part of the embankment, where the filling is deepest. Of course the span and depth of filling has all to do with the thickness of the cover timbers, which are laid crosswise the culvert, with every fourth, fifth, or sixth piece notched 2 ins. over the side timbers to take the thrust of the side walls. The span of opening in timber culverts usually ranges from 3 to 6 ft., partitions being used if a single opening of the larger dimension does not afford sufficient area. Old bridge timbers are not infrequently utilized in culverts of the kind here considered, and what are known as "bridge-tie" box culverts are sometimes built of new timber. Such are constructed of 6x8-in. bridge ties laid on flat in the floor and walls, and edgewise in the covering. On the Tennessee Central Ry. culverts are constructed of oak timber, the largest openings so built being 4 ft. wide and 5 ft. high. The sub-sills are 10x12-in. timbers laid flat and the side walls are 12x12-in. timbers drift-bolted together and stepped off on the faces. The floor is laid with 2-in. oak plank and the covering of the culvert consists of 8x12-in. timbers laid flat, or 12x12-in. timbers, varying with the hight of the embankment.

An interesting application of the scheme of building a wooden culvert to be reinforced later with more durable material inside is to be found on the Chicago, Burlington & Quincy Ry., where a heavy timber barrel culvert is first constructed, and after the embankment has settled the barrel is lined with brick. These culverts, which are made as large as 6 and 8 ft. in diameter, are built of staves 10 or 12 ins. thick, according to the size of the structure, and 8 ins. wide at the outer circumference. The staves are drift-bolted together and formed over heavy rings made of old rails, spaced 10 ft. apart. These rings remain in the culvert, and to prevent distortion of the barrel where the pressure of overlying material is excessive it is propped with heavy posts, and cross bolts are placed to prevent bulging at the side. After the embankment has ceased to settle the barrel is lined with a single ring of brick placed edgewise and faced with a layer of cement mortar, and parapet walls of stone masonry are built.

Stone Box Culverts.—Masonry culverts of suitable weathering stone, if properly built, are very durable, and in localities where such material is obtainable within convenient distance it is frequently selected for permanent work. The side walls of stone box culverts are usually laid with rubble stone, and preferably in cement mortar, so as to provide for discharge under head. Water discharging under head through a dry stone box will be forced behind the walls, gradually carry out the back filling and eventually cause a washout. Sand in embankments will also find its way through the openings in such culverts, leaving cavities which will cause the roadbed to settle or lead to a washout should the culvert become surcharged. Right in this connection attention should be called to the importance of filling over and around the culvert with material which will become compact and form a barrier against filtration through the bank. If the space about a culvert is filled in with loose stones and the water becomes dammed, part of the flow will take place outside the culvert opening, and where the loose stones meet the earth filling the water will cut a hole for itself and cause a washout. Some remarks contained in a letter from Col. E. T. D. Myers to a committee of the Association of Railway Superintendents of Bridges and Buildings, in 1897, bearing on this matter, are to the point. He says, in part:

"I am persuaded that it is rather in the superior construction, the infinite painstaking to insure the safety of a culvert when it ceases to be a mere covered channel and becomes a pipe discharging under pressure. When this takes place the ordinary culvert is too apt to fail to do its duty. Between the hastily constructed dry stone box and the thoroughly-built concrete, brick, or stone culvert there is room for a legion of catastrophes. . . . . I am of the opinion that it is more often the crude method of construction than the underestimation of the area of the waterway that gives us trouble on the railroads. When a railway embankment is called upon to act as a dam, as it may be in great floods, it should possess the qualities of a dam, and the outlet from the piled-up waters above it should possess the same integrity as the drainage culvert of a reservoir. Its foundation should be as secure, its masonry as impervious, the embankment immediately surrounding it as free of voids, the inlets and outlets as carefully protected from abrasion."

Whatever the size of opening required the culvert should, if the depth of filling will admit, be made high enough to permit a man to walk through it—say 4 ft., if possible, although a less hight will answer. On some roads the minimum size of masonry box culverts is limited to convenient dimensions, as on the Northern Pacific Ry., where the smallest opening allowed is 9 sq. ft. clear of all obstructions, the hight of the opening never being less than the width. In other cases it is considered that nothing is saved in making stone box culverts smaller than 3 ft. square, for streams however small. As to width, the natural channel of sluggish streams may be contracted to some extent, where ordinary conditions prevail, but in building over rapid streams or ravines it is not safe to encroach upon the natural width of the stream as indicated by the channel which it has cut for itself. The hight of the culvert floor relatively to the surrounding surface is important. In the case of a well defined stream it is of course necessary to go at least as deep as the bed of the stream, in order to secure a suitable foundation, but in any case the culvert should be low enough to drain low-lying land without backing the water, particularly where the land is under cultivation. But unless the land falls away immediately from the outlet the culvert floor should not be lower than this. Submerged culverts are unsafe, as, sooner or later, they are almost sure to silt up and become reduced in effective area if not completely obstructed. If a channel be cut from the outlet deep enough to drain the culvert floor the culvert may be placed lower than the situation would otherwise permit.

The foundation work of culverts signifies all that the term implies in connection with other structures of permanent character. On a solid substratum, such as rock, hardpan, gravel or firm clay, the matter is easily decided upon, as then it is only necessary to prepare a smooth bed for the footing courses. On yielding ground some additional means of support should be resorted to. This may consist of a timber platform or grillage, to distribute the weight of the walls over more surface than would be possible with the footing courses; or it may consist of a bed of concrete; or a brick or concrete invert; or, if the ground is yielding to an unusual degree, it may consist of piling overlaid with a timber platform or bed of concrete. The use of timber is not advisable unless the foundation is continually submerged. For light walls the timber foundation may consist of a simple flooring of timbers laid in contact, crosswise the direction of the walls, but for heavy work a framework of crossed courses is usually required. Old bridge timbers, ties, floor beams or stringers still in fairly sound condition answer for such work just as well as new timber. On firm ground concrete is much used in footing courses, and on yielding ground it is used in beds or in the form of an invert. Except in rock or hardpan the excavation for culvert foundations should extend at least 3 ft. below the surface. It is a common fault with culverts that the side walls do not extend deeply enough into the ground, the result of which is that in freezing climates the frost heaves them up at the ends.

The original and most common covering for stone box culverts is large flat stones. In practice the thickness of cover stones is independent of the hight of embankment, being about 12 ins. for openings of 3-ft. span, 15 ins. for 4-ft. spans and 2 ft. for 6-ft. spans, which is about the widest clear opening under stone covering in general practice, although in exceptional cases there are openings as wide as 8, and even 10, ft. covered in this manner. It is usually required that cover stones shall have a bearing upon the side walls of at least 12 to 15 ins. and be laid to close joints, which should be filled and spread over with cement mortar, to form a tight covering, lest the filling material might become softened and ooze out through the openings should the culvert discharge under head.

Late years old rails, laid across the opening and covered with concrete, have been much used for culvert covering, as on most roads the material is conveniently available and such a covering gives the maximum permissible headroom under a shallow embankment. Another advantage is that in case of an unstable foundation the rail top adjusts itself better to settlement of the walls than is the case with stone covering or arches. The rail top is proportioned somewhat roughly to the load or amount of filling material supported. This may be done in one way by spacing the rails, laying them close together, with the flanges touching, under the central portion of the embankment, and spreading them apart under the sloping parts of the embankment. For heavy loads the rails may be laid in a double course by inverting the top rails so that their heads hang downward between the rails of the lower course, which stand workwise. Over long-span openings it is customary to reinforce the rails with two or more I-beams of good strength laid among the rails directly under the track, old bridge girders or floor beams being suitable for such purpose. Openings up to 12 ft. and sometimes 14 ft. clear span are covered in this manner, while rails alone, laid in a single course, are considered sufficiently strong for openings up to 8 ft. span. For spans longer than 12 ft. two openings may be used with a common pier between them. On the Portland & Rumford Falls Ry. four pairs of rails riveted together base to base, to form girders, are placed under each track rail to strengthen the covering for openings of 10-ft. span. Rails under the shallower parts of the embankment are usually spaced 6 to 12 ins. apart, according to the span of the opening, and the intervening spaces are planked or set with paving brick placed side by side upon the flanges of the rails (endwise between the webs) to form a bottom for the concrete before it has set. The rails usually extend 12 to 18 ins. over the culvert walls, according to the span. To protect the rails from rust they are usually given a coating of hot coal tar and filled in between the heads and over the tops with cement mortar, which is then covered with concrete. On the Chicago, Burlington & Quincy Ry. rail tops for culverts are laid in 6-ft. sections, separate from the walls, so that if it should become necessary to remove the same in places it can be done without badly breaking up the culvert. The concrete covering for rail-top culverts is made 4 to 18 ins. thick above the tops of the rails, according to the culvert span and hight of fill, and to provide for drainage the top surface is sloped either way from the center of the embankment. This increase in thickness of cover from the ends of the culvert toward the middle also accords with the increase of pressure from the embankment and provides some margin against a dished top in case of excessive settlement under the central portion of the embankment. Weep holes are sometimes left to permit the escape of such water as may collect. Where the grade of a culvert is very steep, as on a rock slope, the covering of the culvert, instead of being laid parallel with the floor, may be stepped, so as to better retain the filling on top. At the ends of the culvert an I-beam, channel iron, stone or concrete parapet is placed upon the rails to retain the foot of the embankment slope. This parapet is backed up by the top step or top course of the wing wall, the first stone of which is doweled to the wall underneath to resist the pressure of the embankment against the parapet.

On the New York Central & Hudson River R. R. rail tops are used on concrete or masonry culvert walls for spans of 4 to 14 ft., the larger openings that are covered in this way being under the higher banks. Old rails in weights of 60 to 100 lbs. per yd., according to the length of span, are used, being first thoroughly cleaned and then painted with a coat of red lead and oil and a second coat of bridge paint. The rails are set workwise, close together, and under each track rail the cover is reinforced with six inverted rails with the heads matched in between those of the bottom layer. The spaces between the rails are then filled with concrete made of finely broken stone or gravel, deposited in a layer 1½ ins. higher than the tops of the rails at the center and ½ in. higher at the sides. The concrete layer is covered with a ¼-in coating of American straight run coal tar pitch. The edges of the covering are finished with a concrete curb 2 ft. wide and 1 ft. thick, and in shallow banks the space above the culvert, as far as subgrade, is filled in with gravel.

For spans of 16 and 21 ft. the Cleveland, Cincinnati, Chicago & St. Louis Ry. has used a covering that is known as "concrete girder" construction. It consists of two layers of old rails embedded as a reinforcement to a thick bed of concrete, one layer of rails being near the bottom and the other near the top. For a clear span of 16 ft. the covering is 2 ft. thick, and the two layers of rails are molded in 2 ins. from the bottom and top, the top layer standing workwise and the bottom layer inverted. Under the tracks the rails in each layer are spaced 9 ins. centers, but between this and the parapets the spacing increases to 11½ ins. and 17 ins. To give the rails holding power in the concrete ⅞-in. dowels 8 ins. long were inserted in holes drilled through the web 12 ins. apart. In the construction of a covering for a double-track structure, 70 rails of 60-lb. section, 20½ ft. long, were used. For a double-track structure of 21 ft. clear span, a composite steel and concrete covering 2½ ft. thick is used. Under the tracks the rails are spaced at 9 ins. centers, as in the design for the 16-ft. span, but outside the tracks the spacing increases to 11½ ins., 17 ins., and 18 ins., centers. The rails in this case are 25 ft. long. These concrete-steel coverings, which have been applied to culvert or bridge openings on the St. Louis division, were constructed at the side of the track and rolled into place afterwards. The side walls are of concrete.

Under deep embankments the walls of culverts may be proportioned to the load, with some economy of masonry, the thickness being gradually increased from the ends, where the load vanishes, to a maximum under the central portion, where the load is greatest. Means must also be provided to prevent the walls of culverts from being forced in by the pressure of the earth filling. On rock foundation the bottom of the wall may be secured by doweling, and in the case of other foundations the paving acts as a strut to prevent crowding of the walls at the bottom. It is customary, however, to build cross walls or concrete struts between the footings, at intervals, to resist the side thrust against the walls. To secure the walls at the top it is usual to abut the rail top or stone covering against a shoulder on the top face of each wall.

In building culverts where the ground freezes to good depth in winter some attention should be directed to the conditions influenced by the quality of filling material over the top of the culvert. If this filling is shallow it will freeze deeper or harder than other parts of the embankment, being exposed both top and bottom. In such cases the filling directly over the culvert should be made with broken stone, coarse gravel, slag or other material which does not heave when frozen. The range of depth to which the necessity for such filling material applies depends, of course, upon the severity of the winters, or upon the thickness of material that will be frozen entirely through, from top to bottom. Then, too, when not deeply covered up the culvert itself is liable to be disturbed by the action of the frost, if the filling material is retentive of moisture. Owing to the action of frost and the jarring effect of trains it is desirable, at least with large culverts, to have a good depth of filling over the top. It is sometimes necessary, however, to make it as shallow as 1½ or 2 ft. Where the available headroom under the track is not sufficient for a single opening of the required area and of desired proportions the requirements may usually be fulfilled in the construction of a wider culvert of less hight, by partitioning. In such event the movement of ice and flood trash and the matter of protecting the culvert against the same may have to be taken into account.

End Construction, Paving etc.—Culverts without end walls should extend from toe to toe of the embankment slopes. It improves the general appearance of things to have the end construction conform to the slope of the embankment. In the case of box culverts, of either timber or masonry, or arch culverts of short span, this is usually done by stepping the side walls beyond the parapet, which is placed about where the top of the culvert meets the embankment slope. With masonry culverts the walls are not usually stepped lower than 3 ft. above the floor, at the end. The stepped portion of the wall should be coped with stones of good size, each step being formed by a single stone (Fig. 7 C), block rubble or roughly dressed stones being used for rubble masonry. Such end construction leaves the walls in convenient shape for the extension of the culvert should occasion arise in double-tracking the road or in the construction of side-track. In rare instances the sloping of stone culvert walls beyond the parapet is done by laying the coping stones to the slope of the wall (Fig. 11) instead of stepping them, while with concrete walls the sloped coping is found more frequently than the stepped coping. To increase the capacity of a culvert built with straight side walls from end to end, as presently considered, the face of the wall is sometimes splayed by gradually decreasing the thickness of that portion of the wall lying between the parapet and the end of the culvert, the wall remaining straight on the back side. Where drift is bothersome stepped culvert walls which run straight beyond the parapet are not considered as safe as walls carried to full hight all the way to the end, for the reason that, should the opening become clogged the full hight at the end of the wall the water may still pour into the culvert through the open top between the parapet and the end of the wall.

Culverts built to carry streams which overflow their banks at times should be provided with end walls to protect the embankment from scour by the currents which converge to the opening. End walls for culverts are of two kinds: head walls, which stand at a right angle to the axis of the culvert (Fig. 12); and wing walls, which stand at an oblique angle to said axis—15 to 45 deg., but usually about 30 deg. (Fig. 8). In either case the end wall usually serves to retain the embankment, as it usually stands on or starts from the meeting line between the top of the culvert and the embankment slope (or some little distance back of such a meeting line, depending upon the hight of the parapet). The coping of the wing wall is usually stepped to conform to the embankment slope. All coping stones should extend the full width of the wall. The earth which slopes past or around the flanks of a head wall is usually retained and protected by hand-placed riprap. To prevent undermining, head and wing walls should be carried down to good depth. For large culverts such walls usually stand at a batter.

The junction between a wing wall and the body of a culvert should be on line with the face of the side wall; that is, at the point where the side wall of the culvert joins the wing wall there should be no re-entrant angle or projection of the side wall into the splayed opening between the wing walls, such as occurs in Fig. 8. The projecting corners or shoulders impede the flow of water at the entrance between the side walls, thereby diminishing the discharging capacity of the culvert, other conditions remaining the same, and they also form lodging places for drift material. A plank or stick of timber floating against such a projection will swing around with the current and, if it be longer than the width of the culvert opening, will meet the opposite wall and become lodged across the channel and held there with great force by the pressure of the current. Danger of obstruction in this manner is greater with small culverts than with large ones, but such construction is inadvisable in any case, because the extra corners increase the cost of the masonry. One way of avoiding this projection is to build the side walls of the culvert to a batter, as in Figs. 8 A and 12 A. To avoid such projections with battered wing walls and plumb side walls it is necessary to set the wing wall inward far enough to bring it flush with the face of the side wall at the top of the culvert or springing line of the arch, and then form to a vertical face, on line with the side wall, that portion of the wing wall corner which would otherwise project into the waterway. For rapid streams of considerable volume wing walls are preferable to a head wall, on the up-stream end, as they increase the discharging capacity of the opening and facilitate the passage of drift material. The intermediate walls of partitioned culverts should be pointed or formed into a cutwater on the up-stream end to split the current and increase the flow at the entrance. On the down-stream end flared walls are not usually necessary.

The floor of a culvert should, if practicable, be laid to a grade, a fall of at least 3 or 4 ins. per rod being desirable. The grade actually required is something more than the average fall of the stream in the vicinity of the culvert. If this is exceeded the increased velocity of the stream through the culvert will keep it clear of sediment and increase the discharging capacity. In deeply covered culverts the grade should be increased over the lower third of the length so as to drain the middle portion in case the culvert sags, which is quite liable to happen, owing to the preponderance of earth pressure over the middle portion. This arrangement, in effect, gives the culvert a camber, with down grade all the way. If the culvert stands level it should be cambered a few inches to allow for sagging. Should settlement at the middle not take place to the extent anticipated, the camber that remains will do no harm, as it will only run the water to the ends in case the culvert goes dry, and possibly cause the culvert to silt up a little at the upper end, which is not so objectionable as to have the culvert sag and silt up nearly its whole length, and deepest at the middle. The sagging of culverts sometimes stretches the walls apart, but where the walls are cambered this is not liable to happen unless the settlement exceeds the amount of cambering put in. In order to prevent parting of the walls in this manner, in culverts where unusual settlement is anticipated, resort is sometimes had to means for tying the walls together longitudinally. For this purpose old bridge rods, old chain, or old rails with drift bolts through the bolt holes, have been embedded in the concrete footings for the walls.

Culvert bottoms are sometimes paved with flagstones, but more frequently with rubble stones set on edge crosswise the culvert. Such paving should be at least 12 ins. deep and, for security, the interstices should be grouted with cement mortar. A bed of concrete 6 to 12 ins. thick is also commonly used for culvert paving. Where timber grillage is used, as in submerged foundations (Fig. 8), it usually answers for the culvert floor without paving. Where stone paving is used it should be laid between the side walls, and not as a foundation for them, as in the latter case the walls are easily undermined if the paving becomes washed out. A very secure way of paving a culvert, sometimes resorted to where the current is strong, is to build masonry cross walls into the side walls, 6 to 10 ft. apart throughout the length of the culvert. These cross walls extend from the foundation up to the floor level and the paving is set in between them. At the outlet of a culvert, particularly where the water falls away rapidly, there should be a paved apron or spillway, extending some distance down stream, to prevent undermining of the foundation; and if the current is strong the bed of the stream for some distance approaching the up-stream end should also be paved. The end of culvert paving which extends beyond the opening should be protected against undermining by deeply set curbstones. The paving at the outlet is usually the more important, as, in the absence of the same, the outflow of water is liable to scour out a hole and then begin to eddy back under the pavement or masonry, causing section after section to fall in, until the culvert is finally washed out or partially destroyed. To fortify against trouble in case the paving should be washed out the end wall or foundation at this end of the culvert should be run down to good depth or to solid bottom. To prevent culverts from being clogged with ice or driftwood a fender of small piles or old rails is sometimes driven across the stream a little distance above the culvert. The piles are usually spaced 12 to 18 ins. apart, in a semicircular row extending up stream. By making the fender V-shaped up stream it will carry the drift to the shores and maintain a clear channel in the middle of the stream. If old rails are used the driftwood can be burned during dry weather without destroying the fender.

Pipe Culverts.—For small culverts vitrified clay pipe and cast iron pipe are in extensive service. In shallow embankments, where there is not sufficient hight to build a masonry culvert, pipe is commonly used, while on some roads, vitrified pipe is used under banks of considerable hight and cast iron pipe under banks of almost any hight. The chief considerations in the use of these materials are cheapness and the rapidity with which they can be laid. In filling open culverts the use of pipe affords a convenient means of maintaining an opening, and iron pipe is extensively used inside old wooden culverts that are about to fail. Vitrified clay culvert pipe is used in sizes up to 36 ins. (and even 48 ins.) diameter, although many roads limit the maximum size to 24 ins. diameter and some roads have established 18 ins. diameter as the largest size. The quality used in railroad culverts is known as "extra thick" or "double strength" pipe, being 25 to 33 per cent thicker than the clay pipe commonly used in sewers. The standard thickness of shell for railroad culvert pipe is one twelfth of the inside diameter of the pipe, while for sewer pipe the standard thickness is one fifteenth or one sixteenth of the inside diameter. The most common length of section is $2\frac{1}{2}$ ft., net, for all sizes, but 2-ft. and 3-ft. lengths are made.

Experience teaches that culvert pipe, both vitrified and iron, but particularly vitrified, must be very carefully laid if good results are to be expected. The pipe must be thoroughly bedded and given a uniform bearing. In firm earth the trench should be rounded out to fit the lower half of the pipe, as well as may be, and the earth (or preferably sand) should be well tamped about the pipe up to the center line. The precaution should also be taken to excavate suitable depressions for the pipe sockets, so that no portion of the under surface of the pipe will have to sustain more than its due proportion of pressure. The too common way of laying the bottom of the pipe on solid bearing, with only a narrow segment of the bottom wall of the pipe supported, and then filling in loose earth carelessly about the pipe, causes almost the entire pressure to fall upon a comparatively small portion of the pipe surface, thus operating to crush the pipe. The same results follow from the use of boards or timber laid in the trench to support the pipe. It is usually recommended that on soft ground the bedding for the pipe should be rammed, but the reliability of such work is questionable. On soft ground a platform of timber, or cross timbers rounded out to fit the bottom of the pipe, or a bed of broken stone, or a pile bent under or just ahead of each socket, or a brick or stone pier under each joint, is sometimes used for the immediate support, but is not generally approved of. A timber platform covered with 2 ft. of sand for the embedment of the pipe is a better arrangement, but a bed of concrete carried up half the diameter of the pipe is still better, and probably the best foundation for either vitrified or iron pipe laid on yielding ground. Without such a foundation the advisability of using vitrified pipe on ground of the character referred to is questionable. The pipe should be laid with the sockets up stream and the joints should be filled with cement mortar; on some roads both cement mortar and oakum are used. If the joints are not made tight roots may enter and choke the pipe, or when discharging under head the pressure of water may wash out cavities around the joints, leaving the pipe unevenly supported and liable to break. The cementing of the joints also strengthens the pipe at the spigot end, which, being thin and not fitting the socket snugly, obtains a bearing on the bottom only, and is liable to spring under the pressure and crush if not firmly packed about. Some manufacturers of vitrified clay pipe groove or corrugate the inside of the socket and outside of the spigot end circumferentially, to give the cement a better bond in the joint. After a joint has been made the cement should be wiped clean from the inside of the pipe, else if allowed to harden in place it may remain a permanent obstruction. Defective pieces of pipe, if at all suitable for use, should be laid next the ends of the culvert, where the pressure is light and where they can be easily removed in case of failure.

As the ground under the center of a high embankment is bound to settle, the pipe should be cambered, if anything more than in the case of masonry culverts, because the foundation of a pipe culvert is seldom carried much below the surface. As previously explained, the best way to do this is to lay the center sections somewhat higher than a plane grade from one end to the other, or lay the upper half level and then drop off from the center to the lower end. The amount of camber to be used in any case is a matter of judgment, as it depends upon the hight of the bank and the bearing properties of the top strata. Two to four per cent of the hight of the fill is sometimes allowed. The cambering of pipe culverts produces the desired effect of forcing the joints together, in case of settlement at the middle, whereas the sagging of pipe laid to an even grade stretches it apart, tending to disjoint the sections. The water which stands in a sagged pipe will cause the pipe to silt up to the same depth and reduce the area of opening by that much, and if water freezes in a vitrified pipe standing more than half full the expansion of the ice will burst the pipe. This consideration makes it undesirable to use vitrified pipe on low-lying ground or wherever water is liable to stand in the opening.

Owing to the heavy expense of replacing vitrified clay pipe in case it becomes crushed, the use of the same under high embankments does not meet with general approval, even among roads where such pipe is extensively used under different conditions. Most roads limit the use of it to embankments not higher than 20 ft., and many roads to banks of still less hight, as is the case with the Pennsylvania and Chicago, Milwaukee & St. Paul roads, where 7 ft. is the maximum fill in which vitrified pipe is used. On the St. Louis Southwestern Ry. the limiting hights of embankment for the use of vitrified pipe are 4 ft. and 18 ft. On the Nashville, Chattanooga & St. Louis Ry. the limiting fill for 18-in. vitrified clay pipe of double strength is 25 ft. high; for 24-in. vitrified pipe it is 15 ft. high. This leads up to the question, frequently raised, as to the load sustained by pipes, arches and other structures which stand under earth filling. Although earth pressure on unit areas is much of an uncertainty, the only reasonable assumption is that, with settled embankments, the load bearing upon any interior area is equivalent to the weight of a prism of the material having a base equal to the given area and length equal to the hight of material above said area. Before the embankment becomes settled the load may be more or less than this, according to the amount of friction set up between masses of settling material and the manner of distribution of the forces arising from such friction. Of these we can know nothing. Owing to the fact that a tunnel through an embankment will stand for some time without supports under the roof it has been erroneously supposed by some that the weight upon a culvert ceases to increase after a certain hight of fill is reached, or, in other words, that the load upon a culvert is not proportional to the hight of fill above it. A little reflection will dispel the fallacy. According to the tunnel hypothesis there should be no load at all upon the top of a culvert under a high fill. As a matter of fact we have no reason to suppose that the arching or beam effect of the earth, as displayed over the roof of a tunnel, existed before the material was removed from the space occupied by the tunnel. If it did we might then suppose that some portions of the interior of an embankment stand under no pressure. But this cannot be, for once pressure is removed from the material at any point there is a gradual movement of material toward the point relieved, as evinced by the bulging of the floor in deep coal mines and in tunnels through soft material. And then, if we were to assume that the distribution of earth pressure takes place through beams or arches of material, why is it not just as reasonable to suppose that the culvert will stand under the end of span of such beam or arch as that it should stand between the end supports? A simple illustration may serve to clarify this matter. In a pile of boards laid in crossed courses there is a beam over every board in the interior of the pile, and a large percentage of the boards in any course may be removed (if not consecutively) without perceptibly affecting the stability of the pile; yet if one attempts to pull boards from the interior of the pile he will find them harder to pull as he proceeds towards the bottom, showing that the beam covering any board is not called into action as such until the board is removed. So far as my reading has extended those who hold to the claims here disputed have not propounded any argument to show that the case is different with earth in an embankment. An unpropped tunnel through earth stands more firmly under a high embankment than a low one because the earth at the bottom of the high embankment is more solidly compacted, and therefore better constituted to hold together in a large mass. The pressure due to live load (the trains) is transmitted through earth filling in diverging lines and approaches uniformity with depth. It therefore acts with greatest concentration through shallow embankments and the crushing effect upon culvert pipe increases with nearness to the track. According to one rule, followed to some extent for vitrified pipe, 1½ times the diameter of the pipe is taken as the minimum allowable depth of fill over the pipe, while on some roads 3 ft., and on other roads 4 ft., is considered the least allowable depth for pipe of any diameter. Where the action of frost must be taken into account either depth seems small enough, in any case.

Culvert pipe made of concrete has been used to small extent on the Texas Midland, the Chicago & Northwestern, the Chicago, Milwaukee & St. Paul and other roads, and to a considerable extent on the Chicago, Rock Island & Pacific Ry. In some cases the results, due perhaps to improper design or workmanship, have been reported unsatisfactory, but on the road last named this kind of pipe has given good service. One advantage is that, concrete being comparatively cheap, the pipe can be made of any desired thickness requisite for strength, and as the materials of which it is made are easily transported the pipe sections can be readily made at the culvert site, thus overcoming any objections on the score of handling. Culverts of this material that have been built in municipal and highway work have given satisfactory service. The pipe is made in sizes up to 3 ft. diameter, the thickness corresponding to this size being 4 ins. The pipe is molded in the annular space between two steel-plate cylinders stood on end, concentrically. The concrete, which is formed of cement mortar and screened gravel, is tamped into the mold and allowed to set. Each cylinder is formed with an open seam and closes to a butt joint, but the edges of the plate will spring to an overlapping position if forced out of abutment. When the molding process is complete the cylinders are made removable by starting their joints with iron wedges, springing the outer one to larger diameter and displacing the edges of the inner cylinder, which permits it to spring to smaller diameter. As the implements are simple and inexpensive and skilled labor not required, such pipe can be cheaply manufactured.

On the Chicago, Rock Island & Pacific Ry. it was found that 24-in. pipe in 3-ft. lengths was best adapted for culverts, and one to seven lines of it, according to the amount of water to be carried, have been used at numerous points. The forms for molding the pipe are shown in Fig. 7. They consist essentially of an outer and inner shell formed of wooden staves and hinged together in sections, the outer shell in two sections and the inner one in three. The form for the bottom end of the mold shapes the spigot end of the pipe and a bevel-shaped form for the top of the mold shapes the socket end. The concrete is rammed into the annular space between the two wooden shells, and after setting 48 hours the forms are removed from the pipe, the outer shell opening outward and the inner shell collapsing, as shown in the figure. The manner of joining the sections together is shown at the right. The thickness of the pipe wall is 3½ ins. The concrete mixture consists of 4 parts of clean sand and gravel, just as it is taken from the pit, and 1 part of Portland cement. The cement and gravel are first thoroughly mixed in the dry condition and then water is added and the mixture is placed in the forms and rammed hard. From experience it has been learned that the pipe should not be placed for filling before it is three months old. This kind of

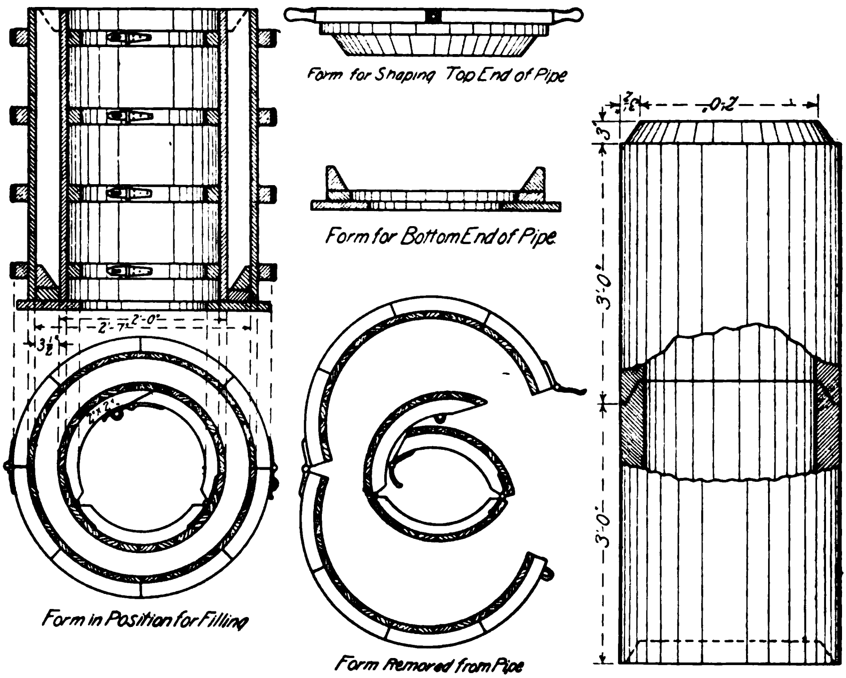

Fig. 7.—Concrete Culvert Pipe and Forms for Molding.

pipe was adopted for the class of structures in which cast iron pipe was formerly used, and at a cost which is only about one-sixth of that of iron pipe. The following are the data of materials used and costs: The solid contents of a section of 24-in. pipe 3 ft. long is 6.57 cu. ft., and the weight is 872 lbs. The material used per section is 8 cu. ft. of gravel and 2 cu. ft. of Portland cement, the discrepancy between the cubical contents and the amount of material required being due to the process of tamping. The average cost per lineal foot of 24-in. concrete pipe is 55 cents, of which the cost of the Portland cement is 35 cents, the cost of the gravel 2 cents, and the labor 18 cents. The weight of a 3-ft. section of 18-in. concrete pipe is 444 lbs., and the cost per lineal foot about 29 cents. The weight of a 3-ft. section of 30-in. concrete pipe is

1207 lbs., and the cost per lineal foot about 77 cents. At $30 per ton, the cost of cast iron pipe in that locality at the time concrete pipe was adopted, 18-in. pipe cost $2.62 per lineal foot, 24-in. pipe $3.75 per lineal foot, and 30-in. pipe $5.30 per lineal foot.

Cast iron pipe is used for culverts in sizes up to 6 ft. diameter, and segmental cast iron culverts are made as large as 7 ft. diameter. The Toledo, Peoria & Western Ry. has segmental culverts of this kind and size, and previous to 1890 the Chicago, Burlington & Quincy Ry. placed a number of such culverts, the largest being 7 ft. in diameter. With the latter road the practice was then abandoned, for several reasons, the principal one being the expense. On a number of roads cast iron pipe of 20 ins. diameter is the smallest size used, as such is about the smallest pipe that a man can crawl through and clean out. Water pipe is commonly employed for this purpose and it is quite largely the practice to select condemned water pipe, or pipe rejected for some defect which does not impair it for use in culverts. Such pipe is commonly cast in lengths of 12 ft., net—that is, exclusive of the socket—but for convenience of adjusting the length of the culvert to the width of the embankment more closely than could sometimes be done with 12-ft. lengths, odd pieces are sometimes furnished in half lengths; otherwise the pipe must be cut, which is usually done by nicking around the circumference with hammer and cold chisel. Pipe of large diameter is sometimes cast in lengths of 8 ft. Following are the usual thicknesses for water pipe of different sizes: 12-in. pipe, ¾ in. thick; 18 and 20-in. pipe, ⅞ in. thick; 24-in. pipe, 1 in. thick; 30-in. pipe, 1⅛ ins. thick; 36-in. pipe, 1¼ ins. thick; 40-in. pipe, 1½ ins. thick; 42-in. pipe, 1⅝ ins. thick; 48-in. pipe, 1¾ ins. thick; 60-in. pipe, 2 ins. thick; 72-in. pipe, 2¼ ins. thick. Standard gas pipe is 25 to 35 per cent lighter, for the various sizes, than water pipe of these thicknesses, pipe 2 ft., 3 ft., 4 ft., 5 ft., and 6 ft. in diameter being respectively ¾ in., ⅞ in., 1⅛ins., 1⅜ins. and 1½ ins. thick. The culvert specifications of quite a number of roads call for cast iron pipe of gas weights, and some for even lighter pipe. To prevent rust the pipe is coated inside and out with coal tar or asphaltum. The Chicago, Milw. & St. P. Ry. uses cast iron pipe culverts extensively, the number in service in 1903 being 4755, and the aggregate length 39.6 miles. This company manufactures its own pipe, from scrap material, on an independent design. The pipe is handled at the foundry as a by-product, a few lengths being cast at each melting. The pipe is made in 6-ft. lengths and is about 35 per cent lighter than the water pipe above referred to, the thickness of 24-in., 36-in. and 48-in. pipe being ⅝ in., ⅞ in. and 1⅛ ins., respectively. This pipe is intended mainly for service in settled banks within old wooden culverts. When used in this manner the pipe has been found strong enough, but it is not intended for use under high embankments newly made. Pipe 60 ins. in diameter and 1¼ ins. thick is also cast by this company, but owing to breakage under earth filling it is now used only occasionally.

As cast iron culvert pipe of the larger sizes is heavy (a 12-ft. length of 48-in. water pipe weighs about 4½ tons, and of 60-in. pipe about 8 tons) it is usually lifted to place with a pile driver or derrick car, if laid under track that is already built, and on new construction it is handled with block and tackle and rollers. Cast Iron pipe should not be dropped from cars upon frozen or stony ground, and when rolling it down a bank care must be taken to prevent pieces from striking against each other. It is always safer, of course, to unload it from the cars with skids and parbuckle and to restrain it with ropes in the same manner when rolling it down an embankment. To prevent crushing, it is customary to prop the inside of large culvert pipes (3 ft. diameter and larger) at intervals of a few feet and leave the supports until the embankment has settled.

In placing iron pipe inside a timber culvert the pipe is usually pulled into place from either end of the old culvert by means of block and tackle and rollers. If the opening is not large enough to admit the pipe the timber is either cut away or the top and one side, and sometimes the bottom, of the timber box are removed and the bank kept from caving by props, if necessary. Where this is done and the bottom not removed, or where there is room within the old culvert when none of the timbers are removed, it is a good plan to raise the pipe off the floor and pack the space underneath with earth. If this is not done the bottom timbers of the old culvert should be rounded out to fit the pipe, and for a short distance from each end all the timbers of the old culvert should be removed, so that no opening may exist for the entrance of water outside the pipe. In some instances where the old culvert is wide enough to receive the pipe a foundation of sand, gravel or hard clay is laid upon the old floor as a cushion for the pipe and the top is then removed to make room for the pipe. In any case earth is firmly rammed into the open space about the pipe. This work must be done as each section is pulled to place, and it is a tedious operation, but easier done with 6-ft. lengths than with 12-ft. lengths.

In laying pipe culverts through embankments where no previous opening existed the most general practice is to make an open cut, supporting the track on long stringers resting upon sills or pile bents. In order to keep the width of the cut within the limits of a desirable span for the stringers it is necessary, in deep embankments, to protect the sides of the excavation with braced planks. Under high embankments, however, it is frequently the practice to drive a tunnel, excavating an open cut well into the slope at either side, to shorten the tunnel, cutting to such slope as the earth will stand or cutting straight down and holding the faces of the cut from caving by braced sheeting. The tunnel should be made only large enough to admit the pipe or afford working room. The roof may be supported by 4-in. plank or old bridge ties, propped with center posts or side planks standing upon plank running lengthwise the opening, and held up to a snug bearing with wedges at the foot of each post. The pipe may be drawn into the tunnel on rollers or dollies, on planks laid side by side. The open space around the pipe should then be well rammed with earth or gravel. If old bridge or other timber is available for this work it may as well remain in place, but otherwise it would most likely be removed and made use of in laying other culverts. Cases have been reported of forcing cast iron culvert pipe through an embankment of soft material with hydraulic jacks, putting the pieces end to end as they are pushed in, the material being removed in advance by working it back inside the pipe.

It of course looks best and seems safest to see the ends of pipe culverts walled up, and where the current is rapid or the intake liable to be submerged at times a wall at one or both ends is usually provided. Such walls are built of rubble stone, brick or concrete masonry. They should extend below the action of frost, which will usually be low enough to prevent undermining. Protection from undermining is also largely a matter of paving outside the culvert ends, particularly at the downstream end, as already explained. By laying end walls something can be saved in length of pipe, as the wall is usually set back from the foot of the embankment a sufficient distance to bring the top of parapet on line with the slope. The best arrangement is to lay flared wing walls from the opening to the foot of slope, as then the current is converged into the channel and the foot of the embankment is protected against side currents. Such walls are sometimes arranged about the opening in the form of a semicircle. In cases where the pipe does not quite reach the desired length of the culvert, the end walls are built to project a foot or two beyond the end of the pipe. The bank around the upper end of a small vitrified pipe culvert is sometimes protected against wash by a plank bulkhead, formed by spiking plank across two posts, set on either side of the pipe, with a circular hole through the plank for the culvert pipe. Such protection is usually set at the slope of the embankment, or at least with a considerable inclination toward the roadbed. In cases such a substitute for an end wall may answer better than no protection at all, and thus serve a purpose, as when, for instance, the need of an end wall is seen where none has been built. In that case the use of a plank bulkhead until a convenient time for building a masonry wall might be advisable.

The necessity for end walls is conceded to be greater with vitrified pipe than with iron pipe culverts, owing to the more numerous joints in the former and the greater possibility that the filling may be washed from around the end sections. Owing to the short length of a vitrified section the displacement of only a small amount of supporting material will cause it to fall down, obstruct the flow of water and open the way for the undermining of the other sections, one by one. Without end walls such action is liable to take place at either end of the culvert, even where there is good paving, because the filling over the sections near the ends of the culvert is shallow, and a slight displacement of one of these sections may open a joint and let water through that will undercut the pipe. The shallow filling over the up-stream end of the culvert is also exposed to the swirl of water about the end of the pipe when such becomes submerged. At such times the scouring action of the water is particularly strong. Another occasion for an end wall at the up-stream end of the culvert is where the stream meets the pipe obliquely. In a case of this kind a strong current will tend to flow past the pipe into the bank and then eddy into the pipe. In order to minimize in length it is customary to place culverts at right angles to the embankment, without regard to the direction of the stream. This arrangement brings head walls parallel with the track, when such are built, but when a stream is crossed obliquely the end wall should be disposed in a manner to protect the bank from the impingement of the current, which can best be done by means of a wing wall to deflect the water toward the opening.

Speaking of practice generally, it seems to be the rule to dispense with end walls fully as far as, if not farther than, conditions will warrant. As a matter of fact it is not, in many cases, essential to any large economy of construction to decide upon the matter of end walls for vitrified pipe culverts when the pipe is laid. Such can be built as indications of the necessity for the same become apparent, without large expense for excavation in excess of first requirements, and the few lengths of pipe removed in setting the ends of the culvert farther into the bank, as when end walls are built, can usually be of service elsewhere. The postponement of end wall construction also gives opportunity to await the settlement of the culvert under the deep part of the embankment. Should such settlement exceed the allowance for the same there is still opportunity to lower the outer sections to correspond, at no great amount of excavation or expense, before the end walls are laid. Owing to the longer sections of iron culvert pipe, such a change is not as readily made with it as with vitrified pipe. Should the end-walling of iron pipe culverts be deferred conditionally it would be well to lay half lengths for the end sections, to be removed in case end walls are eventually built. In practice one finds various substitutes for end walls, as on the West Shore R. R., where the bank surrounding the end of the pipe is roughly dry-paved; and on the Chicago & Eastern Illinois R. R., where the ends of pipe culverts are not protected by masonry of any kind, broken stone being filled in to stop washing when it occurs.

In official reports on pipe culverts one may learn of many cases of breakage, more frequently with vitrified pipe, but to larger extent with cast iron pipe than some might suppose. Undoubtedly one very responsible cause for this can be traced to the manner in which work on pipe culverts is skimped, particularly with respect to the foundation. It is quite common experience to see culvert pipe rolled in and covered up on foundations which no man would think of accepting for masonry culverts. Almost all breakages occur under settling embankments, but where the foundation is looked to carefully and the precaution taken to prop or shore up the pipe inside until the embankment has ceased to settle, good results are usually reported. A method of strengthening cracked or broken culvert pipe of large size that is quite commonly followed is to line it with a ring of paving brick set edgewise; i. e., the 4-inch way.

To keep flood water from backing through pipe culverts and flooding property on the other side of the roadbed a backwater valve is sometimes used at the outlet end of the pipe. This device is very simple, consisting merely in a circular piece of boiler plate hinged to a pair of lugs cast or molded on at the top of the pipe. The plate covers the end of the pipe, which is cut off at an inclination, so that water flowing out of the pipe can easily lift the cover and escape, but when water backs against the end of the pipe the cover is held down by the pressure and water in quantity is prevented from flowing backward through the culvert.

Under a low embankment where there is not room for a single pipe of the desired size, two or more smaller pipes affording an equivalent area of opening are sometimes laid in a "nest." Two or more pipes are used also in place of a single opening of equal discharging capacity where the backing up of the water in order to obtain the full discharge is inadmissible. Division of the waterway in this manner does not permit the passage of driftwood, corn stalks and other flood trash so readily as a large opening of equivalent area, and the danger of clogging is an important matter to be taken into consideration. From a construction point of view the divided waterway costs more for the same area of opening, as the aggregate weight of the small pipes exceeds that of the large ones; and the labor of excavating and laying is something more for the small pipes, but not nearly in proportion to the number of pipes. When two or more pipes constituting a culvert are laid side by side they should be placed far enough apart to permit the earth filling to pack solidly between them in a column of good thickness, say as thick as the diameter of the pipe. The pipes shown in Fig. 7A are not far enough apart. The earth should be thoroughly rammed between the pipes, as well as underneath their outer quarters, and owing to the liability of one of the pipes becoming clogged and throwing the duty of discharging upon the others, the ends of the pipes should be encased in masonry or concrete end walls.

Figure 7A shows a concrete end wall for a pair of cast iron culvert pipes running through an embankment at a skew. The end of the pipe farthest from the observer is farthest from the toe of the embankment, but the construction of the end wall brings the two outlets on line with the general direction of the embankment. The plan of this end wall is therefore A-shaped. An idea suggested by this simple structure is that a culvert pipe which ends a few feet short of the toe of an embankment does not require a high end wall, which would be the case were it necessary to terminate the slope of the embankment directly over the end of the pipe. By laying a form with a core the size of the culvert pipe out as far as the toe of the embankment and depositing concrete within the same the waterway may be cheaply extended to the toe and terminated by a low end wall. The usual arrangement provided for the discharge of a culvert which serves as a cross drain from the ditch in a side-hill cut is a paved ditch or slope, which is quite liable to be washed out if the water gets to cutting under it. About the only safe arrangement of this kind is had by grouting the paving with cement mortar. Figure 7B shows a concrete spillway, consisting of a waterway 18 ins. wide and 14 ins. deep, at the top, with side walls 9 ins. thick. It takes the discharge from a 24-in. pipe and conducts it down a slope about 100 ft. long. The view shows only the upper end of the spillway, the end wall

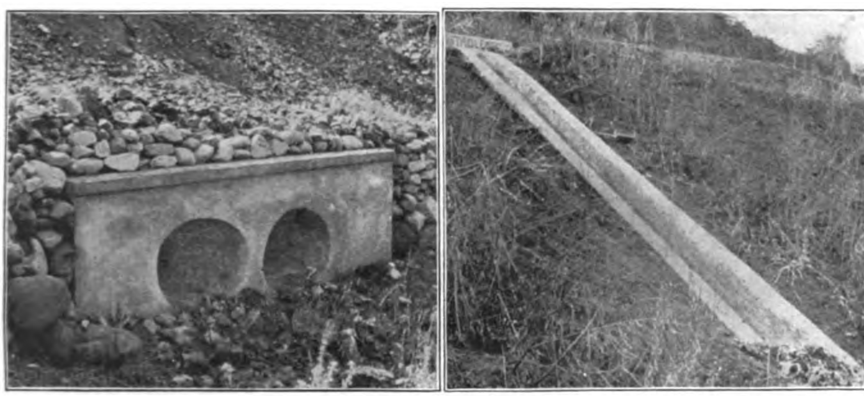

Fig. 7 A.—Concrete End Construction for Pipe Culverts—Fig. 7 B.

of the pipe culvert, also of concrete, appearing at the top of the view. As the speed of flow increases toward the bottom of the slope the depth of the waterway was made shallower at the bottom than at the top.

Wrought iron and steel plate pipes are also used in railroad culverts. The Boston & Maine R. R. has, in a few instances, used riveted wrought iron pipe in culverts standing partly full of water, the freezing of which would subject vitrified or cast iron pipe to danger of bursting. The Union Pacific R. R. has in use a large number of pipe culverts as large as 60 ins. in diameter made of steel plates ¼ to ½ in. thick riveted together with lap joints, like a boiler. This pipe cost about 75 per cent of that of cast iron pipe of the same diameter. The pipe was heavily coated inside and outside with coal tar before laying and recoated inside and outside after being laid. On the Erie R. R. there are in service some steel plate pipe culverts 60 ins. in diameter, weighing 283 lbs. per foot. The pipe is in riveted sections of 30 ft. length bolted together by flanged joints. The flange at each end of each section is formed by a 3x3-in. angle bent around the pipe and riveted to the outside. Six inches from each end there is also riveted around the outside of the pipe a 3x5-in. angle to serve as a stiffener and prevent water from coursing along the outside of the pipe. The cost of this pipe is given in the lower line in Table I, which was taken from a committee report to the Association of Railway Superintendents of Bridges and Buildings, in 1898. The other costs in the same tabulation (24-in.

to 48-in. pipe) are for steel pipe culverts on the Wisconsin Central Ry. The costs for cast iron pipe in the same table are the extreme figures (low and high) taken from a large number of replies to a circular of inquiry sent out to different roads. The cost of cast iron pipe ranged from $14.50 to $16.80 per ton, and the cost of stone masonry end walls from $4 to $8 per cubic yard. The "total" columns do not include the cost of masonry end walls. The Nichols "portable" culvert is of trapezoidal cross section, with the widest side on the bottom. It is made of steel plates riveted to angle irons and is stiffened with angle irons on the outside, giving a smooth surface inside. At each end there is a steel plate portal and wing walls. This structure is brought to the site of the culvert ready made, to be placed upon a prepared foundation. The steel is painted with some preparation to protect it from rust.

Brick Barrel Culverts.—Hard burned brick is very durable material, and well designed structures built therewith are practically everlasting. In municipal work brick barrel sewers are very commonly found, and where conditions will permit of laying them they are consid-

TABLE I.

COST PER LINEAL FOOT OF CAST-IRON PIPE CULVERTS.

Size of pipe.	Material.	Labor.	Total.	Cost of stone masonry ends.
18-inch	$1.11	$0.16	$1.27	
20-inch	1.00 to 1.62	.09 to 1.06	1.76 to 2.08	$43.00
24-inch	1.20 to 3.32	.17 to 1.82	2.09 to 5.19	53.00 to 69.12
30-inch	1.22 to 2.90	.23 to 1.42	3.09 to 4.67	66.00
36-inch	2.51 to 3.69	.30 to 1.64	2.81 to 6.50	78.00
42-inch	3.35 to 5.00	.70 to 1.96	5.08 to 5.70	90.00
48-inch	4.30 to 7.70	.36 to 3.12	5.29 to 10.32	100.00
60-inch	7.94 to 10.61	1.26 to 2.66	10.60 to 11.82	

COST PER LINEAL FOOT OF STEEL PIPE CULVERTS.

30-inch	1.55	.17	1.72
36-inch	2.28	.25	2.53
42-inch	3.00	.30	3.30
48-inch	4.13	.46	4.59
60-inch	8.25	.45	8.70

ered the best waterways that can be built for the purpose. To some extent such work has been imitated in railway culverts. The culvert is laid by rounding out the bottom of the trench to give shape to the lower half of the "barrel," and then the brick rings are laid in cement mortar directly upon the rounded surface of the ground, up to the hight of the horizontal diameter, when forms are placed and the cylindrical structure is completed by arching over the top. Of course such culverts can be built to give satisfactory service only where there is firm earth to support the bottom and under quarters of the structure. Such culverts are used extensively on the Nashville, Chattanooga & St. Louis Ry., in sizes from 3 to 5 ft. in diameter, and on ground which is not firm enough for such construction brick barrel culverts backed up with haunch walls are used in sizes from 3 to 6 ft. diameter. The thickness of the barrel culverts is one ring less than the diameter of the culvert in feet, the brick being laid edgewise in each ring. The bricks used are all very hard burned, but those having vitrified surfaces are selected for the paving of the bottom semicircle. Table II., taken from a paper by Mr. Hunter McDonald, chief engineer of this road, presented before the Engineering Association of the South, gives the cost data of these culverts, as well as of vitrified and cast iron pipe and stone box culverts. The term "brick arch" found in this tabulation is not applied in the strict sense, as the opening in these culverts is circular, the same as with the brick barrel culverts. The distinction between the two designs is in the use of haunch walls in the so-called "brick arch" culverts, to strengthen the barrel, as above stated. These haunch walls are of such thickness that the width of the culvert masonry over the haunch walls, is equal to twice the diameter of the interior of the barrel. The haunch walls are carried up full width as high as the horizontal diameter of the barrel, above which they slope off rapidly to meet the top of the barrel on tangent. The reason for substituting this design for a brick arch with straight side walls and an invert of comparatively large radius is that, for a usual thing, the foundations are in alluvial soil and are somewhat treacherous. By using the semicircular invert, or rather a circular culvert with haunch walls, the load on the culvert is distributed over the entire bottom surface, with the certainty that the invert will not be pushed up into the culvert, which might be the case if the invert was flat—that is, of comparatively large radius. Where it is neces-

sary to increase the hight of these culverts for any purpose other than that of increasing the area of the culvert opening, as, for instance, to allow for the passage of cattle, straight side walls 2 ft. high are put in between the upper and lower semicircles of the culvert and the haunch walls are carried up in proportion. Wherever the nature of the foundation will permit, brick arches with straight side walls and a comparatively flat invert are built. A particular culvert of this class (Fig. 7C) under a 60 ft. embankment has a semicircular arch of 7 ft. span, straight side walls 3½ ft. high, and an invert of 7 ft. radius. The foundation consists of five rows of piles driven about 3 ft. apart in each row, around the tops of which is placed a bed of concrete 2 ft. deep. Haunch walls are carried up to a hight of 7 ft. 9 ins. above the foundation and then sloped off rapidly to meet the top of the arch on tangent. The width over the haunch walls at the foundation is 14 ft. and the batter on the back sides of these walls about 1 in 10, making the top width 12 ft. 5 ins. The plain barrel culverts are used only on hard, firm ground, where the natural surface is above the axis of the culvert and where the hight of the earth above the culvert does not exceed 30 ft. Haunch-wall circular culverts are used wherever the brick barrel will not answer,

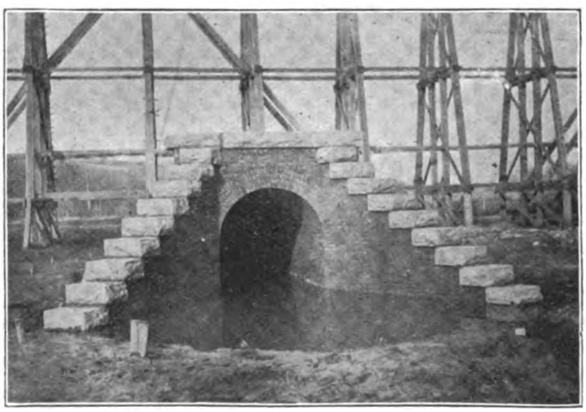

Fig. 7 C.—Brick Arch Culvert, N., C. & St. L. Ry.

and an extra ring of brick is added to the arch for every 15 ft. of fill over 20 ft. high. On solid rock bottom semicircular arches with straight side walls are used. The minimum grade of the culvert floor is ½ per cent. In the haunch-wall circular culverts the barrel is not made as strong as in the plain barrel culverts, as in the former only two rings of brick are used up to and including culverts of 5 ft. diameter. The culvert of 6 ft. diameter of this class has 3 rings of brick. It will be noticed that the culvert shown in Fig. 7C has vertical wing walls and that there are no re-entrant angles at the end of the arched opening.

Arch Culverts.—Well constructed stone arches are considered the highest class of masonry for culverts and bridges, and on many of the best built roads such is the standard construction. Particularly is this the case on the Pennsylvania R. R., where many fine examples of heavy arch construction are to be found. It cannot be expected to here go into the subject of arch construction and masonry specifications comprehensively, but some ruling principles may be considered. In railway work semicircular and segmental arches predominate, with an increasing preference for the segmental arch. This for the reasons that the segmental arch permits of a wider opening where the depth of embankment is a limiting feature (Fig. 7D, for example), and the amount of sheeting in the semicircular arch is the greater and therefore the more expensive, particularly in cut-stone work. First-class work calls, of course, for dressed sheeting stones, but roughly dressed and rubble stones are very commonly used in arches of short span, having quarry-faced stones with chisel draught edge lines for ring stones. The Canadian Pacific Ry. builds rubble masonry arches as large as 60 ft. span, the only cut stone used being in the ring courses or those which show at the ends of the arch. This kind of work laid in Portland cement mortar has cost about $6 per cubic yard, and, owing to the long distance over which cement must be hauled, is considered cheaper than concrete. For abutments and wing walls rock-faced ashlar masonry is quite frequently found in high-class work, while range work and broken ashlar are very common. In the smaller culverts rubble masonry throughout is quite general.

Figure 8, showing the plans of a stone arch culvert of 20-ft. span located near Watervliet, Mich., on the Chicago & West Michigan division of the Pere Marquette R. R., represents a good example of durable con-

Fig. 7 D.—Flat Arch Culvert Construction.

struction for openings of this size. The arch is 29 ft. long, and the total length of the structure, from end to end of wing walls, is 76½ ft. The arch is segmental, with moderate rise to span, the arc or central angle being 139 deg. 58 min., the rise 7 ft. and the radius at the intrados 10 ft. 7¾ ins. The arch sheeting is 2 ft thick and the spandrel walls 2½ ft. thick and 3 ft. 11⅝ ins. high at the crown. The filling over the arch crown, or the distance from the crown to the base of rail is 9 ft. 4 ins. The abutment walls of the arch are 9 ft. 9 ins. high to the springing line. The excavation was carried 4½ ft. below the surface of the water and the foundation consists of timbers placed at 3 ft. centers and overlaid with two crossed courses of 3-in. plank. The wing walls are 24½ ft. long, and open out at an angle of 30 deg. with the center line of the arch. The footing course of the wing wall where it joins the arch abutment is 8 ft. wide, and at the base of the battered portion the wall is 6 ft. wide. The outward face of the wing wall is battered 1 in 12 and on the back the batter is 1½ in 12. The material is sandstone, from Grafton, Ohio. The stone was scabbled at the quarry and required but little cutting to prepare the top and bottom beds. The joints and beds for 10 ins. back from the face were laid in Portland cement mortar and the balance in Louisville cement mortar, except that all the joints in the arch were laid entirely in Portland cement. The centers were struck nine days after the keystone was set. The arch was built under a long trestle which was filled in after the work was completed. The cost of the work was as follows: Stone at the quarry, $1986.06; freight, $1298.21; foundation timber, $502.20; foundation plank, $453.34; 1041 cu. yds. dry excavation, @25c, $260.25; 617 cu. yds. wet excavation, @ 75c, $462.75; 594 cu. yds. channel excavation, @ 25c, $148.50; 495.9 cu. yds. stone cutting and laying, @ $7.50, $3719.25; extra labor $31.90. The cost for material was then $4239.81, the cost for labor $4622.65 and the total cost $8862.46. The cost of the stone work was $14.12 per

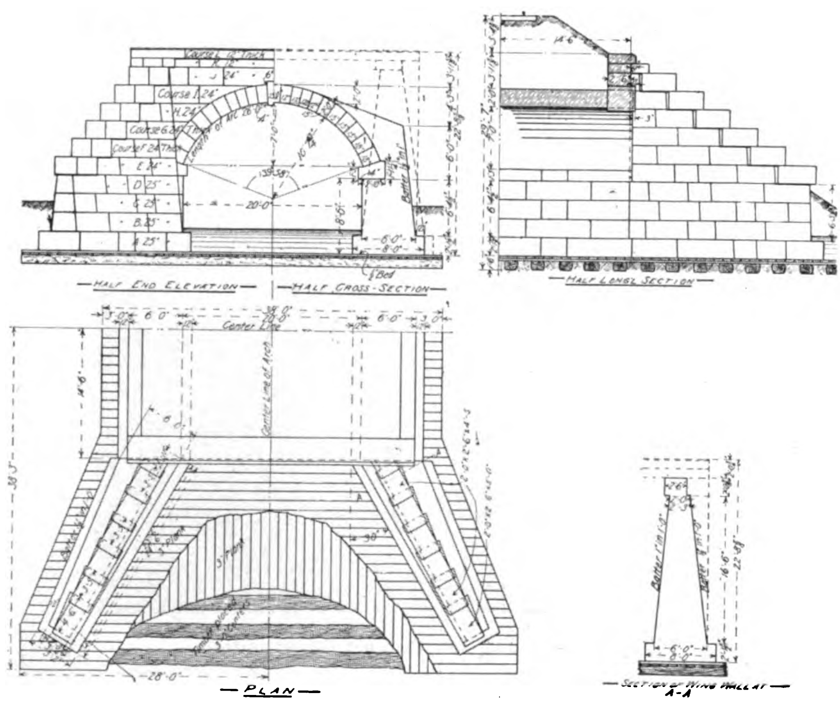

Fig. 8.—Plans of Stone Arch Culvert, Pere Marquette R. R.

cubic yard, of which the cost of the stone at the quarry was $4, the freight $2.62 and the cost of the cutting and laying $7.50.

Figure 8A shows the general plans of the stone arch culverts of 15 ft. span built on the reconstructed Wyoming division of the Union Pacific R. R. The wing walls flare out at an angle of 25½ deg. with the axis of the culvert and they extend 24 ft. 5 ins. from the face of the arch. The reader will take notice of the inclined side walls of the culvert, an arrangement which avoids the objectionable re-entering angles at the mouth of the opening, or where the side walls meet the wing walls.

In most localities where suitable building stone is not to be had within convenient distance good brick, being so widely manufactured that long shipments are seldom necessary, are usually cheaper for masonry construction and quite as satisfactory, so far as durability is concerned. Aside from the cost of material there is also the important advantage that brick can be handled without derricks. In building culverts under track already laid the brick can be delivered to convenient points about the work by unloading from the cars into chutes, whereas in unloading and setting stone of the larger dimensions derricks are a practical necessity; and the expense of moving derricks from place to place, erecting, and operating the same is a considerable figure. Where the bench and wing walls of brick arches are laid with brick or rubble stone the only heavy stones to be handled are the coping stones, and these, being comparatively few, can be moved to place with hand tools. Instance where this principle is carried into effect may be found with the Chicago, Milwaukee & St. Paul Ry., where some arch culverts of considerable span are constructed entirely of brick except for the coping stones. Brick for culverts should be hard burned, laid in Portland cement mortar, and the various rings composing the arch sheeting should be bonded together at intervals. For large contracts the brick are sometimes, but infrequently, molded bevel-shape, to fit the radial lines of the arch. The Atchison, Topeka & Santa Fe Ry. makes extensive use of rubble arches with brick sheeting. Figure 9 shows Bridge No. 200 on the Chicago division, near Chillicothe, Ill. The span of this culvert (or "bridge") is 30 ft. and the arch is semicircular or "full centered," with 6-ft. bench walls, making the headroom 21 ft. at the center. The arch sheeting has six rings of Galesburg paving brick laid on edge in Portland cement mortar. The footing for each abutment wall consists of a bed of Portland cement concrete 7 ft. deep, on a gravel bottom. The rub-

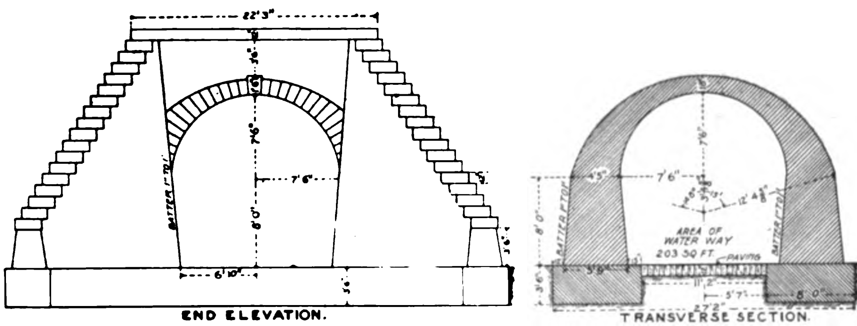

Fig. 8 A.—Standard 15-ft. Arch Culvert, Union Pacific R. R.

ble masonry is laid with natural cement mortar. Owing to the compactness of the gravel in the bed of the stream the culvert is not paved and has not shown any need of paving. This culvert drains 5.38 sq. miles of broken country and at times water 10 ft. deep has flown through it. Bridge No. 201 is a semicircular arch of 14 ft. span, with 8-ft. bench walls, through an embankment 54 ft. high. There are four rings of brick in the arch and the remainder of the masonry is rubble stone. The foundation for each abutment wall is a bed of concrete 3½ ft. deep resting on piles driven 13½ ft. into hard clay. The piles are not capped and extend 1½ ft. into the concrete. Bridge No. 202 is the same size as No. 201 and is built like it except that only three rings of brick are used in the arch, the embankment being but 21 ft. high. Each abutment foundation consists of a bed of concrete 3½ ft. deep resting upon hard blue clay. Both of these culverts are paved with stone, 14 ins. deep, between concrete head walls 2 ft. wide and 3 ft. deep, to hold the paving in place and protect it against undermining. The tops of the head walls come flush with the top of the paving. Between Chicago and Kansas City on this road there are 65 arches ranging from 8 to 30 ft. span, built similarly to the ones here described.

Figure 10 is a progress view of a brick culvert of 8 ft. span under a 63-ft. embankment on the Cincinnati Southern Ry. The culvert is

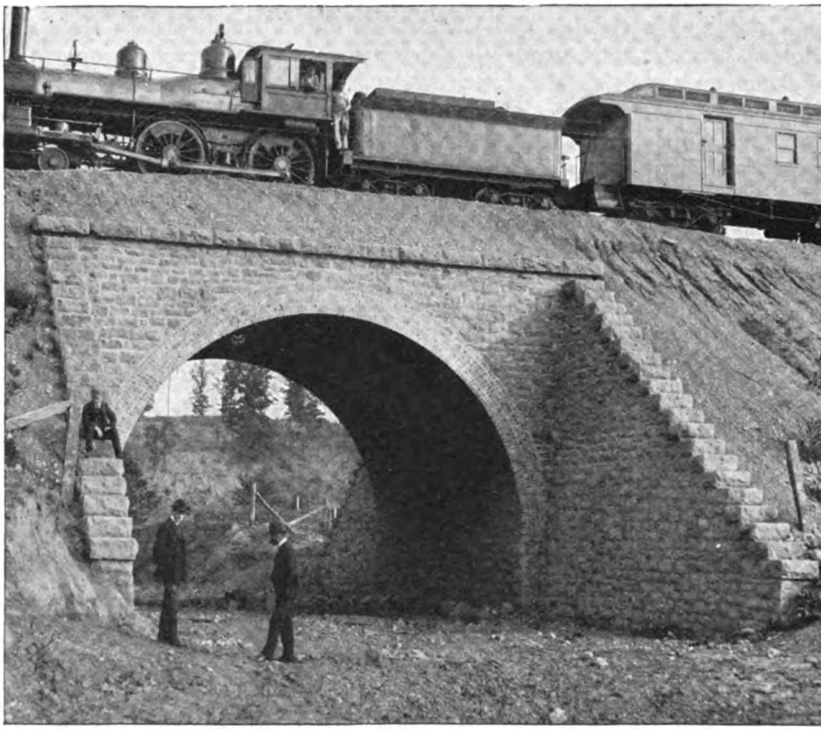

Fig. 9.—Brick and Stone Arch Culvert, A., T. & S. F. Ry.

207 ft. long and, owing to banks at either side of the fill, the culvert had to be built on a skew of 65 deg. with the alignment of the road. The foundation of the culvert consists of concrete walls 4 ft. 9 ins. wide and 4 to 7 ft. deep. Upon these walls there are brick bench walls 3 ft. 5 ins. wide and 4 ft. high. The arch is semicircular and consists of four rings of brick set on edge, backed up with brick haunch walls carried out to the full width of the bench walls and carried up nearly to the top of the arch. These haunch walls had not been laid when the photograph was taken. The end of the arch is finished with brick broken to the face line, as shown in the figure. The culvert is paved with one layer of brick set on edge on a concrete foundation 12 ins. deep. The paving is sloped from either side to form a depression along the middle line of the culvert. Figure 11 shows a culvert of 8 ft, span under a freight yard of the New York, New Haven & Hartford R. R., at Montello, Mass. The culvert is 700 ft. long, and has a solid concrete invert and foundation, with granite side walls, brick arch with concrete backing, and end walls of granite.

Concrete Culverts.—Late years railroad masonry work has been running much to concrete, this material being found particularly well adapted for foundations, retaining walls and culverts. Monolithic work is the rule, large abutments, arch culverts and the like being formed in a single mass. An important advantage with concrete masonry, from the standpoint of economy, is that skilled labor is not required in laying it, which is not the case with stone masonry or brickwork. Carpenters are usually employed to erect the forms and ordinary laborers mix and deposit the material. In ordinary work the forms are easily set up and

Fig. 10.—Brick Arch Skew Culvert, Cincinnati Southern Ry.

the lumber used in the same may be taken down and used over and over. The usual form is made by standing a row of posts in line and lightly nailing on boards or 2-in. planks horizontally for each face of the wall, using planks surfaced one side and two edges if smooth work is desired. The posts usually stand higher than the wall and are braced to stakes driven into the ground; to posts or piles in trestle bents, in case the culvert is built under a bridge; or to other stable objects. To prevent spreading the form apart as the concrete is deposited and rammed the posts on opposite sides are held together with tie rods, top and bottom, the latter remaining in the concrete when the form is removed. On extensive work the concrete is generally mixed with portable machinery. Concrete culverts are usually built either as arches or with rail tops, with any form of end wall construction that is desired. The coping of wing walls in concrete masonry is usually sloped to conform to the embankment slope.

An example of a rail-top culvert built with concrete side and end walls is shown in Fig. 12. It has two openings each 4 ft. wide and 8 ft. high, with a 3-ft. partition between. The head wall on either end of the culvert is 36 ft. long, 2½ ft. wide on top and 14 ft. deep, the back of the

Fig. 11.—Brick Arch Culvert, Stone Trimmed, N. Y., N. H. & H. R. R.

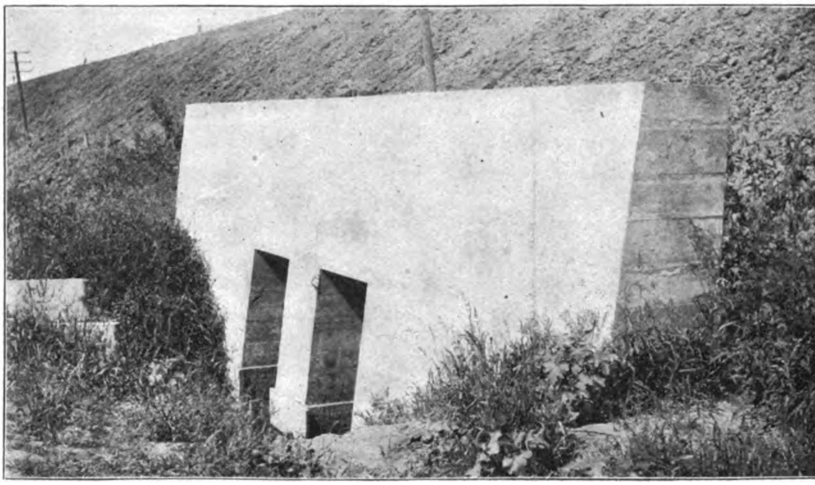

Fig. 12—Concrete Culvert, C., B. & Q. Ry.

wall being vertical and the face battered 1¼ ins. to the foot. The side walls of the culvert are 2½ ft. thick at the top, next the covering, vertical on the inside and battered 1 in. to the foot on the back. The top of the culvert is covered with old rails in 7-ft. lengths spaced 12 ins. centers and filled over with a concrete covering 18 ins. deep. This covering was laid on forms placed in the top of the openings and left in place until the concrete had set, so that the concrete forms a solid mass both between and over the rail supports. The entire masonry work of the culvert is laid upon a grillage of old stringers. The photograph from which this view was reproduced was taken over the edge of the bank, so that the stream and its channel are hidden from sight.

Concrete arch culverts of ordinary spans are now extensively found on railways throughout the country, but not as numerously east of the Alle-

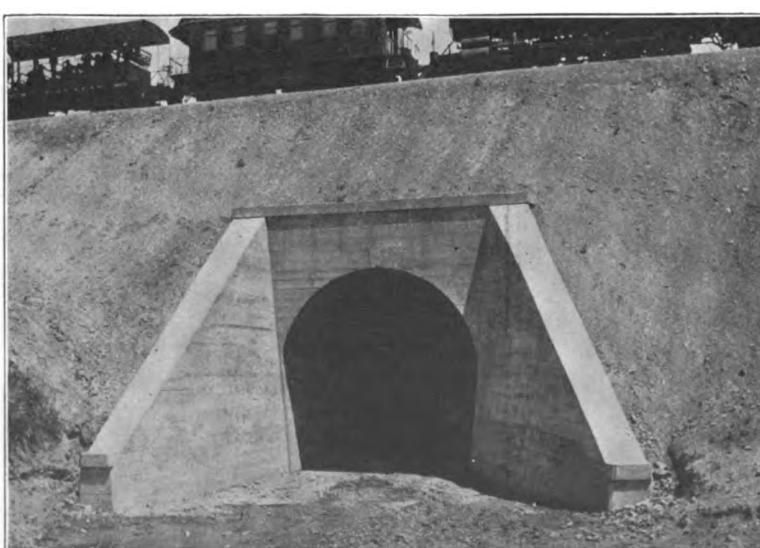

Fig. 12 A.—Concrete Culvert, 20-ft. Span, Union Pacific R. R.

gheny mountains as west of them. A good example of such construction is illustrated in Fig. 12A, being one of the standard structures of this class on the Union Pacific R. R. The side or bench walls of this culvert are 8 ft. thick at the bottom, and are battered on the inside face 1 in 12, so as to meet the battered wing walls without making a re-entrant angle. The arch is full centered or semicircular and is 24 ins. thick at the crown. The clear opening under the crown of the arch is 20 ft. and the length of the culvert is 97 ft. The Chicago, Burlington & Quincy Ry., on its Iowa divisions, has built numerous arch culverts having concrete side walls, wing walls and face walls, but with brick rings. Under high embankments these culverts are built in sections not to exceed 40 ft. in length, with tarred paper between the sections, so that unusual settlement will not break up the solid masonry. This principle of construction is applied to both arch and rail-top culverts on this and other roads. In some of the culverts of the Missouri, Kansas & Texas Ry. burnt clay ballast has been used as a substitute for broken stone in the concrete.

Reinforced Concrete Arch Culverts.—One of the recent developments in the use of concrete in arch construction is the reinforcement of the masonry with steel members. This scheme saves something in concrete, at least in large structures, and binds the material together in such a way

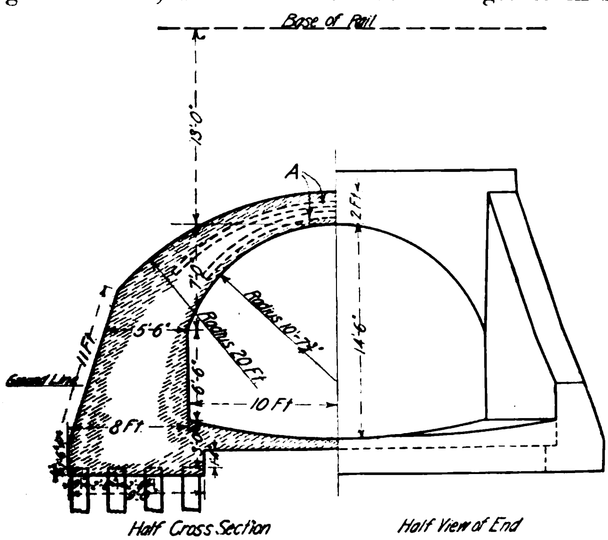

Fig. 12 B.—Reinforced Concrete Arch Culvert, L., E. & D. R. Ry.

that it is not liable to be greatly weakened in case of settlement under high embankments or from lack of uniformity in foundations. In practice there are various types or designs of reinforcement. In some cases expanded metal of No. 10 gage and 3-in. mesh has been embedded in the arch ring, side walls, face and wing walls of concrete culverts. In the standard concrete arch culverts of the New York Central & Hudson River R. R. a netting of No. 8 galvanized wire, mesh 1x2 ins., is embedded in the arch ring.

On quite a number of roads the reinforcing members consist of steel rails embedded in the arch ring. As used on the Lake Erie & Detroit River Ry. these rails are curved to the arch, as illustrated in Fig. 12B, which is a part section and end elevation of a culvert over Little Cedar creek, 29 miles east of Walkerville, Ontario. The arch is 51 ft. long, face to face, and, covering a width of 24 ft. divided across the middle line, there are ten track rails, curved workwise and embedded in the concrete. The abutment and wing walls stand upon a foundation of four rows of live oak piles, spaced 2½x3 ft., driven to a depth of about 16 ft. and cut off at an elevation 6 ins. above the lower limit of the concrete work. The principal dimensions appear on the drawing. The spandrel walls are 2½ ft. thick and extend 1½ ft. above the crown of the arch. The wing walls are 22 ft. long and open out at an angle of 12 deg. Up to the springing line of the arch the face of each wing wall stands vertical, thus permitting it to meet the face of the abutment wall at a vertical corner and avoiding a re-entrant angle. Above the springing line the wing walls are slightly battered and finished without coping at a slope of 1.7 to 1 from the ground line, which is 6 ft. above foundation. The paving of the culvert is a flat inverted arch of concrete 12 ins. thick on the center line and 20 ins. thick at the abutment walls. The paving extends the entire length of the opening between the wing walls, or 95 ft. from end to end, and is curbed at either end with a concrete wall 2 ft. thick and 2½ ft. deep. The material of which the arch is composed consists of 1 part of Portland cement to 2 parts of clean, sharp sand and 3 parts of crushed stone. The concrete in the remainder of the work is composed of 1 part Portland cement to 3 parts of sand and 5 parts of crushed stone. To protect the back of the arch and abutment walls those surfaces were covered with a layer of asphaltum applied hot. The volume of masonry in the structure is 785 cu. yds. The total cost of the culvert was $6700. On the Grand Trunk Western Ry. segmental arch concrete culverts are reinforced with straight pieces of old rail embedded in the arch ring crosswise the barrel of the arch. In this manner they pass close to the intrados at the top of the arch and extend out toward the extrados at the haunches, being cut to such length that the ends of the rail do not project from the arch ring. The spacing of these reinforcing rails is 2 ft. centers under the tracks, increasing to 2½ ft. and then to 3 ft. centers towards the ends of the barrel.

The Luten type of reinforcement, which has been applied to a number of culverts on the Cleveland, Cincinnati, Chicago & St. Louis Ry., consists in the use of single rods passing through those portions of the arch which are in tension when the structure is under live load. The arrangement is illustrated in Fig. 12C. The span of this arch is 18 ft., the clear opening 9 ft.; the curve of the intrados is three-centered, with radii of 5 ft. at the haunches and a radius of 12 ft. under the crown. The thickness at the crown is 17 ins., at the springing line 30 ins. and at the base of the abutments 7 ft. The reinforcing rods, which are smooth, round and 1 in. in diam., are embedded near the intrados at the crown and near the extrados at the haunches, crossing the ring at points of minimum bending moments. They are thus arranged with the intention

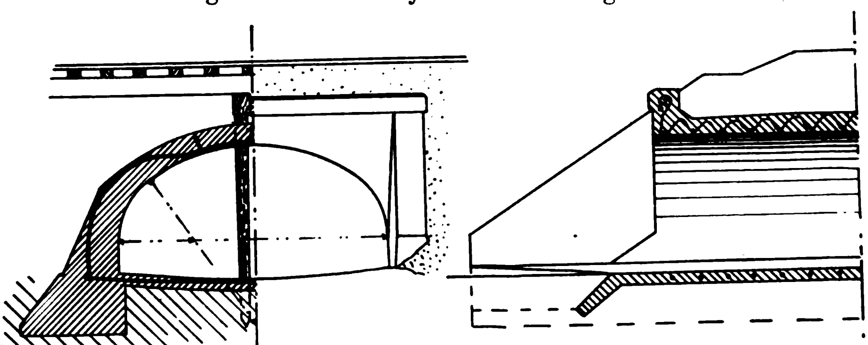

Fig. 12 C.—Reinforced Concrete Culvert at Acton, Ind., C., C., C. & St. L. Ry.

of putting them in tension their entire length. They are spaced at intervals of 2 ft. To resist the horizontal thrust of the arch steel tie rods running from abutment to abutment are joined to the arch rods and embedded in the pavement of concrete in the bed of the stream. Each horizontal tie rod is bent around its corresponding upper rod and then hooked to the adjacent or the second rod from that one, thus bonding the bench wall together longitudinally by either a single or a double row of rods at the base of the wall. The arch and bench walls were built in radial sections of 10 ft., corresponding to the work of each day, and at the base of the abutment or bench walls the sections are bonded together with old steel rails embedded lengthwise the arch or parallel to the opening. The arch replaced an old timber trestle, and was constructed around a pile bent which remained standing in openings through the arch ring until the centers of the arch were struck. The track was then supported by blocking the stringers directly upon the crown until the openings were filled with concrete, the traffic being permitted to pass at ordinary speeds while the work of filling was under way.

The Illinois Central R. R. has built a large number of concrete culverts and bridges (in spans up to 140 ft.) in a variety of forms. One class of structure used for culverts of 10 to 15 ft. span consists of a very flat type of concrete arch reinforced with straight I-beams. It is the rail-top principle of construction with the concrete finished to a three-centered flat arch underneath. The 15-ft. spans have seven 9-in. I-beams 17½ ft. long spaced at 18 ins. centers under each track and embedded in the concrete, which is 18 ins. thick at the crown—3 ins. thick below the beams and 6 ins. thick above them. The top surface of the concrete is flat, except at the sides, where it slopes to 4-in. drain tiles through the parapet or face wall. Over a segment of 11 ft. the intrados is curved to a radius of 20 ft., and at the haunches the radius is 2 ft. The culverts of 12 ft. span have a radius of 16 ft., for a chord of 8 ft., and haunch curves of 2 ft. radius. The reinforcement in these culverts consists of five 10-in. or 12-in. I-beams 16 ft. long under each track, spaced 2 ft. apart. In one double arch culvert the 12-in. I-beams are continuous over both of the 12-ft. arches. For the 10-ft. spans the reinforcement consists of five lines of 10-in. I-beams 14 ft. long, spaced 2 ft. apart under each track. The radii of the intrados are 16 ft. for a chord of 6 ft., and 2 ft. at the haunches. Many of these culverts have concrete inverts 8 ins. thick. In many instances the depth of filling over the culvert is only 18 ins. of ballast, measuring from the top of the concrete to the bottom of the ties. On this road numerous stone arch culverts and bridges have been repaired with a lining or casing of concrete to protect the stone from further disintegration. At one place the arch of a culvert of 16 ft. span was lined with concrete 8 ins. thick and the bench and wing walls were encased with concrete of the same thickness. In some cases a concrete invert has been placed and the bench and wing walls have been faced with concrete, without lining the arch. An account of lining a stone arch of 50 ft. span with concrete (Philadelphia & Reading Ry.) was published in the Railway and Engineering Review of March 31, 1900.

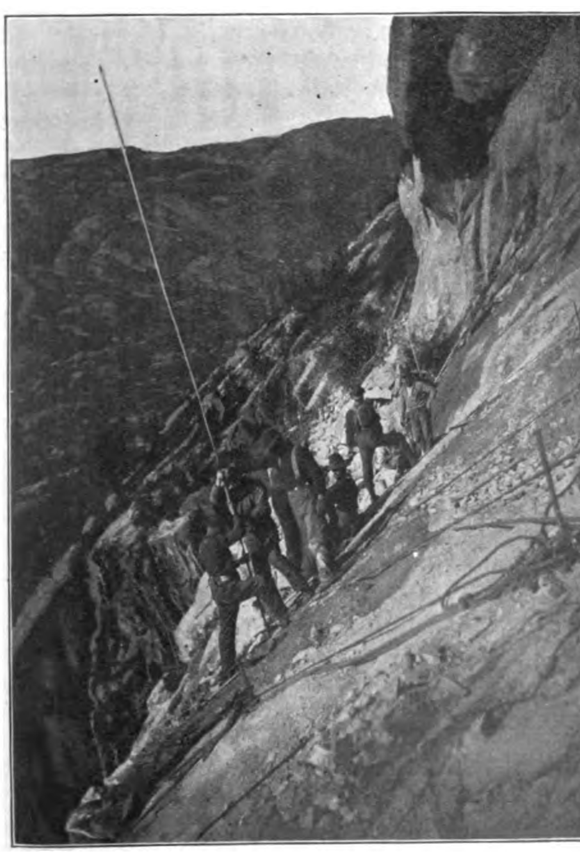
General Considerations.—By way of general conclusion on the subject of culverts it may be said that, as far as is feasible, all structures under the track should be made permanent. The cost of renewing a structure at the end of a period more or less certain is not the only factor to be taken into consideration when figuring out the economy of temporary construction. The service rendered by a temporary structure usually calls for a good deal of the time of the section men, sooner or later, which means interruptions to the track work, but which are not always counted upon in reckoning the ultimate cost of a temporary structure. In building a road where the culverts must be constructed of material shipped in, and particularly if of large stone or heavy pipe, temporary trestles are usually constructed at the openings in the roadbed and the culvert work and filling are taken up in convenient season.

One object which should be continually before the mind of the engineer of construction should be to reduce as far as may be practicable the number of openings under the track. Thus, for instance, the locations for cattle passes may frequently be selected at points where culverts are required, although to do this, in some cases, may require a little diplomacy with the farmers, perhaps. Otherwise there is liable to be a temptation, and one too frequently yielded to, to dispose of such openings with inferior construction, such as pile bents with plank bulkheads, open culverts, or other openings which answer to the same description. If the location of a cattle pass does not call for construction adapted to the flow of water it should nevertheless measure up to the standard of requirements for the roadbed and track, and rail-top culverts or arched masonry openings are to be recommended. The opening of ordinary size for this purpose is 7 ft. high and 5 ft. wide. Where no water is to be carried wing walls are not provided. On some concrete arch cattle passes the barrel of the arch is carried out to, and finished off at, the plane of the embankment slope.

In some situations it is possible to do away with culverts entirely, even where a stream must be taken care of, as in the case where the road crosses a loop in a stream and the scheme of cutting a channel to shunt the stream across on the up-stream side of the track is practicable. In each case of this kind two culverts can be avoided. A remarkable application of this scheme of engineering may be seen just east of Ft. Steele, Wyo., on the Union Pacific R. R. Here the road crosses a bend in the bed of a stream emerging from a canyon through which a great deal of water passes when snow melts in the spring. Within the loop the road cuts across the end of a rocky bluff, and in order to divert the course of the stream, so as to save two culverts, a tunnel 360 ft. long, 6 ft. high and 5 ft. wide was cut through the rock.

There is also a scheme, sometimes resorted to, for shortening the length of a culvert where a fill is made across a narrow and deep ravine. In place of a culvert through the lowest part of the embankment, which in some cases would have to be several hundred feet long, the ravine is filled with loose rock for some distance up from the bottom and provision is made for carrying off flood water by putting in a culvert at a high level and cutting a drain into the solid bank, on one or both sides of the ravine, so that in case the water cannot all find its way through the permeable embankment, the upper opening or openings will prevent the flood from rising to dangerous hight. With such an arrangement, however, there is some question as to whether the ravine would not in time fill with sediment and debris to the level of the culvert. With a culvert of ample size there would appear to be no particular objection to this plan of construction, but, except in rock formation, the necessity for providing a substantial pavement or spillway to prevent wash from the outlet might entail enough expense to offset what was saved in length of culvert. It is to be considered, however, that, as between two openings of the same size, the water will flow away more rapidly through the lower one, should the opening prove to be inadequate to pass the water freely, owing to the greater head possible. It is also true that the lower the culvert is placed, the less likely is the flood water to rise to the level of the track, owing to the increase of flow with head.

A notable example of the application of this principle of construction is the Cascade rock fill on the Erie R. R., near Gulf Summit, 184 miles from New York City. Here the road crosses a narrow gorge formerly spanned by a bridge 275 ft. long and 175 ft. high above the stream. In 1850 this gorge was filled, the bottom part with slaty rock in thicknesses up to 18 ins. The embankment is 480 ft. wide at the bottom of the ravine, and the sides, which are faced with earth, gravel and cinders, stand at slopes varying from 1.58:1 to 1.44:1. This ravine drains about 5 sq. miles of territory, and during ordinary times the permeable rock fill passes the water. Usually the water stands in a pool about 15 ft. deep, but at times this goes almost dry. To provide for floods a tunnel 320 ft. long and 10x13½ ft. in section was cut through the rocky bluff on one side of the ravine, 53 ft. above the normal water level in the pool (the bottom of the tunnel is 96 ft. below grade), and in times of heavy rain or rapid thawing the water rises to this tunnel; frequently the discharge has been known to almost fill the tunnel. The spillway from the tunnel is over solid rock. Apparently the rock in the bottom of this embankment has not been silted to a level higher than 10 or 15 ft. Observation during a period of 12 years (1888 to 1900) showed no change in the normal level of the water passing through the fill.



Building Track Foundation Under Difficulties, White Pass & Yukon Route.

CHAPTER II.

TRACK MATERIALS.

6. Rails.—Among track materials the rail has received more study or careful attention at the hands of engineers than any other one thing, and it has been greatly improved and cheapened. Improvement in the quality of the metal and the decline in cost of manufacture began with the introduction on a commercial scale of that great invention, the Bessemer process of making steel. A Bessemer steel rail was laid on the Midland Ry., in England, as early as 1857, but the behavior of most of the Bessemer steel rails rolled at about that time is reported to have been unsatisfactory, and for seven or eight years their manufacture was abandoned. The first steel rails made in the United States were of Bessemer steel and were rolled in Chicago in May, 1865; the first Bessemer steel rails to be produced on commercial order were rolled in Johnstown, Pa., in August, 1867. Practically all of the rails now in service in main tracks in this country are of Bessemer steel. Iron rails have gone out of use, except possibly on a few unimportant roads where the volume of the traffic has not been sufficient to wear them out, or where they have been taken from main tracks and put into side-tracks. The introduction of the Bessemer process fairly revolutionized the art of rail manufacture and the ultimate effect upon railway building can hardly be overestimated. The cheaper product has made possible the heavier rail of recent years, not to speak of thousands of miles of new lines which, in all probability, but for this cheaper product would not now exist; and this heavier rail, with its increase of strength, has made possible the heavier locomotives and cars of greater carrying capacity now everywhere employed. The amount of historical data essential to anything like a comprehensive statement of rail development would overswell convenient limits of space in this book; hence the story can only be touched upon, and that in a rather disconnected way.

Weight of Rails.—Looked at directly from a financial standpoint, the question which first arises in construction is the weight of rail to be used. Concerning this matter fixed rules are not in fashion, nor, except at more or less wide extremes, can conclusive evidence be deduced from practice which will decide upon anything like a definite weight for the case in hand. First of all, with new roads a prediction of the amount of business for the first few years, at least, must always be something of an uncertainty; but even with old roads which do a good business, and where the amount of it is fairly well established, there is not, in the nature of things, opportunity to clearly demonstrate the most economical weight of rail within perhaps 15 or 20 lbs. per yard. To appreciate the force of this statement one must be able to understand how numerous, how varying, and how indeterminate are the conditions which must be taken into consideration. It is a question depending more upon judgment, as the term is commonly understood, than upon direct or conclusive demonstration. Some general principles are recognized, however, which cannot be far from the facts.

Views respecting the minimum weight which can be profitably used accord pretty closely. It is safe to say that no standard-gage steam road constructed to-day with a view to permanency could afford to use in main track a rail lighter than 60 lbs. per yard. Roads not operating more than ten trains per day, unless the locomotives were unusually heavy, would probably not save anything in the end by going much above this. Within limitations quite generally understood, the logical guide in weight of rail is volume of traffic. When the amount of traffic is known, something approximate to the increased service in years, per added weight of rail, can be ascertained, but just what saving in repairs can be effected by an additional outlay for so many extra tons of rail per mile, as required by the section of increased weight, cannot be stated with any degree of certainty. It is known that there is a saving in repairs by any increase of section, but where such increase reaches the point at which saving in repairs plus the saving due to added life of rail, is balanced by interest on additional outlay, plus depreciation on the extra weight which must go to scrap, cannot be stated with any greater accuracy. Any road making the change to larger section can appreciate the results, and a road doing a paying business is not so liable to feel the cost, even though it may use a rail somewhat heavier than actually results in economy. A company earning large profits could the more easily be induced to adopt a rail of heavy section; and profits have been made the basis for judgment in more instances, perhaps, than has the amount of traffic. Increase in size or weight of rails has been an empirical growth. Increase in wheel loads and in speeds was necessarily accompanied by increased deflection in the rails and greater depression of the track into the ballast, thus calling for more work to maintain the track in surface. When observations of this character made the rail appear too weak the section would be made somewhat heavier, until it seemed to answer the requirements fairly well. It is true of practice to say that the relative amount of work required to keep the rails in desired surface has been the index which has governed rail design so far as the weight was concerned. The conditions of rail support are such that stresses in the rails from the loads imposed by the traffic are not determinable from mathematical calculations—at any rate no man of experience has made bold to propose a method of theoretical investigation of the problem. It remained for Mr. P. H. Dudley, within recent years, to show, by means of his "stremmatograph," what the magnitude of the stresses in rails really were. This is done by actual measurement of the strains in the fibers of the rail base, from which the stresses are deduced by a well known process. The subject is dealt with in some detail in § 181, Chap. XI.

It seems a striking coincidence that, with no attempt at complying with formulated rules, the average weight of rails has maintained a pretty nearly fixed relation with the average weight of locomotives. It is not far out of the way to express this relation by saying that the average weight of rail in pounds per yard has corresponded to the average weight of locomotives in tons. In the days of 50-ton locomotives we had the 50-lb. rail, and later on there were 60-lb. and 70-lb. rails to meet a corresponding increase in weight of locomotives. At present we have 80-ton locomotives and 80-lb. rails in pretty general service, while 100-lb. rails are in use on about as many roads as are 100-ton locomotives. On a comparatively few roads locomotive weights have advanced a good deal beyond 100 tons, but such cases are too rare for the purpose of the present comparison. While it may be true that increase in weight of rails relatively to the increase in weight of locomotives may have been a little tardy, at times, it is nevertheless a fact that the developments along the two lines have moved parallel.

Rails weighing 75 or 80 lbs. per yard are ordinarily found on lines of heavy traffic.* A few years ago it appeared that tendencies were strongly set toward the general use of 100-lb rails in the near future, but the gain in that direction has been slower than was expected. As a matter of history 80-lb. rails (5-inch) were first used in 1884, on the New York Central & Hudson River R. R.; 95-lb. rails (5-inch) in 1891, on the Boston & Albany R. R.; and 100-lb. rails (6-inch) in 1892, on the New York Central & Hudson River R. R. The entire line of the Boston & Albany road (202 miles of double track) was completely laid with 95-lb rails in 1897, the latest section then used having the following dimensions: hight, $5^1/_{32}$ in.; width of base, $5\frac{1}{2}$ ins.; width of head at bottom corners, 3 ins.; sides of head sloping 1 in 16; depth of head, $1^9/_{16}$ in.; depth of flange, 1 in.; thickness of web at middle $\frac{5}{8}$ in.; radius of top of head and of side of web, 14 ins.; fishing angles, 14 deg.; radius of top corners of head and of bottom fillets, $^5/_{16}$ in.; radius of top fillets, $\frac{1}{2}$ in.; radius of bottom corners of head $\frac{1}{8}$ in.; radius of corners of flange, $^1/_{16}$ in.; edge thickness of flange $^5/_{16}$ in.; web $\frac{1}{8}$ in. thicker next the base than under the head. The earliest roads besides the N. Y. C. & H. R. R. R. to begin the use of 100-lb. rails were the New York, New Haven and Hartford; the Pennsylvania; the Chesapeake & Ohio; the Pittsburg, Bessemer & Lake Erie; the Duluth & Iron Range; the Buffalo, Rochester & Pittsburg; the Pittsburg & Western; the Canadian Pacific and the Lehigh Valley. During the eight years after 100-lb rails were first put into service in this country, the total length of track laid with the same was only about 2200 miles, of which the Penna. R. R. had 1085 miles and the N. Y., N. H. & H. R. R. 500 miles, but since then the increase in the mileage of rails of this weight has perhaps been more rapid. Some of the 100-lb. rails are of the American Society of Civil Engineers' standard section and others are of independent design. The rail in use on the New York Central & Hudson River R. R. is 6 ins. high, $5\frac{1}{2}$ ins. wide on base and 3 ins. wide at the bottom corners of the head. The depth of head is $1\frac{5}{8}$ ins.; depth of flange, $^{31}/_{32}$ in.; edge thickness of flange, $^9/_{32}$ in.; thickness of web at narrowest part, $^{19}/_{32}$ in.; web $^7/_{32}$ in. thicker next the base than next the head; radius of bottom corners of head $^1/_{16}$ in. In other respects the section is shaped like, and has the same dimensions as, that of the 95-lb. rail of the Boston & Albany R. R., above referred to. The remarkable features of the section are the broad and shallow head and the unusual hight, the latter contributing to increased stiffness. The metal is distributed in head, web and flange in the proportion of 40.8, 23.5 and 35.7 per cent. The section of the 100-lb. rail in use on the Pennsylvania R. R. (Fig. 19) differs materially, the dimensions being as follows: hight, $5\frac{1}{2}$ ins.; width of base $5\frac{1}{2}$ ins.; width of head at bottom corners, $2^{13}/_{16}$ ins.; sides of head slope 4 deg.; depth of head $1\frac{3}{4}$ ins.; depth of flange, $^{15}/_{16}$ in.; thickness of web at middle, $\frac{5}{8}$ in.; radius of top of head, 10 ins.; radius of top corners, $^7/_{16}$ in; radius of fillets, $\frac{1}{4}$ in.; radius of side of web, 8 ins.; fishing angles, 13 deg.; distribution of metal in head 46 per cent, in base 34 per cent, in web 20 per cent. The 100-lb. section of the New York, New Haven & Hartford R. R. has the same general dimensions as that of the New York Central & Hudson River R. R., except that the head is narrower and

*Heavy traffic, as determined by a committee of "reporters" to the International Railway Congress, in 1900, is supposed to comprise a movement of 10,000 or more trains per year (27 or more trains per day) on one track, or that number on each track of a double-track line.

deeper, the width at bottom corners being $2\frac{3}{4}$ ins. and the depth $1^{23}/_{32}$ ins. The radius of top corners is $^{7}/_{16}$ in., fillet radius $\frac{1}{4}$ in., fishing angles 13 deg., radius of side of web and top of head 12 ins., depth of flange $^{15}/_{16}$ in., web same thickness at base as under the head. The distribution of metal is as follows: head, 41.65 per cent; web, 23.65 per cent; flange, 34.70 per cent.

Rail Design.—For convenience the cross section of the rail is quite easily divided into three distinct parts—head, web and base or flange. Conventionally described, the head includes all the metal above its under sides produced to meet in the vertical axis of the section, the greatest depth being shown by dimension *E*, Fig. 13. The base or flange includes all the metal under its upper sides produced to meet in the vertical axis of the section, the greatest thickness being shown by dimension *G* in the figure. The web includes the remaining metal, or that between the head and flange, the hight of which is shown by dimension *F* in the figure. Regarding the relative proportions of these three parts there has been much discussion. Inasmuch as but little of the metal is usually lost by oxidation or rust, the head is the only portion which usually wears out, and the idea which prevailed for a long time was to put into it as much metal as conditions affecting the other parts would allow. The most important of these conditions arises during the process of manufacture. As the flange is thinner than the head it naturally cools more rapidly, both during and immediately after the rolling process, and if the quantity of metal in the head greatly preponderates that in the flange the disparity in the rate of cooling of the two parts is correspondingly large. In order to produce a straight rail, therefore, it must, after the last pass through the rolls and before it is placed upon the hot bed to cool, be given an amount of camber or upward curvature which varies with the excess of metal in the head over that of the flange; so that at high heat the head is made longer than, or is curved around, the flange. Now while steel is cooling down from the rolling or finishing temperature there are certain stages at which there is, for an instant, a retardation in the falling of the temperature, and sometimes there is a perceptible increase of heat. These stages are known as "points of recalescence" or "critical points." Steel containing less than 0.20 per cent carbon has three of these points, at 1580, 1365 and 1200 deg. F., while ordinary rail steel, with 0.45 to 0.55 per cent carbon, has only one, which lies between 1290 and 1340 deg. F. The phenomena observed in the cooling of a rail from the finishing temperature are about as follows: After cooling a little there is at first a recalescence of the flange, straightening the rail and giving it a slight downward curvature, and later a recalescence of the head, giving the rail camber or upward curvature, frequently exceeding the amount first put into it, until finally it begins to straighten for the third time, and after 40 to 45 minutes, when cool, the rail is approximately straight and is finished by gagging, or straightening under a press.

The effect of this unequal cooling is to produce strains in the metal, as indicated by the flexure, and so far as permanent set takes place in the interior of the metal the strength of the rail is affected. That permanent set does occur in cooling is shown by the fact that the rail does not cool straight; and then to get it straight it must be bent in the cold condition and be given more permanent set. It thus occurs that in order to produce rails of desired quality the design must in large measure suit the conditions of manufacture. These conditions improve as the quantities of metal in head and flange approach an equality, and the preponderance of enlightened opinion stands for that form of section in which these two parts are as nearly balanced as the purposes of the rail and economy of material will seem to permit. With this twofold object in view the aim respecting the distribution of the metal is to minimize the necessary amount of initial camber, and therefore the severity of the cooling strains and the amount of gagging necessary; for the greater the amount of camber used the greater is the liability to kinking while the rail is cooling. Experience has also shown that the life of a rail depends but relatively little upon the amount of metal in the head available for wear, as is explained further along—the dependence in this respect is rather upon the wearing properties of the metal, for in practice the rail usually becomes unserviceable after only a relatively small portion of the head has worn away. The old idea that the rail head should be deep has been pretty thoroughly explained away. Examples in the distribution of the metal over the section have already been referred to, and further along the subject is again taken up.

After settling upon the distribution of the metal in the three parts of the rail, the next matter for consideration is the exact form and dimensions of these parts. Perhaps first in importance is the relation between the hight of the rail and the width of the flange. As strength and stiffness increase very rapidly with increase in hight of section, that dimension should be as large as is consistent with stability and the proper proportioning of the parts. The idea sometimes advanced that a rail can be too stiff for the rolling stock is absurd. This idea probably takes its inception from the fact that rough track in stone ballast (which is the hardest and stiffest ballast) is more severe on rolling stock than in other kinds of ballast; but stiffer rails in such a case would be beneficial. Rails of available weight cannot be made as stiff as it is desirable to have them. Assuming that the cross sections of rails of different weights are similar (This is not strictly true, but the approximation is close enough for practical considerations), it follows from mechanical laws that the strength (measured by safe load) varies as the cube of the hight and the stiffness (measured inversely by deflection) as the fourth power of the hight. For example, a rail 5 ins. high is practically twice as strong and 2.4 times as stiff as one 4 ins. high, although it is only $1\frac{1}{4}$ times as heavy. An 80-lb. rail (hight 5 ins.), which is $33\frac{1}{3}$ per cent heavier than a 60-lb. rail (hight $4\frac{1}{4}$ ins.), is 62 per cent stronger and 91 per cent stiffer. The increase of stiffness with hight of section in rails of the same weight is also surprisingly large. Although the stiffness of the track does not increase in proportion to increase of stiffness in the rail (the supporting power of the ballast and roadbed having to be taken into account), nevertheless the relative stiffness of the rail is an important matter in maintenance economy. Increase of stiffness in the rail distributes the load farther from the bearing point—that is, over more ties—thus reducing the pressure per unit area of the ballast and roadbed, which reduces the rate of settlement of the track. It is also to be noted that stiff rails do not cut into the ties as badly as the more flexible ones. That stiffness could be carried much farther than it is in practice, without making the rail too weak laterally, is true; but to do so would necessarily draw metal from and weaken the flange, which, for reasons to be stated, is not advisable.

The points of advantage in a wide flange are that it distributes the load over more tie surface, thus operating less destructively upon soft ties; it gives the rail side stability and it also gives it stability against canting or tilting on curves. Of such importance are the claims for both high rail and wide flange (and the fact that one cannot be carried far without affecting the dimensions of the other) that, in the largest practice, a compromise has been struck at making the two equal. Any variation in this relation is usually in favor of the hight, but not more than ½ in., in the largest rails.

As to the proportions of the head, everything seems to favor the broad head as against the deep one. The wider the head the wider is the bearing for the wheel tread, the effect of which should be to prolong the life of both rail and wheel. The shallower head broadened out adapts itself much better to rolling, as it cools more quickly than the deep one and thus reduces the cooling strains. The broader and thinner head also makes room for deeper and thicker angle bars—a matter of great importance as affecting the stiffness of rail splices.

Concerning the top of the rail head some claim that it should be flat, while others go farther and say that it should be flat and also inclined to correspond to the coning of the wheels. It is supposed that thereby the tractive power of locomotives would be slightly increased and that the treads of wheels instead of wearing concave and reversing the conicity, as really does happen, would better retain their original form as wear takes place. It is also claimed for the flat-top rail that flow of metal and consequent scaling of the head, from wheel pressure, cannot so readily take place. Against these claims it is argued that while the flat-top rail would undoubtedly increase to some extent the tractive power of the locomotive, at the same time the resistance which such a rail would offer to rolling wheels would be greater, so that, after all, the effectiveness of the locomotive would not be increased, if indeed it would not be very much diminished. As a reason for this it is explained that on flat-headed rails wheels run with considerable noise, while with the same wheels on a rail having a radial top the noise is very much less. As noise in machinery indicates wear and loss of power, it is inferred that such is the case with wheels running on a flat surface; and hence a compromise between reduced locomotive traction on the one hand, and added rail resistance to wheels, on the other, is arrived at by shaping the top of the rail head to a comparatively long radius, 10 and 14 ins. being the minimum and maximum in common use.

It was formerly taught that friction is independent of extent of surface except at limits of abrasion. It is generally conceded now, although not well formulated as yet, that this does not apply to rolling friction, at least, but that rolling friction decreases with decrease of bearing surface, and hence, for car wheels, both train resistance and wear on the rail are less for the radial-top rail. Regarding the traction of the locomotive it is well known that driver tires soon wear to fit any shape of rail head, for which reason any loss in tractive power due to small bearing surface for the driver will take place during only a short time while the tire is new, or immediately after it has been turned down. It is also pointed out that the side play in the wheel is bound to wear the tread hollow, and the hollow tread will in turn wear the rail head to a curve. Repeated observation of this mutual wear has shown that the rail top is worn approximately to a curve of 12 ins. radius, whatever the shape of the head. While this consequence may not follow as quickly with a flat-top as with a radial-top rail the same result is nevertheless eventual. So far as bearing is concerned the worn tread obtains full bearing upon rails with curved top, but as for new wheels on a radial-top rail the ideal conditions are supposed to obtain, so that, taking conditions as they are bound to occur, everything seems to favor the rail with a curved top. Facts above stated explain why a curve of 12 ins. radius is considered the natural shape of the rail top. The practice of increasing this radius is defended by those who favor it, on the ground that the larger the top radius the less severely is the head indented by the gags in the straightening press during manufacture.

There is another argument put forth to prove that the rail having the radial top reduces the rolling friction of wheels to a minimum. The coning of wheels is practiced for two reasons; viz. to effect a slight gain of speed of the outer wheel over the inner one on curves, and to facilitate the adjustment of the speed difference of two wheels on the same axle having slightly different diameters. It is the latter reason which it is desired to consider here. It will occur to any one that to always get two wheels of exactly the same diameter on the same axle must be a difficult matter; also that a difference in hardness between the metals in the two wheels will result sooner or later in a difference in diameters from the unequal wear. Were the wheel treads cylindrical this difference of diameters would cause the wheel of larger diameter to constantly outrun its mate, so that the axle would always take a position somewhat diagonally to the track, keeping the flange of the wheel of smaller diameter constantly grinding against the rail. If the tread of the wheel is coned, however, there is a constant adjustment of the wheels from one side to the other; for just as soon as one wheel is crowded over against its rail it is then rolling on a portion of its tread which is of larger diameter, and it sooner or later is able to gain on the other wheel and swing the axle back into line. This action can be observed of any pair of coned wheels running on straight track. The movement of the wheels, first to one side and then to the other, is not therefore an indication of a wrong condition, but that the wheels are properly adjusting themselves to difference in speed, and therefore to least resistance. If the wheels take a straight course, keeping always to one side, it may be inferred that their diameters are not the same, and that the constant running of one flange against the same rail increases the resistance. Now this coning of the wheels will give the desired effect on a rail head of any uniform shape, but another point arises in connection with the coning. Suppose the rail head be flat and beveled to correspond to the coning of the wheel. The contact between tread and rail may then be likened to a straight line drawn squarely across the rail head. Now the points of the tread in contact with the rail at opposite ends of this line—that is, at the gage side, and at the outside, of the rail head—are points on the extremities of unequal diameters. This means that in running a bevel-treaded or coned wheel on a bevel-headed rail, one part of the tread in contact with the rail must constantly slip ahead or else the opposite part slip back, or else both forward and backward slippings take place at the same time, as with reference to a point at the center of the line of contact, thus increasing the rolling friction of the wheel to some extent and consequently the abrasion of the rail. The force necessary to constrain a conical pail to roll straight across the floor furnishes a familiar illustration of the wasted power here referred to in the action of the wheel on the flat-top rail. With regard to the matter of abrasion, however, it might be disputed that the flat-top rail suffers the more in the end, especially when considering the effect of locomotive drivers; or it might be shown that locomotive drivers operate more severely on the radial-top rail, while ordinary car wheels, which are not so heavily loaded and which hold the coning longer, are more severe on the flat-top rail. Where, however, the top surface of the rail head is curved, the contact between wheel tread and rail is a point, or, more correctly, a small circle or ellipse, and consequently a speed difference between the outer and inner portions of the rolling tread in contact does not occur. The radial-top head undoubtedly contributes toward a minimum of rolling friction between wheel and rail as long as the coning lasts. After that the conditions would seem to be about the same in either case.

Ideas on the necessity for wide contact between wheel and rail have led to the practice of tilting the rail to fit the coning of new wheels. On European roads and in India it is the general practice to adz the ties to give the rail an inward cant of 1 in 20. This practice has been adopted on the Lehigh Valley road, in this country, where the rail (90-lb.) is canted ¼ in. toward the inside. Aside from the increased traction which this arrangement is supposed to afford, it does give considerable side stability to the outer rail on curves, some claiming that it answers every purpose of the use of rail braces. On European roads it is found that on straight track the pressure of the wheel on the canted rail has a tendency to cant the rail more, and does actually narrow the gage. On curves the tendency to cant toward the inside is opposed by the centrifugal pressure from the wheel flanges and the gage tends to widen.

Another point in rail design upon which opinions differ is in regard to the side of the head—whether it should be vertical or sloping. It was formerly the practice to use sloping heads more than it is now, the idea being that the side of the head should fit the wheel flange and thus remove the cause of vertically worn flanges. On this point opinion has largely changed, and there are now but comparatively few who endorse the principle of the flaring head. The evil effect of flange wear lies not necessarily in vertically-worn flanges more than any other, but in flanges so worn as to grind against the side of the rail head. As such takes place sooner on rails with a sloping or flaring head than on rails having a head with vertical sides, the preference would seem to be with the vertical side. As between wheels worn to fit the rail the state of things would seem to be the more favorable with the vertical-sided rail head and vertically-worn wheel flange, because on a sloping head there must be greater tendency for the wheel to climb the rail. For the same quantity of metal in the head the sloping side narrows the bearing for the wheel tread, and unless such rails are gaged at the top corner of the head there is permitted a considerable amount of side play in the wheels in addition to the customary clearance of ⅜ in. + wear of flange. It should be noted that, by reason of the closer fit of the wheel to the rail, this excess play is greater than the amount of slope or batter in the side of the head. With gages of the usual form (having vertically depending lugs) it is not practicable to gage the rails from the top corners, and, as a matter of practice, they are not so gaged. In some cases the gage lugs are shortened and the gage of the track is taken at a point midway up the side of the rail head. In other cases gages with ordinary lugs are used, and consequently the gage is measured at the lower corner of the rail head, such being the case on the New York Central & Hudson River R. R. It has been the practice on the Lehigh Valley R. R. to measure the gage from a point ½ in. below top of head.

The rail section designed by Mr. Robert H. Sayre for the Lehigh Valley R. R. many years ago has always been the criterion of rails with side-sloping heads. Formerly the side slope in the head of this rail was 10 deg., but in 1891 a modified section was adopted in which the slope was reduced to 5 deg. In 1899 this design was abandoned by the Lehigh Valley company for the American Society standard section, described farther along. The extreme of designs opposed to the wheel-fitting idea is found in the "pear-head" rail, in which the sides of the head slope inward from the top.

Rails of this shape are standard on some of the roads in Europe, but in American practice the idea has never been strongly entertained, although it has been tried to a small extent.

The point over which the largest amount of discussion has taken place is in regard to the radius of the top corners of the head. Authorities on the subject now advocate radii varying all the way from $\frac{1}{4}$ to $\frac{5}{8}$ in., the largest number, if not a majority, apparently, being in favor of $\frac{1}{4}$ in. In earlier years the upper limit of preferences was much larger, being $\frac{3}{4}$ or $\frac{7}{8}$ in. Those who approve of the longer radii incline to the wheel-fit idea, and point out that the use of a small radius produces more nearly the effect of a sharp corner in the wear of the wheel flange; that inasmuch as the wheels and rails on curves eventually wear to fit each other, anyhow, were the corner radius of the rail in the first place made more nearly that of the wheel flange fillet ($\frac{5}{8}$ in.) the flange could longer retain its shape. Those who incline to the opposite view explain that when the corner of the rail fits the fillet of the wheel flange there are parts of the wheel making contact with the rail which are not of the same radius; which means grinding action between the surface in contact and hastening of the time when the worn flange will grind against the side of the rail head. While it is true, as those who favor a longer radius claim, that on curved track the flanges will in time wear down the corner of the head to their own curve, still with the small radius such time is necessarily prolonged. It is also to be said in favor of the small corner radius that on straight line, where there is but little tendency to side wear from the wheels, the corner of small radius will keep the wheel flanges from grinding in the fillet and from contact with the side of the rail head for a long time, possibly as long as the rail remains in service, whereas if the corner is of comparatively long radius the wheel fillet will grind against it, and grinding of the flange against the side of the head will take place much sooner. Increase in length of radius of the top corners has also the effect of narrowing the top bearing surface of the rail, and it permits increase in side play of the wheels, as is explained in connection with the side-sloping head. Mr. M. N. Forney has shown that as between a corner radius of $^{11}/_{32}$ in. and one of $\frac{5}{8}$ in. the latter permits $\frac{3}{8}$ in. more side play in the wheels ($^{3}/_{16}$ in. on each side of the track) than the former, on rails gaged the same in either case.

In order to afford the greatest practicable bearing surface for the splice bars the lower corners of the rail head should be rounded but little, and a radius of $^{1}/_{16}$ in. for these corners meets with general approval. The radius for the corners of the rail base should also be small and the sides of the base vertical, so as to afford good bearing surface for the spikes. In some rails of the older designs the top corner and whole side of the base were rounded off to meet a sharp bottom corner which cut the spikes badly. For the further reason that rails with sharp corners are uncomfortable to handle it is desirable to avoid such features in rail design.

As to the shape of the web three forms are used: the web with straight sides; the web with concave sides, the thickness at head and flange being equal, the least thickness coming then at the middle; and the web with concave sides but thicker next the flange than next the head. It is claimed that concave or radial sides work an advantage in rolling, inasmuch as the web, being thinner than either the head or flange, should be thicker next those portions of the rail, which cool more slowly, since it is in those portions of the web that the greatest cooling strains occur. Radii which have been used for this purpose vary from 8 to 30 inches. The web with concave sides and thicker at the base than under the head has largely gone out of use. The object aimed at in this design is perhaps to give the section the appearance of stability, which, of course, is unnecessary. Rails with straight-sided webs have been used extensively, and the difficulties supposed to attend the rolling of the same without undue cooling strains are not generally concurred in. In rails of the same weight, with the same distribution of metal and fillets of the same radius, the web with straight or parallel sides leaves more bearing surface for the splice bars on the under sides of the head than does the web with radial sides.

There seems to be an idea somewhat prevalent that rails are rolled to be used as "rights" and "lefts," and some have professed to understand that the side bearing the rolling-mill brand is intended for the gage side. This is a mistaken idea. Both sides of a rail are supposed to be rolled alike, and if the rolling is properly done the rails may be laid without reference to the branded side. The custom of regarding the sides of a rail with respect to the manufacturer's mark, for any good reason, has been due to carelessness in manufacture, by permitting the rolls to remain in use after they have become unequally worn (as between top and bottom rolls), thus producing a rail of unsymmetrical section. Under such circumstances it is necessary to lay contiguous rails uniformly with respect to the position of the brand, else there will be lip at the joints. In such cases the position of the brand—whether inside or outside—is, of course, immaterial, so long as it is not changed on the same line of rails. It is perhaps needless to remark that if the rails were properly inspected at the mill there would be no necessity for the trouble of sorting them or of changing them from side to side of the track when they are laid. Bolt holes should be drilled, and not punched, lest the web may be fractured. In the old iron rails the bolt holes were sometimes punched and made oblong, so as to allow the rail to expand or contract without straining the splice bolts, but with steel rails provision for this requirement is made by drilling the holes in the rails larger than the bolts and in punching oblong holes in the splice bars.

Not so many years ago the designing of rail sections had become a fad. Most engineers in position to do so felt called upon to get up an independent design, and nearly every road had its own standard section, which would undergo modification as often as changes took place in the personnel of the engineering department. The result was an almost endless variety of designs differing to suit individual ideas, but comprising many collections which were practically identical except for slight and unimportant differences in dimensions. In keeping with this situation each rail manufacturer was obliged to carry a numerous assortment of rolls in stock, and attempts to reduce rail making to desirable standards were confusing. As a matter of record the rail mills at one time had no less than 188 different patterns which were considered standard, and 119 patterns of 27 different weights per yard were regularly manufactured. The situation was investigated by the American Society of Civil Engineers and, in 1893, after deliberating more than three years a committee* of the society reported upon a general type of section and series of sections conforming thereto, for rails varying in weight by 5-lb. increments, from 40 to 100 lbs. per yard. This report was accepted by the society and

*This committee was composed of the following eminent engineers: G. Bouscaren, Foster Crowell, S. M. Felton, Jr., J. D. Hawks, Robt. W. Hunt (Secretary), Geo. S. Morison, E. T. D. Myers, Samuel Rea, H. Stanley Goodwin, Thos. Rodd, A. M. Wellington, Virgil G. Bogue and F. M. Wilder.

recommended to the railway companies for adoption in practice, and the type of section has come to be known as the "American Society standard."

The form of this section is shown by Fig. 13, together with the following constant dimensions for all the sections embraced by the range of weights: Radius of top corners of head, $^5/_{16}$ in.; radius for bottom corners of head and corners of flange, $^1/_{16}$ in.; radius of fillets, $\frac{1}{4}$ in.; radius for top of head and side of web, 12 ins.; fishing angles 13 deg.; distribution of metal, in head 42 per cent, in web 21 per cent, in flange or base 37 per cent. The dimensions which vary with weight of rail appear in Table III. The hight of rail and width of base for each section are equal. It may prove a matter of some interest to state that out of 10 sets of preliminary designs for standard sections submitted by 11 of the 13 members of this committee, independently, in 1891, and previous to any discussion or comparison of views, all were in agreement upon 12 ins. as the top radius and nine were for $\frac{1}{4}$ in. as the top corner radius and for a head with vertical sides. Three sets of designs favored a web with straight sides and five favored concave sides on a radius of 12 ins.; the two other sets of designs offered radii of 9 and 30 ins. Only two of the 10 sets of designs proposed uniform percentages of metal in head, web and

Fig. 13.—Standard Rail Sections, Am. Soc. C. E.

base throughout the several sections of a set. The average distribution of metal for all the sections submitted stood 42.49 per cent for the head, 20.92 per cent for the web and 36.59 per cent for the base, or practically the percentages finally decided upon. The fishing angles proposed varied from 11 to 14 deg. Six of the 10 sets of designs (7 members) stood for a width of head exceeding $2\frac{3}{4}$ ins. for the 100-lb. rail, the maximum width proposed being $2\frac{7}{8}$ ins. (three designs). Seven sets of designs stood for equality in hight of rail and width of base; one set of designs (two members) made the hight of rail $\frac{1}{4}$ in. less than the base width and two sets of designs made it greater for the heaviest sections (100 lbs. in one case and 90 and 100 lbs. in the other case). The final decision upon $^5/_{16}$ in. as the top corner radius was the result of a compromise to get the two members who favored a larger radius ($^7/_{16}$ in. for rails of 50 lbs. per yard and lighter, and $\frac{1}{2}$ in. for heavier rails) to agree to other features of the proposed sections. Mr. Morison presented a minority report proposing the same width of head ($2\frac{1}{2}$ ins.) for all sections from 50 lbs. and upward, with a uniform distribution of metal at $41\frac{1}{2}$, 21 and $37\frac{1}{2}$ for all weights of rail. His argument was that, owing to interchange of cars, the same wheels must run upon rails of various weights, and in order that uniformity of wear on wheels and rails might obtain, the wearing surface of rails of all weight should be of the same shape and width; and in order that the wheels might properly track down the center line of each rail, the distance between the center line and the gage line should be kept constant on all rails. Mr. Wellington's views on this point admitted that on flat-top rails the application of the principle would be important, but he believed that on rails with a 12-in. top radius the side play in the wheels would naturally cause the treads to wear to a 12-in. radius for a width exceeding that of the widest rail head, so that, "on the principle of the ball-and-socket joint," the worn tread should fit any rail head not over 3 ins. wide. Coming down to fine points, the ball-and-socket principle could hardly apply with rigid axles, but the scheme of constant width of head is somewhat objectionable from another viewpoint, in that, for sections heavier than 80-lbs. the relative depth of the head is increased. The student of rail design should not fail to carefully read the progress report (1891) and final report (1893), with the appended correspondence, submitted by this committee of the American Society of Civil Engineers.

The adoption of rail sections of the American Society standard is on the increase. During the year 1903 rails of this type of section constituted fully 75 per cent of all rails rolled in American mills. The general adoption of a standard type of section should work for economy in several ways: As mills can keep running steadier in dull times, owing to the certainty that the product will find sale when orders begin to come in. and as there is less expense in fitting up rolls and less time lost in changing them, the rails should be made cheaper. Rails should also be made better, because the mills can more frequently avoid rush of work, and constant manipulation of rails of the same form gives a better opportunity to study the physical characteristics of the section and the requirements of rolling it.

Chemical Composition.—Regarding the chemical composition of steel rails it may be said that the impurities inherent in the iron or introduced into the same must be regulated to form a combination of physical properties not usually associated together in such degrees in any other article of manufacture. A railroad rail must be hard, in order to resist flow of metal under wheel pressure, and at the same time it must necessarily possess great toughness, in order to withstand the sudden and severe shocks of ponderous rolling loads. The impurities commonly found in the raw material are carbon, manganese, silicon, phosphorus, and sulphur. The first three are easily within the control of the manufacturer and are desirable, in more or less certain proportions, in order to give the rail its requisite properties; while the other two, as a matter of expense, cannot be entirely eliminated.

Carbon is first in importance among the desirable elements. By itself, alone, up to 1 per cent, it increases hardness and tensile strength but decreases the ductility or toughness. It was formerly used in proportions varying from 0.25 to 0.50 per cent, but late years the tendency is to higher carbon, in order to effect gain in hardness required to meet the increased wheel pressures. The properties of the metal also depend largely upon the manner of mechanical treatment, as frequent rolling at comparatively low temperatures will produce a fine grain and compact structure which will improve the wearing qualities of the rail, whatever amount of carbon is used, and the same treatment will make up, to a degree, the toughness lost by the use of higher carbon. Generally speaking, 0.40 per cent or under, of carbon, is now considered low; 0.40 to 0.55 per cent, medium;

and above 0.55 per cent, high. The most common practice, perhaps, is to use 0.45 to 0.55 per cent of carbon, but even as high as 0.70 per cent is sometimes used. It is deemed to be safe practice to increase the carbon with increase in weight of rail, for the larger rail is stronger, and, as less work is done upon it under the rolls, the hardness due to the extra carbon is needed to make up for loss in compactness of structure, in order that the wearing qualities may not be impaired. The proportion of carbon must also depend somewhat upon the percentage of phosphorus present: the higher the phosphorus the lower the allowance of carbon, and vice versa. A uniform specification for all grades of steel is not considered good practice.

Manganese is necessary to take up the oxides of iron formed while the metal is in the molten state, the products of the combination passing off in the form of slag. It also tends to prevent the formation of oxides while the heated metal is being worked into shape. In sufficient quantity it assists toward a more uniform distribution of the carbon through the iron. It facilitates the chemical combination of the carbon with the iron, at high temperature, and tends to prevent separation into graphitic carbon or graphite as the iron cools down. If not used to excess it imparts strength and toughness. If the iron is low in carbon the effect of manganese is similar to that of carbon alone, but diminishes the ductility in less degree; it may therefore replace carbon to some extent. It is considered an effective antidote for sulphur. When used in high percentages it has the effect of making the rail hard and coarsely crystalline, and its tendency is to brittleness, much the more as it exists in unnecessary quantity. Its use varies, according to circumstances, from 0.70 to 1.40 per cent.

Silicon is useful in that it acts as a flux, and, like manganese, and in the same manner, tends to prevent injury by oxidation of the iron. In this way it prevents the formation of blow holes, and imparts to the metal a solid structure of small crystallization. When of just sufficient amount it gives added toughness, but any increase beyond this tends to brittleness. It has a hardening effect and, to a limited extent, may replace carbon. Its use ranges from .10 to .20 per cent.

Sulphur and phosphorus are both objectionable elements, but difficult to eliminate entirely from the metal. They perform no useful combinations in any way not more satisfactorily obtained by other elements, and must be kept low, sulphur generally not to exceed .07 per cent, and phosphorus not to exceed .085 per cent. Rails high in either cannot be so high in carbon, as already stated. Sulphur produces red-shortness or hot-shortness (brittleness at high temperature), thus imparting to the metal a tendency to crack and form seams in rolling. Phosphorus increases the size of the crystallization and causes cold-shortness, making the metal hard and brittle and liable to crack or break in cold weather. It should be said, by way of parenthesis, however, that for steel very low in carbon a small percentage of phosphorus (not to exceed .04 per cent) is claimed to be beneficial, in that it seems to add strength to the metal. In the metallurgy of iron and steel there is apparently no rule which holds good throughout the range of combination of any one of the alloys, and this fact in respect to phosphorus would seem to be only one of the exceptional cases.

Traces of copper are frequently found in rail steel, and sometimes it runs as high as 0.80 per cent, although specifications do not usually require it or place limitations upon the percentage used. It was formerly understood that the tendency with copper was to produce red-shortness, but recent experiments (by Stead and Evans) made known to the Iron and Steel Institute, and others, are offered to prove that between 0.5 and 1.3 per cent copper has no deleterious effect on either the hot or cold property of steel. In small quantities it slightly raises the tenacity and elastic limit, without tendency to brittleness, but reduces the toughness, although this effect is not pronounced when the quantity is small.

Oxide and slag generally exist to the extent of 0.10 to 0.12 per cent, but are not usually determined. When present in quantity sufficient to render the metal spongy the wearing qualities of the metal are impaired. In the molten metal the tendency of these constituents is to float to the top of the ingot, and formerly it was the practice in the mills to cut off and reject sufficient material from the top part of the ingot to discard these impurities. In later practice, however, owing to the cheap price of rails and the rapid handling of the metal, this has not been done unless required by the specifications. Authorities on steel manufacture recommend that this precaution should be insisted upon, for they say that the upper portion of an ingot in cooling intercepts considerable quantities of gaseous matter. These are retained in small spherical cavities which roll out flat during the blooming process without welding together at the sides, thus leaving cracks in the metal.

In a general way rail steel, exclusive of the iron, has about the following range of composition:

	Limits.	Most General Practice.
Carbon,	.30 to .70 per cent	.45 to .55 per cent.
Manganese,	.70 to 1.40 per cent	.80 to 1.00 per cent.
Silicon,	.10 to .20 per cent	.10 to .15 per cent.
Phosphorus,	not to exceed .10 per cent	.06 to .085 per cent.
Sulphur,	not to exceed .07 per cent	.05 to .07 per cent.

Chemical specifications, however, are considered only an approximate guide, because much depends upon the mechanical and heat treatment of the metal during the process of manufacture. During late years chemical specifications have not been considered as highly important as they once were. More stress is now being laid upon the production of rails to meet certain tests of strength and stiffness, or on a guarantee of serviceability for a stated period, than upon the chemical composition. It has come to be the custom with many roads to leave the chemical composition, within wide limits, or entirely, to the discretion of the manufacturer.

Physical Properties.—The wearing qualities of a rail are dependent in large degree upon the fineness of the grain and the compactness of the metal in the head. In order to produce rails of this character and secure the best results it is necessary that the metal shall pass the rolls at a comparatively low temperature, and a relatively large number of times; that is, meet with a small reduction at each pass. In fact, the consensus of expert opinion now maintains that the question of chemical composition is subordinate to the physical treatment of the metal. It is a fact well established that equally good service has been obtained from rails with widely varying chemical components, not excepting the carbon. When steel cools from a high temperature without being worked it takes on a coarse crystalline structure. The higher the initial temperature and the slower the cooling, the larger the crystals and the coarser the grain of the metal; and, as above intimated, coarse-grained steel is inferior from the point of view of rail wear. If the metal is frequently worked while cooling from the high temperature the crystallization into large grains is prevented, but if the work ceases before the heat has fallen to a certain point known as the "critical temperature," crystallization will take place until the critical temperature is reached; in cooling below this critical temperature there is no further crystallization or perceptible change of structure. It is therefore desirable to continue working the metal until the temperature has dropped nearly to the critical point. Relatively speaking, work on the metal at high temperature merely changes the form of the mass without changing the structure. If the work is stopped before the critical point is reached there will be some crystallization, the amount or degree of which will depend upon the range of temperature through which the metal cooled in an undisturbed condition. This critical temperature for ordinary rail steel is about 1300 deg. F., as already shown. At temperatures below the critical point, or, at all events, much below that point, it is undesirable to do work on the metal, for the structure cannot be changed in any desirable respect and there is possibility of distorting the crystals and producing permanent strains in the metal, which results in brittleness. If work is done upon the metal at successively lower temperatures until it cools to the critical point the crystallization becomes smaller and smaller and the result is a metal of fine granular structure best fitted to stand the abrasive action of heavily loaded car and locomotive wheels. The bad effects of finishing steel at high heat seem to increase with increase of carbon and other impurities; in other words the proper regulation of the heat treatment permits the use of higher carbon than otherwise. The foregoing seems to be the gist of the question of producing good wearing rails.

It is a trite saying that the wearing qualities of rails made during late years, particularly the rails of heavy section, have been disappointing; that they do not compare with the service obtained from the 50-lb and 60-lb. rails rolled about the year 1880. The reasons explanatory of this experience have been discussed until the situation is quite generally understood. Making due allowance for the effect of the largely increased wheel loads and train speeds, the currently accepted views of the situation may be summed up briefly in the statement that competition and the desire of the railway companies to purchase rails at the lowest possible price forced the manufacturers to resort to quicker and cheaper methods of handling the metal in process of rolling, with the result that the rails were finished at a too high temperature to obtain the benefits of the rolling action on the steel, or the "working" of the steel, as it is called. In course of time the competition largely disappeared and the manufacturers fixed their own price for rails, but the quality of the metal was not improved. More in detail, it may be explained that rails are now run or, according to Mr. D. J. Whittemore, "squirted" through the rolls in nine to eleven passes from the bloom, at a speed of 900 ft. per minute, and finished (or nearly finished) at temperatures of 1800 to 2000, and even 2200 deg. F., whereas in former practice the rail was given 13 to 15 passes after blooming, at a speed of 400 ft. per minute, and finished at a temperature of 1300 to 1600 deg., or, say, about 500 degrees cooler. And then, in the former practice the metal was permitted to cool and consolidate itself after each operation of casting the iron from the furnace, blowing in the converter, and blooming the ingot; while now, with the modern appliances in service, the melted metal is handled by direct processes and so rapidly that it does not get a chance to cool or come to rest molecularly, from the time it is cast from the furnace until the finished rail is run upon the hot bed to cool. In fact the process is hastened at every stage. The furnace is hard driven in smelting the ore and the metal is blown more rapidly and in larger quantity in the converter. It is supposed that in either case less opportunity is given for the thorough combination* of the various chemical elements. The old method of permitting the metal to cool between the successive steps of manufacture is believed to have improved the molecular structure or crystallization of the metal, and it gave opportunity to carefully examine the blooms for flaws, which, if discovered, were chipped out with hammer and chisel. In present practice 16x18-in. ingots (the average size, some being as large as 20x 24-ins. on the base) are rolled down to 8x8-in. blooms in 11 passes, as against reducing 14x14-in. ingots to 7x7-in. blooms in 13 passes, in the old practice, or of slowly hammering the ingots into blooms, as in the still earlier practice. While there is more reduction from ingot to bloom in present practice than formerly, the rate of reduction is faster per pass through the rolls, not considering the higher speed of the rolls. The bloom of ordinary length will now roll three or four 30-ft. rails in one piece, or a rail 90 to 120 ft. long. In some mills the ingot is long enough (4 or 5 ft.) to roll into a 5-rail bloom, which is then cut in two, one piece making three, and the other two, 30-ft. rails. Taking into consideration the increased weight of rails the reduction from bloom to rail at the present time is just about the same as formerly, but, as above shown, the rate of reduction is much faster, as regards both diminution of section per pass through the rolls and the actual speed in traveling through the rolls. All this haste leaves the rails hotter at the finish.

On the part of the manufacturer it is desired to handle the metal at high temperature, so that it will roll easier, or, in a measure, compensate for the extra work imposed upon the rolls by the faster rate of reduction of the metal at each pass and the higher speed at which the roll train is driven. Although the change from the old to present methods and the effects thereof are well understood by both consumer and manufacturer, there is no disposition on the part of the latter to return to lower initial temperatures or to slower rolling. To start the rolling at a relatively low temperature would throw more work upon the rolls, and to reduce the speed of the machinery would decrease the output of the mills. As either plan of improvement would increase the cost of the rail, the manufacturers have not been inclined to adopt it.

The agitation among railway engineers over poor rail metal and the demand upon manufacturers to produce better wearing rails induced the latter to increase the proportion of carbon and other hardening elements to as large percentages as they thought could be used without making the rails brittle, but these chemical changes did not give the desired results. For many years railway engineers had been demanding of the mill men that rails should be rolled at lower temperatures, and eventually some of the railway companies began to introduce into their specifications what is known as the shrinkage allowance clause, requiring that on leaving the rolls at the final pass the temperature of the rail should not exceed that which requires a certain shrinkage allowance at the hot saws, and that no artificial means of cooling the rails should be used between the finishing pass and the hot saws. The idea in fixing the

*Somewhat in this connection it is a significant fact, discovered through microscopical examination, that rail steel is not a homogeneous material. Certain constituents formed by the chemical union of two or more elements separate out from the mass as it cools down, leaving the steel in some degree a mechanical mixture. Whether this condition may result wholly or in part from a too hasty manipulation of the metal in the molten state does not appear to have been investigated.

shrinkage allowance was that the railway companies, through their inspectors, could thereby control the temperature at the last pass. The plan of rolling from a lower maximum temperature was not in favor with the mill men, because the metal would be harder to roll, and some difficulties might be introduced which would either reduce the output or require heavier machinery, as above explained. It was therefore represented that if the metal was brought to the desired temperature before making the last pass through the rolls, all the benefit that railway men were looking for could be accomplished without reducing the output. This plan was put to trial. During December, 1900, the Carnegie Steel Co. introduced at its Edgar Thomson Works what is known as the Kennedy-Morrison rail finishing process, whereby the rail, after the next to the last pass, is held on skids until it can cool to a point from which it will make the last pass at a desirably low temperature. The details of the process are described below.

The Kennedy-Morrison Process.—The process known as the Kennedy-Morrison method of rolling rails consists in allowing the rails to accumulate on a cooling table located just in advance of the finishing rolls, where they are held for a short interval of time to regulate the heat condition of the metal for the last reduction. The bloom is first passed forward and backward through five passes in the roughing rolls and then run to the intermediate or "short" rolls, where it receives five passes in the same manner. The partially rolled rail is then run upon the special cooling table, being laid on its side with the head against the flange of the rail next ahead. Four to six or more rails are held on the cooling table at one time, and as each rail is drawn on it pushes over all the rails before it, a rail being taken off the far side and sent through the finishing rolls as each one is drawn on the front side. The idea in placing the rails head to base is that the flange being thinner tends to cool quicker than the head, but since it is in contact with the head of the rail lying next behind it will receive heat therefrom, so that the heat in heads and flanges is maintained more nearly at a balance than would be the case if the rails were placed workwise or were allowed to cool separately. And then as each rail arrives at the outside of the table its head lies exposed (but the base does not) while it awaits its turn to enter the finishing pass. The difficulty of cooling down the head to a desirable temperature without getting the base too cold for working is therefore to some extent overcome. The rails enter the cooling table at a temperature of 1750 to 1900 deg., and are held 45 to 90 seconds, the temperature meanwhile falling to somewhere about 1500 deg., when they are put through the finishing pass. As this method of rolling does not interfere with the rapidity or continuity of action of the mill the production is not diminished.

This departure in rail rolling has been a subject of much discussion, and for a time railway men seemed to rest under the impression that they had gained their point. While it is thought that rails held to cool before finishing have shown some improvement in wearing qualities it is an open question whether the process is as effective as direct rolling from a lower maximum temperature to reach the same temperature at finishing. The practice of holding the rails for the last pass has no particular regard to the initial temperature of the ingot, or the temperature when rolling starts on the bloom. The criticism of the metallurgists is that the rails may be allowed to cool undisturbed through such a large range of temperature during the time they are held for the last pass that the work performed in the final reduction has only a superficial effect. The amount of reduction at this last pass is 5 to 10 per cent. In this way 90 to 95 per cent of the reduction is carried on at relatively high temperature, and only 5 to 10 per cent at the lower or "finishing temperature." It is explained that this final working does not break up the granular structure deep enough; that it toughens the steel only "skin deep," so to speak, producing a case-hardening effect on the exterior, but leaving a coarsely granular structure in the interior; that not enough work is done after the cooling, and that much better results might be obtained if the material was held for cooling at an earlier stage in the rolling process; some suggest immediately after the bloom is cut off, so that a very large reduction may take place while the metal is cooling down to a point near the critical temperature; a reduction sufficient to work the steel thoroughly to the center. Another principle of rail manufacture in this same connection is that the rolling of rails direct from the ingot produces better structure than rolling from reheated blooms, the reason being that the bloom goes through the roll train at a lower temperature than is the case in a reheating mill where the bloom is rolled at a high temperature to the final pass and is then held a sufficient time to obtain the desired shrinkage allowance. Mills built to roll direct are of heavier construction, with rolls which will stand the harder work of the cooler rolling. In this country there are only a few mills that roll rails in this manner, but abroad the practice is more generally followed.

From the foregoing it is easy to see how the wearing qualities of the rail may be greatly affected by the rail design. As the desirable end is to have the rail head obtain a large amount of work (large reduction slowly performed) from the rolls at relatively low heat it is apparent that a rail of the best structure cannot be rolled with a deep head and thin flange, because on such a design the rail head must be finished at a comparatively high heat in order to avoid working the more rapidly cooling flange after it has become too cool. In order to hold the flange at a proper temperature for rolling to the finish the tendency is to heat the bloom too high to produce a head that is physically hard and compact. On these grounds there has been some agitation for a change in the section of the heavier rails—85 lbs. per yd. and upwards. It is proposed to increase the thickness of metal in the flange in order to carry the heat longer and permit working the head at a lower temperature.

An interesting modification of one of the standard sections, although not primarily to improve the mill treatment of the metal, has been made by the Grand Trunk Ry. In order to increase the bearing surface of the rail on its cedar ties this road has widened the base of the 80-lb. section 1 inch and thickened it by adding $\frac{1}{8}$ inch of metal to the bottom thereof. The modified section is the A. S. C. E. standard 80-lb. section in every respect except for the changes stated, which make the section 6 instead of 5 ins. wide and $5\frac{1}{8}$ instead of 5 ins. high. The additional metal increases the weight to 90 lbs. per yd.

Straightening and Gagging.—After the rail receives its final pass at the rolls it is sawed off 5 to 7 ins. longer than the intended final length, to allow for contraction in cooling, and then it is run through a cambering machine and curved upward 3 to 16 ins., according to the temperature and depth of head. It then goes to the hot bed, where the rails are spaced 6 to 8 ins. apart. The behavior on the hot bed is described under "Rail Design." After the rail has cooled, whatever crookedness exists must then be removed under the straightening press. The machinery consists of an anvil, on which are placed supporting blocks for the rail, and a plunger which rises and falls vertically over the anvil about 60 times per minute, being operated by a revolving shaft to which a heavy fly wheel is attached. The rail is moved lengthwise over the supports to bring each crooked portion under the plunger, which does its work through a die or fuller called a "gag." This tool has a slightly rounded face and is applied to the rail at points indicated by a man who does the sighting. Long curves in the rail are straightened by several slight bends. If the rail has been too heavily cambered it must be straightened by hitting it with the gag every 18 ins. or 2 ft. over its entire length. If the supporting blocks are spaced too close or the blows of the plunger administered too severely the rail will be sharply bent or kinked and the head indented. These indentations and bends are known as "gag marks," and when they become pronounced the surface of the rail is uneven and imparts a jolting motion to the cars. Gag-marked rails are difficult to maintain in surface, because the vibration or rough running of the wheels causes them to pound down the track. Rails heavily gagged are more liable to break at the indented points than elsewhere, owing to the permanent set in the metal due to the cold straightening. The evil effects from gagging may be largely avoided by designing the section and working the metal to require as little cambering as possible, and then looking carefully to the spacing of the anvil blocks or supports. Mr. P. H. Dudley's specifications require that the anvil supports for 60 and 70-lb. rails shall be spaced at least 3 ft. apart between centers; for 75 and 80-lb. rails, at least 40 ins. apart, and for 100-lb. rails at least 44 ins. apart.

Specifications.—Rail steel may be made by either the Bessemer or the open-hearth process, but practically all the rails in service in this country are of acid steel made by the Bessemer process. In §197 of Supplementary Notes there is a brief explanation of the different ways in which rail steel may be made, together with some account of the proposed deviations in this direction and in rail design.

While some railway companies purchase rails under chemical specifications of their own, it may be said that in most cases the technical conditions of manufacture are left to the discretion of the manufacturer. The purchaser's interests are then secured either by a stipulation that certain tests shall be made to determine whether the metal has the desired physical properties, or by exacting from the maker a guarantee against breakage and unusual wear for a service period of five years. Rails which fail within this period are replaced by the manufacturer, and usually he is required to pay the railroad company an indemnity of $1.00 for each defective rail sent back, this to cover the expense of removing it from the track, handling, etc. A synopsis of American rail specifications prepared by the American Section of the International Association for Testing Materials, in 1900, referred to 11 different sets of specifications drawn by railway companies, while 155 roads and their branches used rails made to manufacturers' specifications. The specifications of the Pennsylvania R. R. in force at that time (carbon 0.30 to 0.50 per cent) were used on 19 roads. Many of the railways specify only the carbon, silicon and phosphorus limits, leaving the manganese and sulphur percentages to the maker. It is sometimes specified that the test pieces for analysis shall consist of bars ¾ in. wide and about 10 ins. long, each to be taken from the web of a rail made from each charge or blow. More frequently, however, the analyses are made on drillings from small test ingots taken from each blow, the manufacturer furnishing the inspector daily with carbon determinations of each blow and a complete analysis representing the average of the other elements which the steel contains.

The chemical specifications of the manufacturers conform to, or pretty nearly to, one or the other of two sets of specifications now recognized as standard in accordance with geographical and commercial conditions. Thus, for instance, available ores west of the Allegheny mountains are higher in phosphorus than eastern ores, and this fact exercises an important modification on the proportion of carbon. In the Scranton and Bethlehem districts the New York Central & Hudson River R. R. specifications are considered standard and may be taken as typical of a large percentage of the rails made from eastern ores. In these specifications there is a progressive increase of carbon and manganese with increase in weight of rail. For 65-lb. rails the carbon content is .45 to .55 per cent, the rails to be rejected if the carbon is below .43 or above .57 per cent; for 70-lb. rails, carbon .47 to .57 per cent, the rails to be rejected if the carbon runs below .45 or above .59 per cent; for 75-lb. rails, carbon, .50 to .60 per cent, with allowable limits of .48 to .62 per cent; for 80-lb. rails, carbon .55 to .60 per cent, with allowable limits of .53 to .65 per cent; for 100-lb rails, carbon .65 to .70 per cent, with allowable limits of .60 to .70 per cent. In these specifications the silicon runs from .15 to .20 per cent, sulphur not to exceed .069 per cent and phosphorus not to exceed .06 per cent, for all weights. For 65-lb. and 70-lb. rails the manganese runs from 1.05 to 1.25 per cent; for 75-lb. and 80-lb. rails, from 1.10 to 1.30 per cent; and for 100-lb. rails it runs from 1.20 to 1.40 per cent.

In the specifications of the western rail mills the carbon content for various weights runs as follows: 50-lb. to 60-lb. rails, .35 to .45 per cent; 60-lb. to 70-lb. rails, .38 to .48 per cent; 70-lb. to 80-lb. rails, .40 to .50 per cent; 80-lb. to 90-lb. rails, .43 to .53 per cent; 90-lb. to 100-lb. rails, .45 to .55 per cent. The phosphorus must not be over .10 per cent and the silicon not over .20 per cent, for all weights. For 50-lb. to 70-lb. rails, manganese runs .70 to 1.00 per cent; for 70-lb. to 80-lb. rails, .75 to 1.05 per cent; for 80-lb. to 100-lb. rails, .80 to 1.10 per cent. Mr. Robt. W. Hunt's specifications, also much used for rails manufactured west of the Allegheny mountains, are lower in phosphorus and higher in carbon than the standard of the western rail mills, being about intermediate between the two standards just referred to, and running as follows: Carbon, .43 to .51 per cent for 70-lb. rails, .45 to .53 per cent for 75-lb. rails, .48 to .56 per cent for 80-lb. rails, .55 to .63 per cent for 90-lb. rails, and .62 to .70 per cent for 100-lb. rails; silicon not below .10 per cent; phosphorus not to exceed .085 per cent; manganese and sulphur left to the makers.

The rail specifications of the Pennsylvania R. R. provide that if the phosphorus exceeds .07 per cent the carbon shall not be less than 0.40 nor more than 0.55 per cent, and the manganese not higher than 1.00 per cent. If the phosphorus is .07 per cent or less the carbon shall not be less than 0.45 nor more than 0.60 per cent, and the manganese not more than 1.20 per cent. The phosphorus must not in any case exceed 0.10 per cent.

For ascertaining the physical properties of the metal the general practice with the American roads is to use the drop and bending tests. The standard weight or "tup" of the drop testing machine weighs 2000 lbs. and the striking face has a radius of about, or not to exceed, 5 ins. The test rail is usually placed workwise—but sometimes with either head or base upward—on solid supports 3 or 4 ft. apart. Some specifications require that the anvil block, of which the supports are a part or to which the supports are secured, shall weigh at least 20,000 lbs. The hight of drop varies with different railways from 16 ft. for 60-lb to 75-lb rails, to 20 ft. for 70-lb. and 75-lb. rails, and 20 to 24 ft. for 80-lb. rails, on supports 3 ft. apart, all the way up to 20 ft. for 100-lb. rails, on supports 4 ft. apart. In some cases a drop of 16 ft., and in other cases 18 ft., is specified for 75-lb. rails on supports 4 ft. apart, while in still other cases a drop of 20 ft. is specified for all rails heavier than 70 lbs. per yard, on supports 4 ft. apart. The specifications of the Philadelphia & Reading Ry. require a drop of 18 ft. for rails weighing 70 lbs. per yd. and under, and 23 ft. for rails heavier than 70 lbs. per yd., solid iron or steel supports 3 ft. apart (between centers) in all cases. The test piece is placed with either head or base upwards, or upon the side, and in this respect the same practice is followed by the N. Y. C. & H. R. R. R.

The standard drop test recommended by the American Railway Engineering and Maintenance of Way Assn. requires that the test rail shall lie head upward and that the supports shall be placed 3 ft. apart for all weights of rails. The hight of drop is 15 ft. for rails weighing 45 to 55 lbs. per yd., inclusive; 16 ft. for rails 56 to 65 lbs., inclusive; 18 ft. for rails 66 to 75 lbs., inclusive; 20 ft. for rails 76 to 85 lbs., inclusive; and 22 ft. for rails 86 to 100 lbs., inclusive. Various specifications require that the test rail or butt must not be longer than 6 ft. or shorter than 4 or 4½ ft., for supports 3 ft. apart. It should be cut from that part of the rolled product which has come from the top of the ingot, and the report of the drop test should state the atmospheric temperature at the time the test was made. To guard against brittleness, the specifications of the Russian government railways, previous to 1899, provided that drop tests might be carried out on rails at freezing temperatures.

In order to pass the test the butt is supposed to stand up under one blow from the falling weight without breaking. The specifications of the Pennsylvania R. R. require that the test pieces from 100-lb. rails must not deflect more than 3¾ ins. from the first blow. The specifications of the Louisville & Nashville R. R. require that the butt must not bend more than 6 ins., and, upon reversal, must stand, without breaking, a blow on the convex side from the weight (2000 lbs.) falling through half the standard hight, which is 16 ft., 20 ft., and 24 ft. for 58¼-lb., 70-lb. and 80-lb. rails, respectively, supports placed 3 ft. apart in all cases. A test is usually made on a butt from each heat or blow of the converter, but some specifications require that if the quantity of metal converted exceeds 9 tons there shall be two tests. The specifications of some roads require that 90 per cent of the butts must stand the test without breaking, and in addition to this it is sometimes required that the metal in the inch under greatest tension must show an elongation, at or before breaking, of 4 to 5 per cent. For measuring this extension an inch scale about 6 ins. long is prick-punched on the under side (head or base, as the case may be) of the test rail, opposite the point of impact, before testing, and if the rail does not break or bend sufficiently to develop the required stretch at the first blow the test is repeated until it does. In the largest practice, however, it is specified that if any test piece should break under a single drop of the tup, another butt from a rail of the same heat may be tested, and if it fails all the rails of that heat shall be rejected; but if the second test stands, still another butt must be tested, and the rails shall then be accepted or rejected according as this third test piece proves a success or a failure. This is the standard specification of the Am. Ry. Eng. & M. W. Assn. It is seen that by this method a single test may determine the result of a heat, but in still another way of drawing specifications it is provided that two butts out of three must stand the test in order that the rails shall be accepted. The specifications adopted by the American Society for Testing Materials provide that one drop test shall be made on a butt not longer than 6 ft. selected from every fifth blow of steel, the rail to be placed head upwards on the supports. If any rail fails to stand the test, second and third tests may be made on other rails from the same blow of steel, and if both of these meet the requirements all the rails of the five blows shall be accepted; if either fails, all the rails of that heat are to be rejected. Should the rails from the tested blow be rejected, the preceding and succeeding blows shall be tested and the rails of each of these blows accepted or rejected according to the same specifications. If the rails of either of these two blows shall be rejected similar tests may be made of the previous or following blow, as the case may be, until, if necessary, the entire group of five blows is tested.

The falling weight or drop test subjects the metal to sudden and severe duty, such as the rail must stand in actual service, and is a check on brittleness. It is therefore to some extent a measure of the toughness, especially when the elongation requirement is introduced, but the special test for toughness is the bending test. This test requires that a bar ½ in. square and 18 or 20 ins. long, drawn at one heat, by hammering from a test ingot 2½ or 3 ins. square in section and 4 ins. long, shall be bent cold to an angle of 90 deg. by the blows of a sledge, without breaking. Two test ingots are cast, usually from the steel in the first and last ingots poured from the same heat. The usual requirement is that both bars drawn from these two ingots must stand the test, but should one of them fail a third bar may be taken from the same ingot, and if this stands it may be accepted in lieu of the failed one. The bending test of the Cambria Steel Co. requires that two test ingots shall be taken from the middle portion of an ingot of each heat while the ingot is being bloomed, and if one bar ½ in. square forged down at one heat stands the test the rails of that heat shall be accepted; if the bar fails, a second one shall be prepared, and if this one fails the heat shall be rejected.

In this country the testing of rail metal for tensile strength is not in general practice, but test pieces from rail steel of good quality will usually show an elastic limit of 55,000 to 65,000 lbs. per sq. in. and an ultimate strength of 110,000 to 120,000 lbs. per sq. in., at breaking, with an elongation of 12 to 15 per cent in a specified length—usually 8 or 10 ins—and a modulus of elasticity of 29,000,000 to 30,000,000 lbs. In this country no tests for hardness are imposed, but the physical hardness can be quite closely determined from the chemical hardness—that is, by the amount of carbon and phosphorus present. Some attempts at measuring degrees of hardness have been made by observation of the indentations on the rail of loaded knife-edges of hardened steel, but the use of such tests and others of different character does not seem to have passed the realm of experimentation.

As to the process of manufacture specifications, as a rule, have fewer requirements than formerly. In order to equalize the heat it is usually required that ingots shall be kept in an upright position in the heating pit, or until rolled, or, in any case, until the interior of the metal has had time to solidify. The shrinkage on the upper side of ingots which lie horizontally is liable to form a "pipe" or split in the interior of the rail. "Bled" ingots, or ingots from the interior of which the liquid steel has been permitted to escape, are always supposed to be rejected. Reference has already been made to the practice of discarding ojectionable material from the top of the ingot, and it is usual to specify that spongy material shall be cut from the ends of blooms. Many years ago hammered ingots were preferred, owing to the beneficial effects from that manner of working the metal, but owing to the demand for cheaper rails the practice had to be abandoned; it is still in vogue to some extent in Great Britain.

The specifications as to branding usually require that the name of the maker and the year and month of manufacture shall be rolled in raised letters on the side of the web and that the heat number shall be stamped on each rail, usually on the side of the web and in such position that it will not be covered by the splice bar. In addition to these some specifications require that the weight of the rail and the initials of the railroad shall be rolled on the web.

With a view to control the finishing temperature, it is usual to include in rail specifications a clause which limits the amount of shrinkage that may take place in the rail from the time it is cut at the hot saws until it reaches the normal temperature. For 30-ft. 85-lb. rails the Pennsylvania R. R. specifies $5\frac{1}{2}$ ins. and for 100-lb. rails $5\frac{5}{8}$ ins. The Am. Ry. Eng. & M. W. Assn. recommends that "The number of passes and speed of train shall be so regulated that on leaving the rolls at final pass the temperature of the rail will not exceed that which requires a shrinkage allowance at the hot saws of .... ins. for 85-lb. and .... ins. for 100-lb. rails, and no artificial means of cooling the rails shall be used between the finishing pass and the hot saws." The practice adopted at the Edgar Thomson Works of the Carnegie Steel Co. for rails of 75-lb. to 100-lb. section is to allow a shrinkage of $5\frac{3}{8}$ ins. for 30-ft. lengths and $5\frac{3}{4}$ ins. for 33-ft. lengths. This is accomplished by holding rails of the various sections different lengths of time on the cooling table before they pass through the finishing rolls. In order to meet the intentions of those who would wish to control the finishing temperature there should be a time qualification in this specification, for the mill conditions, such as the distance of the saws, might permit the rail to cool down a good deal while passing from the rolls to the saws, so that the shrinkage after leaving the saws would be a great deal less than the shrinkage after the finishing pass, which is really the measure of the finishing temperature. Twelve seconds after leaving the finishing rolls is considered the proper time limit for cutting the rails to length.

It is well enough to bear in mind that control of the finishing temperature is not necessarily a control of the heat treatment throughout the rolling process. Although, with a proper time limit, the shrinkage allowance may control the temperature at the finishing pass, it does not put a check upon the practice of rolling the metal very hot and then holding it to cool down just in advance of the last pass. It may not, therefore, serve as a good index of the structure of the metal. The specification of the Philadelphia & Reading Ry. in reference to heat treatment would seem to be drawn with this liability in view. It is as follows: "The temperature of the ingot or bloom shall be such that with rapid rolling and without holding before or in the finishing passes or subsequently, and without artificial cooling after leaving the last pass, the distance between the hot saws shall not exceed 30 ft. 6 ins. for a 30-ft. rail, or a proportionate distance for other lengths."

Other specifications are referred to in connection with the following matter on rail inspection.

Rail Inspection.—The proper place to inspect rails is, of course, at the mill, as then if bad rails appear further manufacture of the same may be prevented at once. The inspector representing the purchaser is supposed to see that the proper physical tests are made, if the rails are bought on that basis, and that the finished material conforms to the specifications. Facilities for these purposes are furnished by the manufacturer and the inspector is granted free entry through the works. Each rail should be carefully examined for flaws, crookedness, kinks and indentations from gagging, and to see that it conforms to the templet of the standard cross section and that uniformity of section is maintained. New rails should not camber in the least, since if they do the joints in the track will naturally dip; on the contrary, a small amount of sag or "back sweep" is not objectionable, as in that case the spring in the rail assists the splice bars to hold the joint in surface. The inspector must, of course, have a "good eye," according to the meaning of the term among trackmen. It is quite generally the practice with railway companies when purchasing quantities of rails to employ experts who make a business of rail inspection, charging for their services according to the quantity of rails inspected, five cents per ton being a figure quite frequently paid. Some of the large railway systems have their own expert, who fills the established office of "rail inspector," and some railways send their roadmasters or engineers in the track department to the mills to inspect their rails.

Rails are bought and paid for on the actual weights. It is usual to permit a variation of 1 per cent in the weight of individual rails and ½ of one per cent in the weight of an entire order. To ascertain how individual rails are running some specifications require that a rail shall be weighed every hour, as the rolling proceeds. It has been customary to allow a variation of $^1/_{32}$ in. over and $^1/_{64}$ in. under the standard hight of section, although some railway companies put the limit at $^1/_{32}$ in. either way (Southern Ry.) and others put it at $^1/_{64}$ in. either way, the latter being the practice with the Michigan Central and Wabash roads. In this respect the specifications of the New York Central & Hudson River R. R. provide as follows: "A variation not exceeding $^1/_{64}$ of an inch of excess in hight may be permitted in a delivery of 10,000 tons of rails of any section, after which the rolls must be reduced to the standard hight for such section."

The hight of rails of the same section varies with the wear of the rolls, and in order to make smooth joints when spliced, rails which vary even as little as the limits permit should not be mixed together in the shipments. For instance, a rail which measures $^1/_{32}$ in. over the standard hight of section would not make a smooth joint with one measuring $^1/_{64}$ in. under the standard. With a view to the requirements of the service the gaging of the vertical dimensions of the rail section should be controlled by the type of joint splice to be used. With ordinary angle-bar splices the important vertical dimension is the depth of head rather than hight of section, because the manner in which the running surfaces will match at the joint depends upon the thickness of metal above the top edges of the splice bars. With joint splices which engage the bottom of the rail flange it is obviously necessary that the total hight of the rails should be uniform or within limits. It is customary to permit a variation of $^1/_{16}$ in. in width of base. The requirements as to base width stand in relation to the use of tie plates, which are punched for the spikes a fixed distance apart.

As the fit of the splice bars should be maintained as nearly perfect as is practicable no misfit of the fishing templet is allowed. The allowable variation from specified length is ¼ in. This is measurable without temperature correction at 60 deg. F. Rails should be sawed square at the ends, but it is customary to permit a variation of $^1/_{32}$ in. between length of head and base. It is usual to accept 10 per cent of the order in lengths shorter than standard, varying by even feet down to a length specified, which, in largest practice, is 24 ft. for 30-ft. rails. This minimum length varies with different railways from 22 to 27 ft., and some specifications require that the average length of short rails shall not fall below a specified length; as, for instance, the minimum length acceptable with the Chicago, Burlington & Quincy Ry. is 24 ft., and the average length of the short rails must not fall below 26 ft. The percentage of short rails acceptable is sometimes put as low as 4 per cent. The Am. Ry. Eng. & M. W. Assn. recommends that 10 per cent of the order may be accepted in lengths shorter than standard (33 ft.) and that the minimum length acceptable shall be 27 ft. Specifications provide, of course, for the spacing of the bolt holes, requiring that they shall be drilled accurately and left without burrs. The burrs on the rail ends made by the saw should be chipped and filed off, particularly where they would interfere with the fit of the splice bars.

Rails made from heats the test pieces from which have failed to stand the drop test or the bending test; rails having small flaws in the head and base, usually not to exceed $\frac{1}{4}$ in. in depth, if in the head, and $\frac{1}{2}$ in. in depth, if in the base; and rails possessing any other injurious physical defects, which, however, do not impair their strength, are designated second quality and are distinguished by having their ends painted. Specifications usually provide for the acceptance of a small percentage of second-quality rails, 3 to 5 per cent of the order being a common figure.

Rail Wear.—The conditions attending the wear of rails have not been thoroughly investigated, and so a good deal that is pretended to be known about it has come by theorizing. It is generally assumed that the natural wear between car wheels and rails is due largely to rolling friction, which is supposed to be the interlocking of the surface particles of the two bodies in contact, much as the teeth of cog wheels fit together. The friction between these meshing particles and the crushing of particles which fail to mesh are supposed to set up a sort of pulverizing action which gradually wears away the rail and wheel surfaces. The powder formed thereby may be seen by drawing the tip of the finger across the top of a rail just after a train has passed. Such is the commonly accepted explanation for rail wear on straight and level track. As for curved track, we know that other conditions obtain, for there is a grinding of the wheel flanges against the side of the rail head and there is a skidding action of the wheels across the rail top. The rapid rate of wear of rails on curves, as compared with that of rails of like quality on straight line, under similar traffic conditions, is too well known and understood to require lengthy discussion. It will suffice to illustrate a few examples of such wear. In Fig. 14 are exhibited a number of diagrams of worn rails, sketched from rails actually removed from the track. The legends noted on each section explain the length of service and other essential matters pertaining to the manner in which the rails were handled With the exception of the 90-lb. rail, laid in May, 1896, all of the rails were of the American Society standard section. It is particularly interesting to notice the small amount of wear upon the top surface relatively to that on the side of the head.

On grades, also, increase of wear, over that which takes place on level track, is an important exception to the explanation based upon rolling friction, and the difference is generally understood to be due to the predominance of the tractive effect of locomotive wheels. On the rolling friction theory this increased wear from traction is undoubtedly explainable in some part by the reaction between the minute particles of wheel and rail which gear with one another, between which there must be a constant tendency to slipping, if indeed slipping does not actually take place to greater extent than may generally be supposed. As the tractive effect of the locomotive on level track differs from that on grades only in degree, it is reasonable to suppose that no inconsiderable part of rail wear on level track must be due to locomotive traction. While the wearing effect of the car wheels may be essentially different from that of the locomotive drivers, we have to consider some tendency to slipping in the former due to inequality of circumferences, so far as such may exist between pairs of wheels on the same axle.

The actual behavior of rails under loaded wheels, particularly with reference to the conditions obtaining at the surfaces of contact, has been the subject of some investigation and experiment, and the data obtained certainly have some bearing on this subject of rail wear, even if opportunity to connect the same with formulated statements or rules of practice has as yet failed to materialize. Mr. Octave Chanute, when chief engineer of the Erie R. R., many years ago, made some experiments to determine the

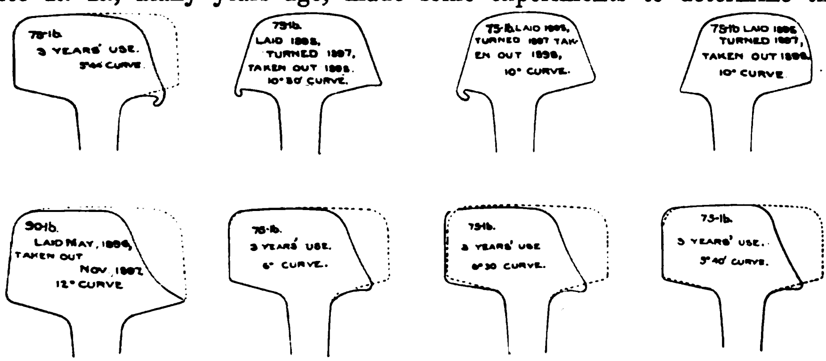

Fig. 14.—Examples of Rail Wear on Curves.

bearing area of locomotive driving wheels on steel rails, and subsequently Mr. D. J. Whittemore, chief engineer of the Chicago, Milwaukee & St. Paul Ry., and the late Prof. J. B. Johnson, at the time connected with the Washington University, at St. Louis, have conducted experiments with a like object in view. By jacking up a locomotive and placing sheets of carbon paper and tissue paper together under the wheels Mr. Chanute found that the area of contact of the wheel was about ¼ sq. in., as shown by the imprint of the carbon sheet upon the tissue paper. The driving wheels of the locomotives used in these experiments were 4½ ft. and 5 ft. in diameter, and were loaded with 11,350 to 14,000 lbs. per wheel. Mr. Whittemore, experimenting on a locomotive with 70-in. drivers carrying 16,000 lbs. each found, as the mean result of several experiments, an oval-shaped contact area having a major axis of 1.48 ins., across, the rail, and a minor axis of 1 in. longitudinally with the rail. In this case the tires were well worn and the (steel) rail had been in service five years. Another test with an engine having 64-in. drivers with loads of 13,800 lbs. per wheel, the tires having been in service about six months, gave a contact of similar shape, the major axis being 1.27 ins., the minor axis .79 in. and the area enclosed about .86 sq. in. Prof. Johnson experimented with locomotive drivers and car wheels, with loads imposed by a testing machine. On a steel rail with a top radius of 13½ ins. a 44-in. driving wheel with flat tread, loaded to 25,000 lbs., gave a contact which was approximately circular and 1¼ ins. in diameter. A new 33-in. chilled car wheel loaded to 15,000 lbs. gave an oval contact with a major axis of $1^1/_{16}$ ins., across the rail, and a minor axis of $^{13}/_{16}$ in. In another experiment a 44-in. driver with flat tread, loaded to 25,000 lbs., on a 75-lb. steel rail with a top radius of 14 ins., gave a contact approximating to a circle of $1^9/_{16}$ ins. diam. A car wheel loaded with 15,000 lbs. gave an oval contact measuring $1^3/_{16} \times \frac{3}{4}$ in.

So far as the actual area of contact is concerned the results of these experiments can be considered only approximations to conditions which may obtain in actual practice, for, in the first place, the loads were statically applied, and in the second place, the shape and size of contact would necessarily depend very much upon the condition of wheel tread and rail top with respect to wear. Neither did these experiments discover any relation between the chemical composition of the rail (hardness) and the effect of wheel pressure. By applying successively varying loads, however, Prof. Johnson deduced some laws which seem to shed a good deal of light upon wheel contact with rails. It was determined that the area of contact increases directly with the load, which shows that the mean intensity of pressure, in these experiments found to be about 82,000 lbs. per sq. in., is a constant for all loads. It was also found that the maximum deformation, which took place at the centers of the areas, in each case, was twice the average deformation, from which it follows that the maximum compressive stress for all loads is about 164,000 lbs. per sq. in. Permanent set of measurable magnitude, on either wheels or rail, was apparently not produced by these loads, from which it might be said that the elastic limits of the materials had apparently not been reached for this condition of contact, although for ordinary conditions the elastic limit of the rail steel was about 50,000 lbs. per sq. in. The principle that mean intensity of pressure and maximum intensity of pressure remain the same for all loads would seem to have an important bearing upon rail wear, as then the problem reduces itself to the relation of wearing effect to area of contact.

Whether the relations above stated might not undergo some modification for conditions which obtain more generally in practice might be worthy of inquiry. If, as is claimed, wheels and rails wear to the same curve (contour of cross section) we should expect that wheel contact under normal conditions would extend nearly or quite entirely across the top of the rail, approximating closely the form of a parallelogram with rounded corners. In that case it would seem that the maximum compression would occur along a line extending across the top of the rail instead of at a point or comparatively small area at the center of a circular or elliptical contact surface. On general principles, however, it would seem that the maximum intensity of compression could exert but little influence on rail wear, in any case, as if the rail should wear more rapidly on the line where the compression is greatest, the displacement of the material there would necessarily reduce the compression along that particular line of contact, thus affecting a redistribution or equalization of the pressure.

The allowable extent to which rails may be worn in depth of head before they are supposed to become unfit for main-track service seems to vary between $\frac{1}{4}$ and $\frac{1}{2}$in. quite generally, being $\frac{3}{8}$ in. in most cases, perhaps. It is true that a wear of $\frac{5}{8}$ or $\frac{3}{4}$ in. in depth of head, or even a greater depth, is occasionally reported of rails in main track, but such cases are so comparatively few that they may properly be regarded as exceptional. The condition usually considered to be the cause for the removal of rails from main track is very seldom charged to insufficient strength due to loss or abrasion of metal. On sharp curves where the lateral wear is excessive such a condition may sometimes obtain. The usual cause for removal is the roughening of the running surface, due to slivering or uneven wear of the metal, by which it sometimes becomes wavy. Of course this state of wear will depend largely upon the constitution of the metal with respect to homogeneity, but sometimes there are other causes for the removal of rails from main track before the limit of wear on the running surface has been reached; among which may be named deformation of the rail and abnormal wear of the running surface at joints, particularly at the receiving end of rails in double track; wear at the bearing surfaces of splice bars, and side wear on the outer rail of curves. The care exercised in keeping rails to smooth surface, particularly at the joints, is an important factor of their durability. Thus, for one or another of these causes, it will usually be found that rails of whatsoever weight will wear down about the same amount in depth of head, when they become unserviceable for further use in the main track. It would appear that, with the same quality of metal in either case, the larger rail, which would usually have the wider head, should wear the longer, but, as already explained, some rails of the larger sections have been disappointing in this respect.

It has long been a desire with maintenance-of-way officials to find some relation between the tonnage carried by rails and the endurance of the metal. It would be particularly useful if the wearing capacity of rails in relation to their chemical composition and known physical properties could be ascertained, for the quality of the metal is all important in rail wear. Such a diversity of results is obtained in practice, under apparently the same traffic conditions, that any attempt to draw conclusions as to the wear of rails from traffic, based either upon tonnage or the number of trains, without taking into account the quality of the metal, is futile. Occasionally some student of the question will formulate a rate of wear intended for general application, without reference to specific conditions, but the figures obtained do not usually agree with any widely prevailing experience. Taking into consideration the actual conditions there is but little about such a conclusion which seems strange. As hardness and compactness of the metal in the rail head, grades, curvature, the braking action of wheels, the number of trains, tonnage, and undoubtedly the wheel loads, all have some influence on rail wear, it could hardly be expected that a rate of wear based only on tonnage, number of trains or any other conveniently designated condition, would meet with general application. Nevertheless the wear of rails is usually referred to without any details as to the chemical composition and physical properties of the metal, wheel loads, speeds, curves, grades etc., when it is a question worthy of investigation whether with light rolling stock at moderate speeds a rail might not carry a much larger tonnage than with heavy rolling stock at high speeds, or whether the wear of soft rails under light loads might not be equivalent in some respect to the wear of harder rails under heavier loads. At least one consideration which would give weight to such comparisons would be the increased severity of the heavier loads on the joints. In Europe, where the population is more dense and the distances between stations shorter than in this country, a good deal of stress is placed upon the wear of rails under the braking action of wheels. On some of the French roads the rate of wear of rails at points where all trains stop is shown to be five times what it is at points intermediate between stations.

However these things may be, figures have been produced which serve to convey some idea of the duration of rails, within limits, even if one is not sure of being able to make a desired application of such figures; and then it is always possible to strike an average of any set of results howsoever various. The life of rails is variously estimated at from 100 to 250 million tons of traffic, depending upon the location of the rail with reference to straight line, curves, and grades. Some experiments conducted by the German Railroad Bureau during the years from 1878 to 1884 serve to show relative rail wear under different conditions of grades and curvature. The wear of the rails in depth of head per million tons of traffic passing over the rails was as follows:

Conditions.	Wear.
Level track on tangent	.0016 inch.
Level track on 2½-deg. curves	.0028 "
Level track on 5-deg. curves	.0039 "
Single-track tangent, grades ½ to ¾ per cent	.0067 "
Double track, 1¾-deg. curve, up grade ½ to ¾ per cent	.0032 "
Double track, 1¾-deg. curve, down grade ½ to ¾ per cent	.0043 "
Curves 2 deg. 50 min. to 1¾ deg. on ¾ to 1 per cent grades	.0087 "
Curves 2 deg. 50 min. to 1¾ deg., grades 2 to 2½ per cent	.0122 "
Curves 6 to 9 deg., grades 1½ to 2 per cent	.0087 "
Curves 6 to 9 deg., grades 2 to 2½ per cent	.0201 "
Curves more than 9 deg., grades 2 to 2½ per cent	.0378 "

On the basis of ⅜ in. wear the rails in level track on tangent, above referred to, should carry about 234 million tons of traffic, while under the most rapid rate of wear, namely that for rails on grades of 2 to 2½ per cent in curves exceeding 9 deg., the rails would carry only about 10 million tons. An interesting comparison is between rails on the up and down grades (as the trains run) of ½ to ¾ per cent, the wear being greater for the down grades than for the up grades, which seems difficult of explanation, even when the effect of braking the wheels on the down grade is taken into account. It is not stated in what manner the effect of side wear on the curves was taken into account.

The St. Gothard Ry., in Switzerland, has collected a very large amount of data with a view to determine the normal wear of rails under different conditions of grades and curvature. The following is a condensed summary of 87,000 measurements on the vertical wear of rails, the rate (average) in each case referring to a million tons gross carried: For the whole system (including grades) the rate of wear on straight line was .00134 inch.; for the whole system including curves, the rate was .00224 in.; for track on level grades the rate was .00209 in.; for track on mountain lines, down grade, 2.7 per cent, the rate was .00201 in.; for track on up grades, same lines, .00284 in.; for track on 2.6 per cent grades, traffic both ways, the rate was .00213 in. The sharpest curvature on these mountain lines is 6¼ deg. On this road it is found that the rate of wear on down-grade lines does not exceed that for level track. In respect to wear on curves the following coefficients were obtained, taking the rate of wear on straight line as unity: for curves below 2½ deg., coef. 1.3; for curves 2½ to 4½ deg., coef. 2.2; for curves of 4½ to 6¼ deg., coef. 3.1. It was also found that on curves the sectional wear on the inner rail was practically equal to that on the outer rail, for although the inner rail showed no lateral wear the vertical wear was more rapid than on the outer rail. This experience coincides with that on some of the lines in this country which carry a heavy freight traffic.

Mr. Richard Price Williams, an English authority, gives, as the result of numerous tests and observations, the average wear of rails of good quality to be about $^1/_{16}$ in. in depth of head for each 20 million tons of traffic carried. Allowing ⅜ in. as the limit for wear this would put the wearing capacity of an average steel rail at 120 million tons. The French engineer Couard puts rail wear at 1 millimeter for each 16,800,000 tons of traffic, and states that the limit of wear coming under his observation is about ⅜ in. This amount of wear would correspond to a carrying capacity of about 160 million tons. The wear of 100-lb rails outside the Fourth Avenue tunnel on the New York Central & Hudson River R. R., in New York City, is stated to be $\frac{1}{8}$ in. for 80 million tons of traffic, the average driving wheel load of all the locomotives passing over the rails being 22,000 lbs. About the best results noticed in this country are reported of 80-lb. rails on tangents, in use nine years, on the Michigan Central R. R., where the wear has been $^5/_{64}$ in. in depth of head, the rails carrying an estimated traffic of 90 million tons. If the service of these rails should hold out to the full extent of $\frac{3}{8}$ in. wear at the same rate the traffic carried would amount to 432 million tons. Some authorities think that the number of trains is a more logical basis for measuring the service of rails than tonnage. Passenger trains, while lighter, on the average, than freight trains, run at faster speed, and should be expected to wear the rails at a faster rate, ton for ton, than slow trains. So far as relates to parts of the rails at and near the joints there can hardly be any doubt about this. Tonnage multiplied by average speed is perhaps the proper basis for measurement of rail service, but as this product is practically the same for all trains, it is considered just as accurate to compare the wear with the number of trains. On mountain grades the tonnage of freight trains ascending is, of course, relatively small and the speed slow, but the wear from locomotive traction is relatively much larger than that from the car wheels, especially where the grades are so steep as to require pusher engines, and the frequent use of sand is also severe.

Some careful students of rail wear claim that it is an open question whether hard rails (speaking relatively) give longer service than rails of mild steel. The results of an experiment in this line carried out on the Dutch State Railways are quite interesting. Rails of hard and mild steel of known chemical and physical properties were laid in experimental sections under identical conditions of tonnage, speed, tie supports, ballast, alignment, etc. After 30,000 trains had passed over the rails they were taken up and weighed, and it was found that those made of mild steel showed 28$\frac{1}{2}$ per cent more wear than the hard rails. The rails were then put back and after 65,000 more trains had passed over the trial sections the rails were again weighed, when it was found that the hard rails had lost 9$\frac{1}{2}$ per cent more weight than the softer ones. The loss of weight under the whole 95,000 trains was approximately the same for both kinds of rails. Another interesting fact (which is similar to results observed elsewhere) was that the rate of wear per 10,000 trains was greater with the first 30,000 trains than with the next 65,000 trains, in the case of both kinds of rails. The rate of wear on single and double-track lines, other conditions being equal, was approximately the same. An extended study of rail wear completed about 1886 by Mr. Chas. B. Dudley, of the Pennsylvania R. R., showed conclusively that the rate of wear on rails of mild steel was slower than on rails of hard steel. Mr. Dudley has explained that the cold rolling effect of car and locomotive wheels on rails tends to increase the brittleness of the hard steel, and that the wear on brittle steel under rolling friction is more rapid than on mild steel. These results he has confirmed by experiments independent of those observed in the track.

Another phase of the rail-wear question which has received some attention is the effect of the traffic on the strength of the metal. Opinions regarding the "fatigue" of metal subjected to live loads or repeated stresses vary, and the theory is not generally accepted, at least as applying to rails. Test specimens cut from rails which have been in service long enough to wear the rail out have failed to show loss of strength in the metal, as compared with new metal of like chemical composition and manufacture. As to rails, the metal has comparatively long periods of rest during which "recovery" may take place after stress, and the "fatigue" theory is not put forth as prominently as is the effect of the face hardening of the running surface due to cold rolling from the wheels. It is claimed that from this cause the contact surface is broken down to a depth which varies according to the degree of hardness of the metal. According to some accounts it has been ascertained that a thin skin of metal on the rail top has, from the cold rolling of the wheels, been found to be twice as hard on the scale of hardness as the metal throughout the remaining portions of the rail. It is also claimed that the wearing qualities of rails of mild steel are affected to a greater degree from cold rolling than are hard rails. As already stated, it has been observed that rails wear most rapidly early in their life, which is explained by the gradual hardening of the top surface due to cold rolling by the traffic. One matter which should not escape consideration in this connection, however, is that an abnormal rate of wear should be expected of new rails until the top of the head becomes worn to fit the treads of the wheels. Especially is this the case where rails have been renewed with those of a new section having a considerably wider head. The grooves worn in the locomotive tires on the old rails are then liable to wear or crush down rapidly the metal on the corners of the head of the new rail. Prolonged seasons of freezing weather, when the rail is held rigidly to its duty in frozen ground, and frequent snow storms, which make traction difficult, also increase the rate of wear on rails.

Mr. W. G. Kirkaldy, in a paper before the Institution of Civil Engineers, in 1899, presented data obtained from a series of observations, to show that minute flaws or cracks are induced in the running surface of rails by the rolling action of the wheels, which impair the strength of the rail under certain test conditions. He fortified his claims by performing bending tests on butts of service-worn 75-lb. bull-head rails, in the normal direction and inverted, showing that the strength of the rail in the inverted tests was much less than when placed with the head upwards, as in service. As the head portion of bull-head rails is larger than the base portion the reverse would naturally be expected. In all the tests the loads were applied gradually, in increments of 2000 lbs., midway between supports 5 ft. apart. In six sets of experiments the butts tested in the normal direction were deflected 6 to 9 ins. (average 6.77 ins.) under loads varying from 48,355 lbs. to 63,670 lbs. (average 56,435 lbs.) without breaking, except in one case, where the rail snapped at a deflection of 5.62 ins., under a load of 57,705 lbs. In the inverted tests the rails snapped in every case at deflections of .28 in. to 1.31 ins. (average .86 in.), under loads varying from 33,980 lbs. to 40,080 lbs. (average 38,485). The rails had been in service 20 years and the metal on the running surface showed deterioration to some extent, although no visible flaws appeared except in one case. By tensile tests on specimens taken from the interior of the head and base portions it was proved that the deterioration was confined entirely to the top or running surface of the rail, and that "fatigue" of the metal throughout the section had not been produced. Substantially similar results have been shown by tests at the Watertown arsenal, in this country. Rails taken from the track and loaded in a testing machine, broke under relatively low stresses when the head was on the convex side of the piece tested, but by planing a thin skin of metal (about $^1/_{16}$ in.) off the top of the head the rails were able to resist the tests much more successfully. Microscopical examination in the Kirkaldy tests showed that the deterioration consisted of minute shallow cracks running across the top of the rail. It is a feature of carbon steel that a crack or flaw, however small, in the outer fibers of the piece greatly impairs its strength when subjected to bending stress which brings the defective fibers in tension. Impairment of strength in the manner shown by these experiments would not, however, apply to rails in service, because the tensional stresses imposed upon the top fibers by the undulations of the rail are small relatively to the tension in the bottom fibers. Neither would it be expected that impairment in any respect should become more pronounced with age. As the cold-rolling effect extends only "skin deep" and wears away as fast as it penetrates the head, it should be no deeper after a long service than at only a comparatively short period of the rail's life. So far as special tests and experience have proven anything, rails of good chemical composition produced by proper methods of rolling are—save for loss of strength by reduction of the section—no more liable to break in service when worn out than when they were new.

A simple way to compare the wear of rails of different composition and manufacture is to lay them alternately on sharp curves where the traffic

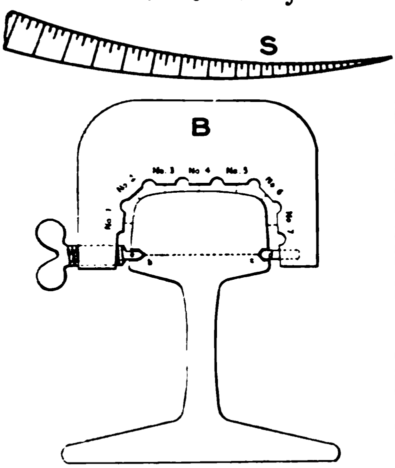

Fig. 15.—Instrument for Measuring Rail Wear.

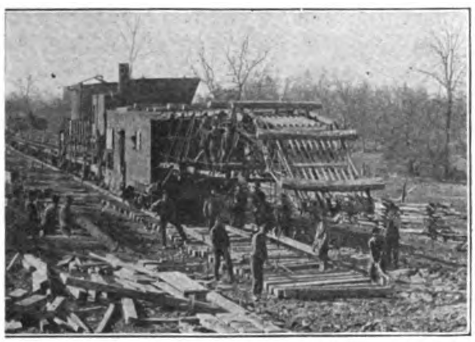

Fig. 16.—Hurley Track-Laying Machine; Front View.

is heavy. The rails will then be subject to uniform conditions of service, and any considerable differences of wearing qualities will soon become evident. By repeating this experiment on the same curve each year and keeping a rough check upon the volume of the traffic, the data collected should be useful for comparison of results from rails received from year to year, and might be valuable in deciding upon the kind of metal to be finally adopted. One way to determine the amount of wear on rails is to take the rails up and weigh them, but in experiments on an extended scale this method requires a good deal of labor; it also makes necessary a small correction for metal lost from the flange and web by corrosion, which can only be estimated. For obvious reasons ordinary calipers are not suitable for measuring rails to ascertain both lateral and vertical wear, or even the vertical wear over the whole width of the head. Various instruments and devices have been contrived for this purpose. One idea that has been put into service is to apply molds to the sides of the rail and take a plaster of Paris cast, from which precise measurements can be obtained in various ways. The instrument shown in Fig. 15, consisting of a clamp (B) and a curved-tapering scale (S), was designed by Mr. Stephen W. Baldwin, of New York City. The clamp is $\frac{3}{8}$ in. thick and is applied to the head of the rail by means of a thum-screw (e) and stud (d) in $^3/_{16}$ in. holes drilled into the rail at points where it is desired to take measurements. As the splice bars do not interfere these holes may be drilled as near the end of the rail as is desired. Presumably each rail would be measured at the middle and near the ends. The center line *b c* between opposite holes is the base line for all measurements, and as this is fixed and not affected by wear (the hole in the gage side should be drilled deep enough to place its pointed end beyond the reach of wear from the wheel flanges) the clamp, when adjusted, will always occupy the same position. To prevent corrosion in the holes they may be filled with wax after each time the instrument is used. The measurements taken between the working faces of the rail and the reference heads on the clamp (No. 1, No. 2....No. 7) are thus accurate records for comparing the size of the rail head at different times. The purpose of curving the tapering scale is to prevent bridging depressions in the rail surface. This scale is tapered and graduated to measure the open space between the clamp and the rail within $^1/_{200}$ of an inch.

7. Splices.—No subject concerned with track appliances has been discussed more than that of joint splices. A student of the rail joint question who would set about to read all that has been written concerning it by men of learning and experience would become weary before getting half way through. In this day and generation it is hardly possible to say anything on the question that is original; the arguments have all been repeated hundreds of times. Nevertheless it is appropriate to a work of this character to set forth the situation, and in that connection some treatment of the principles involved in the case seems desirable. The evolution of joint fastenings has advanced through three stages: first, the chair, which maintained the ends of the rails in alignment and served as a bearing piece or plate upon the joint tie; second, the fish plate, which afforded the rail ends some support under the head, but greatly improved matters by stiffening the junction of the rails vertically; third, the angle bar, which, combining the features of the fish plate, effected a great improvement in both the vertical and horizontal stiffness of the junction. The angle bar has long been the universal joint fastening, and, speaking generally, of course, it still maintains that distinction. Amidst the confusion of claims presented by the numerous designs of joint splices intended as improvements on the angle bar, railway men have been judiciously conservative about adopting new devices. The reasons for this moderation are apparent to any maintenance-of-way man of experience. Although the plain angle bar is not entirely satisfactory as a joint fastening, it is nevertheless safe, simple, easily applied and adjusted, cheap in first cost, fairly efficient and withal not such a rattletrap affair as some theorists would have us suppose. There is no getting around the fact that it is serviceable. Notwithstanding this there is a general demand for an improvement in joint fastenings, for, relatively, rail joints are the weak points of the track structure—not necessarily weak in an absolute sense, but comparatively so when measured by the stiffness of the solid rail. This relative weakness is an important factor of maintenance expense, for it interrupts the uniformity of conditions of support, so closely concerned with the maintenance of smooth surface, and it contributes to abnormal wear at the rail ends. Such consequences have not been removed by increase in weight of rail. The speed of trains may still be measured by the sound of the wheels passing the joints.

In order to thoroughly investigate the joint-splice question it is necessary to begin with first principles. A structure or body of any kind which rests upon the earth (where it is not solid rock or its equivalent) and bears up weight will settle into the ground. As proof of this statement it is only necessary to observe the walls or ground sills of old buildings, the sills of lumber piles, old stone fence, or indeed any heavy object lying upon the ground for a considerable time. The factors of the rate of settlement are extent of bearing surface, pressure, time, and weather conditions; settlement taking place much more rapidly during wet weather than during dry weather. All these conditions being present with track, it should not be surprising that track will settle. Track is composed of rails, fastenings and ties. The ultimate support for the track is the earth; the immediate support is the ballast. The bearing of the track upon the ballast is through the ties. The functions of the rail are to constrain the wheels and to distribute the pressure from the same over the ties. As we cannot expect to entirely prevent the settlement of track the highest result we can hope to attain is to get it to settle uniformly; but such cannot take place unless the pressures from the ties upon the ballast are approximately uniform. The difficulty in this respect is found at the joints, where the rail is relatively weak and unable to distribute the wheel pressure over the average extent of tie supports. The abnormal depression of rail and ties at this point gives rise to shock or suddenly applied loading, which still further augments the inequality of the pressure upon the ballast. The ideal service to be desired of a joint splice is, then, to make the rail as stiff at the joint as at any intermediate portion, and to so maintain it.

A mathematical investigation of rail flexure and stresses under an assumed loading is beset with two principal difficulties: the supports for the rail yield with the pressure, and they present a considerable extent of bearing surface, so that for different positions of the wheels, we are not sure that supposed points of support remain at fixed distances. As these conditions render it impossible to determine upon length of span, and as we know of no uniform conditions of settlement for ties under pressure, the solution of the problem defies computation. As a matter of practice, however, the depression of the ties is the only fact which gives us trouble. The depression of the unbroken rail between ties is too small to be of any consequence. We can compute the strength and relative stiffness of rails, but we cannot compute the relative stiffness of ballast or roadbed. In considering the sustaining power of rails we cannot separate the track from the roadbed: the two must act together. The fact that the two combined do not yield to satisfactory analysis surveys the whole difficulty. In approaching the question of joint splicing and support the same proposition confronts us. In fact, if the ties were not yielding supports there would be no joint problem at all; it would then only be necessary to "support" the joint upon a tie and bolt on a splice of sufficient horizontal stiffness to hold the rails in alignment. This is all very simple, but the principles stated have been frequently overlooked. Most men who have gone into the subject mathematically have figured the strength of rails and splice bars on the basis of rigid supports.

Following general principles still further let us consider the case of rails subjected to load without joint splices. Such a condition virtually occurs, so far as the support for the joint is concerned, whenever a splice in the track becomes loose. If the ties afforded rigid support to the rail each one in succession would have to sustain the entire load as the wheel rolled along, because, with the load directly over a support, a flexible beam is incapable of distributing any portion of the load to adjacent supports without being deflected. With the wheel at the end of a rail projecting past the last tie, as at a suspended joint, the joint tie in that case would sustain a pressure greater than the weight of the load, because the load would have a leverage over the tie. With yielding supports, such as we find in track, the conditions are essentially different. In that case the wheel load at an intermediate portion of the rail is sustained by three to six ties, according to the position of the wheel and the strength of the rail, and a single tie, as ordinarily bedded, never sustains the entire wheel load. So, also, at the end of the rail, two or three ties on each side of the joint are depressed as the wheel rolls past that point, and the tie next the joint, or underneath it, does not sustain the entire pressure from the wheel at the end of the rail, as in the case with rigid supports. Instead of a leverage over the last tie the wheel now has a leverage over two or three ties. The tie nearest the joint sustains the largest share of the load, but just what proportion of it we have no means of telling. From mechanical principles, however, we know that this tie sustains more pressure than ever comes upon a single tie at an intermediate point of the rail.

An error that is commonly made in analyzing the joint problem is the assumption that the joint ties are rigid supports and the rail ends cantilevers of the typical sort. On strict reasoning there is no illustration of beams in flexure, to which formulated mechanical principles apply, which fits the case. One writer has compared the situation with that of a flexible beam supported over water, on floats. We cannot treat the rail exactly as a beam continuous over several supports, because the tie at about the point where the deflection changes from downward to upward is sustaining only a small portion of the load, at the most. It is a case falling somewhere between the one where the load is all borne by one support at a time and one where the load is evenly distributed over a number of supports. It is customary, in comparing the deflection of the rail at a suspended joint with the deflection of the unbroken rail at some intermediate point, to liken the relative conditions to those which obtain with a cantilever sticking out of a wall and a beam "fixed" at both ends and suspended between two walls, the length of the cantilever being equal to half the span of the beam. In a case of this kind the deflection of the cantilever end is eight times that of the middle of the beam, for the same loading, and the relative stiffness is in the inverse ratio. As already suggested, however, such assumptions as to mechanical action are not warranted by the actual conditions. The depression of the ties and ballast nullifies the assumptions as to length of span of the deflected rail, and the undulation of the rail is not accordant with "fixed" end supports. The fact that the deflection of the rail between the extreme points of flexure does not take place over a clear span renders comparisons with deflection under known conditions largely conjectural. Thus, it may be doubted whether at the end of the rail any close resemblance to cantilever action ever obtains, because the length of the deflected end of the rail is always longer than the distance to the nearest tie, and the total length of rail deflected does not hang freely or unsupported, as does the end of a cantilever from the face of a wall. The fallacy of the situation is perhaps more easily seen when attempting to apply the cantilever principle to a supported joint. If in that case the tie "supported" the joint there would clearly be no cantilever, but the fact that it does partially support the joint leaves us quite at sea as to what length we should assume for the cantilever end. Some calculators have "cut the knot" by assuming the extreme condition that the tie affords no support at all, thus entirely changing the nature of the problem, for in that case we get a suspended joint of abnormal span. As to the actual flexibility of rail joints without splices, compared with that of the solid rail, experiment has shown the deflection of the joint to vary from five to 12 times that of the solid rail for the same loading, but in these results it was, of course, impossible to determine what influence the relative stability of the ground in the two places may have had on the deflections measured in the rail.

When we come to consider the dynamic action of the load we find that the rail ends, the splice and the joint ties undergo much greater pressures than can come upon the rail or ties at an intermediate portion of the rail. There has been much discussion as to whether a rolling load, like a train, passes over a rail as a load gradually or suddenly applied; and many have even questioned whether high speed in such a rolling load may not increase the pressures to something even greater than take place with loads suddenly applied—whether, indeed, such pressures may not be considered blows of less or more severity. Considering intermediate portions of the rail, and laying aside all reference to the effect of counterbalance and the rocking motion of the load, we may reason that the deflection of the rail in advance of the load fulfills the condition of a load gradually applied. Certain it is that in advance of the portion of the rail which is under full deflection there is some portion of the rail under partial deflection. But with the rail end the case may be different; for with a splice too weak, or too short, or too loosely fitted to fully transmit to the rail ahead of it the flexure in the rail behind, as such flexure proceeds toward the joint, the load may come upon that joint as a suddenly applied one. If little or no deflection precedes the wheel across the joint the wheel may meet the end of the next rail with a blow. Hence the severity of the conditions at that part of the rail where the deflection for even statically applied loads is greatest, must be apparent. Such is one of the causes of excessive wear to the rail on the receiving side of joints on double track: on the leaving rail end the load is gradually or statically applied, while on the receiving rail end it is suddenly or dynamically applied, or it may strike as a heavy blow.

In considering the strength of the rail at the joint we have to take account of the combined strength of the rail ends and the splice bars, for both assist in holding up the joint. Such is the fact for the reason that the rail is continuous beyond the joint ties. If we had to consider simply a beam supported at the two ends the case would be different. The same principle applies in considering the strength of the rail at an intermediate portion, for its supporting power depends not alone upon its resistance to bending at a point directly underneath the wheel load, but also upon the resistance to deflection due to the continuity of the rail over adjacent ties. As already indicated, the usual method of computation is to assume the rail ends to be cantilevers extending half a tie space beyond rigid supports (suspended joint), and then consider the pair of splice bars as a beam either supported at the ends or "fixed" at the ends, and loaded at the middle. By computing the deflection in terms of two unknown quantities (the proportional parts of the load sustained by the rail ends and splice bars) a ratio of the stiffness of these two means of support is found; and then by solving for the unknown quantities the proportionate loads carried by the rail ends and the splice bars are ascertained. It is then customary to double these figures for indefinite repetitions with reversal of stress, and then double again for suddenly applied load or shock. On this line of reasoning some pretty heavy stresses are found for the splice bars. As, however, no account is taken of depression of supports and the actual manner of the deflection of the rail, the figures obtained are necessarily conjectural. As a matter of practice splice bars seem to stand service much better than can be accounted for on the diagnoses of some of the doctors. A satisfactory analysis of the part which a splice must play in the support of a joint under actual conditions, with a view of arriving at even an approximation to the stresses in the parts, is indeed a perplexing proposition.

In discussing the joint question it is conventional to first point out the deficiencies of the angle bar and then look for such improvements as will overcome the stated defects. The plain angle bar fails to meet the ideal requirements of a splice in two important respects: it is not strong enough, and wear on the top edge, in the immediate vicinity of the joint, frustrates the maintenance of a close union of the parts. Taking up these defects in detail, we know that angle bars of ordinary make are not strong enough because they bend and take a permanent set in service, and occasionally one will break. As an improvement angle bars might be made much thicker than they usually are. In general practice railway men have been too sparing of metal in angle-bar splices, the weight of both pieces per yard being, in a great many cases, only 70 to 85 per cent of the weight of the rail. On a comparatively few roads the angle-bar splices are as heavy as the rail. It is entirely practicable to increase the ordinary weight 50 per cent without adding much metal to the horizontal leg of the bar, where it does not count for vertical stiffness. Such an increase will produce a pair of bars heavier than the rail, length for length, but, owing to the shallower depth, it is not practicable to make them as strong as the rail in resistance to deflection. On a rough calculation the weight of a pair of plain angle bars as stiff as the rail for which they are designed would necessarily have to be about three times as heavy as the rail, length for length. It then appears that there is no danger of overdoing the matter of strength by increasing, within practicable limits, the thickness of angle-bar splices. Thus it is shown how the plain angle bar fails to meet ideal conditions, for, inasmuch as the rail is broken at the joint, it is necessary, in order to preserve uniform stiffness past the junction, that the splice should be as stiff as the solid rail. Still, taking matters as we find them, any increase in the thickness of the bar must be considered an improvement. A good way to test the efficiency of a joint splice is to couple two rails together, end to end, and then let them swing clear from supports at the extreme ends. Loading should then be applied near the middle of the long span, with the rail in both the service and reversed positions. If the rail sags to a true curve and the splice does not take permanent set before the rail does it is shown to have bending strength equal to that of the rail.

The thickness of the top edge of the bar should be limited only by the width of the fishing surface of the rail head, due allowance being made for room to tighten the splice after wear takes place. Splice bars for rails with broad heads can be made thick, and in order to make the thickness a maximum the vertical leg of the bar may extend outside the plane of the side of the rail head, the projecting corner being beveled off or chamfered to give clearance to the wheel flanges. The inner faces of the bars should be flat rather than concave or dished out, as in the usual form. While this feature of design adds metal which does not largely increase the vertical stiffness of the bar, and while the space so filled may work some inconvenience in fitting bolts, if the rails have widely pulled apart, yet it does add considerable weight to the bars, which gives to the splice the advantage of greater inertia and should lessen the tendency to vibration and wear in case the bolts become slightly loose. Splice bars are dished out along the middle line to save metal and to facilitate punching the bolt holes. A thickened bar does not, however, stand in the way of making an oblong bolt hole, for a hole can be drilled the size of the shorter diameter and then finished by punching. As a matter of fact oval holes in the splice bars are not necessary to prevent the bolt from turning. The bolt may be made with an L-shaped head which engages with the horizontal leg of the bar, or it may be made with a square head which is prevented from turning by a shallow groove in the bar on line with the bolt holes, which may then be drilled. Splice bars with circular holes, grooved for a bolt with a square head, are standard on the Boston & Albany and the Chicago, Burlington & Quincy roads. In the former case the inside splice bar for the 95-lb. rails of the road has a groove $\frac{1}{8}$ in. deep and the circular holes for the bolts are $\frac{7}{8}$ in. in diameter. The holes through the web of the rail to correspond are 1 in. in diameter. The standard splice bar for the 100-lb. rails of the New York Central & Hudson River R. R. is 36 ins. long and has six bolts spaced 5.6 ins. centers. The shank of the bolt is $\frac{7}{8}$ in. square and it is held from turning by a hole in the splice bar $^{15}/_{16}$ in. square with rounded corners or fillets of $\frac{1}{8}$ in. radius. The other bar of each splice has circular holes $\frac{7}{8}$ in. in diameter. The web of each bar is $^{9}/_{16}$ in. thick and the weight of a pair of bars is 80 lbs.

Besides the severe bending stresses imposed upon the joint splice it is subjected to heavy shear. In the case of the plain angle-bar splice the shearing forces are applied through the fishing surfaces of the rail at and very near the joint. The top and bottom bearing surfaces of the bar are unequally fitted for the wear from this shearing force. Some writer has pointed out the humor of the situation in the remark that the rail is "hung up by the ears," which is a good illustration of actual conditions. The bottom bearing surface or horizontal leg of the bar is well designed to stand heavy pressure, but the top bearing surface is comparatively narrow, and the intensity of the shearing force, being concentrated on a length of only 2 or 3 ins. adjacent to the joint opening, first compresses the top edge of the bar, after which it is worn down by repeated blows from the springing of the rail ends. A close examination of an old angle-bar splice in track will usually show something like this: the splice will be found to fit the rails tightly at the end bolts, but will be .01 to .03 in. loose at the ends of the rails, or at the joint. This wear is mutual, taking place on both the splice bar and the under side of the rail head, and usually leaving a ridge of metal on the top edge of the bar in the expansion opening, where the wearing action is absent. Let it also be understood that the fishing surfaces of rails and splice bars are imperfect and not always capable of a close fit. One may observe on newly laid rails, with new splices tightly bolted, that occasionally a rail end will show slight looseness, and play up and down as wheels pass the joint. This looseness, whether due to badly fitting bars, in the first place, or to wear, is a serious defect of the plain angle-bar splice, for it permits of some deflection of the joint before the splice is brought under stress, thus reducing the efficiency of the splice. It may be seen, therefore, that the efficiency of a splice is not altogether a question of strength. In order that the strength of the splice may fully serve its purpose there must be a tight fit, so as to hold the two rail ends relatively immovable.

The conditions which bear some relation to the wear of splice bars are extent of bearing surface, the nature of the fit and the hardness of the metal. The importance of thick bars, particularly on the top edge, to afford a wide bearing surface, has already been dwelt upon. As to the fit of the splice, a good deal depends upon the length of the bars. Explaining more in detail what is above intimated, the finish of rails and splice bars is rolled surfaces, more or less rough, uneven and coated with oxide. As soon as the fishing surfaces adjacent to the joint opening begin to wear, a hinging motion of the rail ends takes place as the rail is deflected under wheel pressure; and the shorter the splice the greater is the hinging action for a given amount of wear; that is, with the shorter splice the rail ends have more chance to play without bringing stress upon the splice. In consequence of this fact the shorter the splice the more rapid is the wear. In illustration of this principle there are many familiar examples. In jointing up a fishing rod, for instance, one pushes the sections well into the ferrules, for the reason that if any looseness exists in the joint a short gripe of the ferrule permits of too much movement of the section. Examination of an old angle bar will disclose that it has come in contact with the rail at only a few places; sometimes only one bright spot can be found where it has come into close contact with each rail, and usually such spot is only a small portion of the available surface intended for contact. It must be obvious, then, that the shorter the splice the greater is the movement allowable for the rail within its gripe. If the fishing surfaces of rail and angle bars were planed surfaces, it might be possible to make a tight union with a short splice, and maintain it in that condition to better satisfaction than is the case in practice, but as such refinement of splicing is impracticable we have to look to the long splice as the next best thing of the plain angle-bar type.

Angle bars are usually designed to have the horizontal leg come even with the bottom of the rail. This arrangement divides the bearing between the rail and the splice bars. With a view to throw all the bearing upon the rail base, the bars are sometimes designed to stand $\frac{1}{8}$ in. clear of the ties, but the difference in this respect is quite likely unimportant. The spikes hold better on angle bars which come down even with the base of the rail. If the horizontal leg of the bar stands off the tie face the bearing comes against the spikes some distance above the tie, and they do not resist the lateral pressure as well as when it comes even with the tie face.

Length of Splice.—In practice the length of angle-bar splices varies from 20 to 48 ins. A splice less than 26 ins. long may be considered short and one exceeding 32 ins. in length may be considered long. The usual spacing of the bolts in splices of short and medium length is 5 to 6 ins., uniform spacing being customary but not always the practice. A spacing as short as 4 ins. is quite frequently found and 9 ins. is about the longest spacing. Short splices take four bolts and long splices six, but splices as short as 26 or 28 ins. sometimes have six bolts. Personally, my preference is for a long splice—not shorter than 42 ins. For a bar of that length I would space the bolts the following distances apart in inches: 8—6—6—6—8. For rails as heavy as 90 lbs. per yard I think it would pay to make the splice even longer—say 48 ins., with the bolts spaced at distances of 10—7—6—7—10 inches. Long angle-bar splices have been in service for many years, and the results, as compared with the use of short or medium-length bars, have been satisfactory in some cases and the reverse in others. So far as I have been informed the long splices which have failed to give better satisfaction than shorter ones have not been made heavy enough, being so light that they would bend under the traffic and in time take permanent set and hold the rail ends out of surface. I have never heard the opinion advanced that long splices would wear more rapidly than shorter ones; on the contrary the evidence always seemed to point the other way. The objection that long splice bars hold the rail so tightly as not to allow proper expansion for change of temperature, can be met by the argument that long bars, in order to hold the rail as firmly, do not need to be bolted up so tightly as do short ones.

Quality of the Metal.—Referring to the hardness of splice bars, it is to be noted that formerly they were made of wrought iron, and this practice still obtains to some extent, old iron rails being utilized to provide the material. Owing to the greater hardness and the consequent slower wear of the top fishing surface, steel is preferable. Steel for splice bars is usually of low carbon—about 0.10 to 0.12 per cent, 0.15 per cent being the maximum most commonly specified and .08 per cent about the lowest used. The manganese ranges from 0.30 to 0.60 per cent, silicon is not specified, and the limits on phosphorus and sulphur are about the same as in rail steel. Various standard specifications call for metal having an ultimate strength of 48,000 to 65,000 lbs. per sq. in. (usually 55,000 to 64,000) with an elastic limit as high as half the ultimate strength. The tensile tests must show an elongation of not less than 25 per cent in 8 ins., and a test specimen cut from the head of the splice bar must bend 180 deg., or flat on itself, cold, without fracture on the outside of the bent portion. In some cases the specifications require the same bending test to be made on an unpunched splice bar, the angle being flattened out before the bar is bent.

A few roads have used much higher carbon in splice bars than is provided for in the usual specifications. The New York Central & Hudson River R. R. standard specifications for bars not exceeding $^9/_{16}$ in. in thickness call for 0.25 to 0.30 per cent of carbon, with manganese, phosphorus and sulphur about the same as in the rail steel of the road. For bars exceeding $^9/_{16}$ in. in thickness the carbon is kept down to limits of 0.10 to 0.12 per cent, with manganese, phosphorus and sulphur about the same as in the other case. Silicon is also determined and fully considered. The bars made of the higher carbon steel are limited as to thickness of web so that they can be punched, it being found that with this quality of metal the punches and dies will not stand any reasonable amount of work on bars of greater thickness. It is to facilitate the punching of bars exceeding $^9/_{16}$ in. in thickness that the steel of lower carbon is used. A limited number of these low-grade steel bars is carried in stock by this company to meet repairs on leased lines where various types are still in use, but the high-grade bars are far more satisfactory and are used wherever high-speed trains are run. The Michigan Central R. R. has experimented since 1897 with splice bars of high-carbon open-hearth steel, the carbon running 0.65 to 0.75 per cent and the phosphorus about .05 per cent. In the testing machine splice bars of this metal show much better recovery after deflection than low-carbon bars, and in the track, when laid with new rails, they seem to give considerably better service than bars made of iron or of low-carbon steel. When applied to worn rails, however, these splices did not seem to maintain the joints in much, if any, better surface than the low-carbon bars which had been removed from the same rail.

Finish.—Splice bars should be rolled to a smooth surface finish, so as to fit the rail accurately, fishing tightly between the head and flange; and due allowance should be made to adjust for wear. The inside faces of the splice should not quite reach the web of the rail, no matter how tightly the bolts are screwed up. In order to fit in this manner the inner corners of the bars (which must be of small radius, so as not to unduly reduce the top bearing surface) should not fit snugly up against the fillets where the web of the rail meets the head and flange. Particular attention should therefore be paid to the hight of the bars, as determined by the fishing angles, in relation to the proper distance from the vertical center line of the rail section. Splice bars may be inspected for fit by applying them to a section of the rail for which they are made.

Specifications usually call for accurate shearing as to length and require that the punching shall not bulge the fishing surfaces opposite the bolt holes; and that the holes must be free from burrs. Some specifications require that the entire four or six holes, as the case may be, must be punched at one operation. Another point of much importance is that angle bars should be straight. In punching the bolt holes through the bar and in shearing it off it is liable to be bent and so left, making it impossible to fit the rail closely, for the bolts cannot be depended upon to straighten the bars. The extra expense of cutting off the bars by sawing would no doubt be found justifiable by the absence of crooked ends and "fins." The name of the maker and the year of manufacture are usually rolled in raised letters on the vertical leg of the bar, in such position as not to come under the heads or nuts of the bolts. The designation of the particular rail section to which the splice applies is sometimes included.

Devices for Taking up Wear.—Returning to the matter of the wear of splice bars, it may be noted that in foreign countries various devices are being used or experimented with as a means of reducing the shearing movement of the rail ends due to this cause. On many of the roads of France, Germany and Austria-Hungary metal packing pieces or liners made of hoop iron, or sheet steel cut to the desired form, are inserted between the bearing surfaces of rail and splice bar, in the gaps between the worn parts, to take up the motion due to wear. Of 17 companies reporting to the International Railway Congress on the use of metal lining pieces three expressed no opinion as to their utility, three attributed only limited success to their use, while eleven companies declared without reservation that they had obtained good results by using them. On the Emperor Ferdinand's Northern Ry. metal lining pieces for worn splice bars have been regularly employed since 1892, and are officially reported to have proven an excellent means for strengthening worn joint fastenings. These lining pieces are of a thickness of 1, 1½ or 2 millimeters, according to the conditions of wear. On lines of heavy traffic, carrying 8 to 10 million tons yearly, they last two or three years and are then replaced.

On the Prussian State and Imperial railways, of Germany, experiments are being made with a form of splice with auxiliary fishing plates of short length, which admit of being tightened independently, to take up wear. The splice proper, as will be seen in Fig. 17, consists of two Z-bars, the lower legs of which depend below the rail flange, to give depth to the splice, being cut away at the corners sufficiently to permit the (metal) joint ties to be brought to proper spacing. The upper leg of the Z-bar fits snugly against the web of the rail, but is not quite wide enough to meet the under side of the rail head. The proper fitting of the splice into the fishing sur-

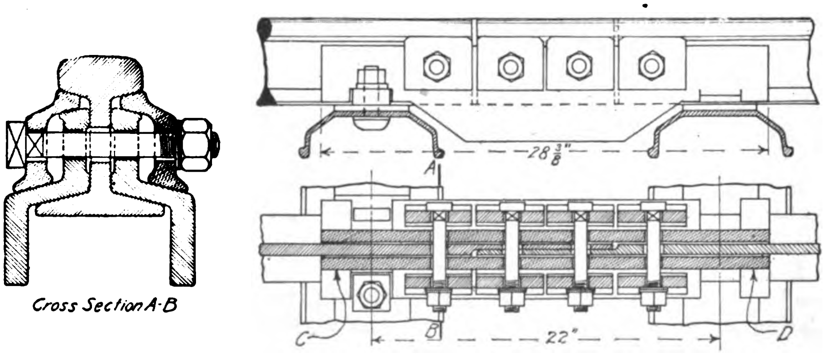

Fig. 17.—Splice with Auxiliary Fishing Plates, Prussian State Rys.

faces of the rail is then secured by means of four auxiliary wedge-shaped fishing plates, which fit into the space between the top edge of the Z-bar and the under side of the rail head, and upon the horizontal leg of the Z-bar. These auxiliary fishing plates are each about 4 ins. long. Being entirely independent of one another each may at all times be adjusted to maintain a close fit with the rail and to meet variable conditions of wear. As used on the roads named, there are, besides the form shown, two modifications of the same. There is one pattern in which a special bolt is used at each end of the Z-bar splice, being screwed up against the Z-bars direct, as at *C* and *D*, in the figure. In another pattern the general arrangement is as shown in the figure, except that when used with a lap joint one of the intermediate auxiliary fishing plates is omitted on each side. It is reported that this device has been giving good satisfaction.

Breakage of Splice Bars.—Splice bars break occasionally, and they usually, but not always, break by cracking from the top edge downward, either at the middle of the bar or through one of the bolt holes next the joint. The reason for this manner of failure is evident enough. The splice is subjected to bending stress in two directions, and as the top of the bar has no flange (none to speak of) it is very much weaker than the bottom and, of course, is the part where the heaviest strains occur. Running a few feet ahead of a rolling wheel there is an upward flexure of the rail which puts the top of a splice bar in tension. As the wheel draws near the joint the stress in the top of the bar changes to compression and so remains until the wheel is some distance past the joint, when it changes to tension again. Under a fast train, and particularly while the locomotive is passing, this reversal of stress takes place many times a second—about 12 times per second, at 60 miles per hour. As measured by Mr. P. H. Dudley (§ 181, Chap. XI.) the strains in the rail due to upward flexure seem to reach the maximum when there is a wheel on either side of the point under observation. This reversal of heavy stress is what cracks the bar, the metal undoubtedly being deteriorated most from the compressive stress, this being the heavier. If the top fibers become strained beyond their elastic limit it is only a question of time when they will part under the stress reversals. This is the reason why metal with a low elastic limit, such as iron and low-carbon steel, is considered by some to be less suitable for splice bars than metal of a higher grade.

A splice bar which has become worn in the middle or which has become bent down and taken a permanent set may not receive the full intensity of bending stress when the wheel is over the joint, owing to the extra burden imposed upon the rail ends. The heaviest duty which comes upon a permanently bent splice at a low joint occurs just after such a joint is raised to surface. When, in that case, the joint is lifted the tops of the splice bars are put in tension, and all the more so if the joint is raised a little higher than surface and the joint tie or ties tamped more strongly than the shoulder ties, to allow for settlement and to straighten the splice when the load comes on. Under traffic the tension on the top fibers of such a splice becomes excessive, and it is in this manner that large numbers of splice bars are cracked from the top downward. Such practice is approvable, because it is the only way to bring bent joints back into surface. The danger from cracked or broken splice bars is not as great in all cases as is sometimes supposed. Splice bars seldom break suddenly, but usually begin to fail by cracking, and the crack gradually deepens, so that opportunity is usually afforded to replace the defective bar before it fails completely. In view of the fact that splices in service are frequently found so loose as to afford no support to the rail ends, the breaking of a splice bar need not be regarded as a very serious matter, so far as joint support is concerned. If the broken bar is on the outer rail of a curve the danger of lip is the feature of greatest apprehension, but such cannot take place unless both bars break; and unless both bars break straight down, exactly opposite the joint opening, they may still be able to hold the rail ends in line. The point which I desire to make is that the breaking of a splice is not in all cases as serious a matter as the breaking of a rail.

Splice bars should not be notched for slot-spiking at or near the middle of the bar. Destructive consequences are bound to follow the notching of the outer fibers of a steel bar at a point where the greatest bending moment would bring the severed fibers in tension. A bar so notched is weakened to far greater extent than would be the case if the whole edge of the bar was planed off back as far as the notch extends into the bar. The best way to arrange for spiking splice bars to prevent or impede creeping of the rails is to make a bar with a wide horizontal leg, and then punch the spike holes through the leg instead of notching the edge. This arrangement makes both outside and inside spikes effective against spreading of the joint, and the splice bar cannot run away from the spikes, as it sometimes does when the latter are driven in notches the corners of which become rounded off by wear.

Effect of the Joint Opening.—Many students of the joint question seem to hold to the belief that the joint opening is the principal, or, at least, a very considerable, cause of low joints, by reason of the pounding effect due to the dropping of the wheels into the opening. The drivers of a locomotive are so large that they drop at the ordinary joint opening a distance which is not perceptible. A 33-in. wheel will drop into a joint opening of $\frac{1}{4}$ in. about .00048 inch. After a time it will be found that the edge at the rail end has been blunted back a little, so that the points where the wheel last touches the rail behind and first touches the rail ahead are about $\frac{5}{8}$ in. apart; into which space a 33-in. wheel will drop about .003 in., a fall hardly sufficient to give an appreciable blow. Indeed the tendency of the track to settle from the pounding of the wheels into such a small open space must be very small as compared with the tendency from the increased load which comes on the joint ties through decrease of stiffness in the rail at this point. That this is so is shown by the fact that there are places to be found in track where the joints have remained in surface several years; but if the blow delivered on every open joint was appreciable as a cause of settling track, the track at every such joint would either settle or else the blow would take effect upon the edge of the rail end and batter it. But the latter effect is not the case, for after several years' service good steel rails are not usually found battered as much as would result to the end edge by a single blow from an 18-lb. sledge hammer. At the joint opening there is usually some flow of metal, but with steel of desirable hardness this flowing does not become serious.

With the view of determining the effect of wheel pounding the experiment of cutting a narrow groove across the top of the rail with a hack saw, at an intermediate point, has been frequently tried. As a result the flow of metal under the rolling action of the wheels closes the groove and a slight depression is formed in the rail, but the pounding effect is not noticeable, so far as the surface of the track is concerned.

After a joint has settled some there is then a pounding which takes effect upon the track more and more as the joint settles farther down, for the sudden lifting of the wheel out of the depression greatly increases the pressure of the wheel upon the receiving rail. On double track this effect always takes place upon the same end of the rail, which accounts for the unequal wear of the two rail ends at the joint. Also, when a splice becomes loose, the rail ends shear by each other, up and down, as the wheel passes the joint, and the pounding effect upon the end of the receiving rail must be considerable, because the leaving rail end is depressed and the wheel meets the receiving rail end in the raised position, and must climb up on to it, as it were, thus delivering to it a blow which not only batters the metal but must also impart some momentum to the rail end in its deflection. The familiar clicking sound from the wheels passing the joints is due in some measure to the joint opening, but it is always louder when there is some play between rail and splice. As the wheel rolls by the joint, when it leaves the end of one rail and strikes the end of the other, it drives the rail head down upon the top of the two splice bars with a blow which gives out a cracking sound. This movement of the rail within the splice can best be seen when the rail is wet; that is, during or shortly after a rain, for then muddy water may be seen to squirt out of the loose places as the load comes on.

Miter Joints.—The supposed evil effects from an opening squarely across the rail at the joint has led to numerous schemes for carrying the wheel past the opening without dropping into it. One idea which has served this purpose is to so cut off the rail at the end that the joint opening does not extend squarely across the rail or else not entirely across it at one place. The miter joint (Engraving *T*, Fig. 20) is made by cutting the rail end off obliquely, or on a skew, usually so that the plane of the rail end makes an angle of 45 to 65 deg. with the vertical plane passing longitudinally through the web. Miter joints have been tried with varying success. They seem to have been experimented with most extensively on the Lehigh Valley R. R., where this form of joint, also known as the "Sayre" joint, was standard for many years, but was finally abandoned for the ordinary square-end joint. On some other roads the results from the use of the miter joint have been fairly satisfactory, and it is regarded as an improvement over the square-end joint. Such conditions as unsatisfactory quality of the metal and an unnecessary width of expansion opening may account for the shortcomings of the miter joint in some cases. An angle of 55 deg. is easier cut by the saw than one of 45 deg. and in some quarters is believed to give superior service, as the corners of the rail head are shorter and not so sharp.

It must not be understood that the miter joint entirely eliminates the dropping of wheels into the opening. As the rail top is curved, or eventually wears to that shape, only such wheels as fit the rail will pass over the joint opening without dropping into it. The contact between a new wheel and a rail with a curved top is so small that the wheel can find the edges of any joint opening at a practicable angle. In a certain contingency, as when a derailed wheel shears the splice bolts, the mitered end might form a dangerous joint, owing to the lip due to the lateral displacement of the rail ends, especially on the outside rail of curves; or during hot weather when the metal is expanding and there is a tendency for the rails to shove by each other. In anticipation of such trouble it has been proposed that the rail ends should be skewed as rights and lefts and the rails so laid on double track that the wheels will trail the points, in which case no danger from lip could exist.

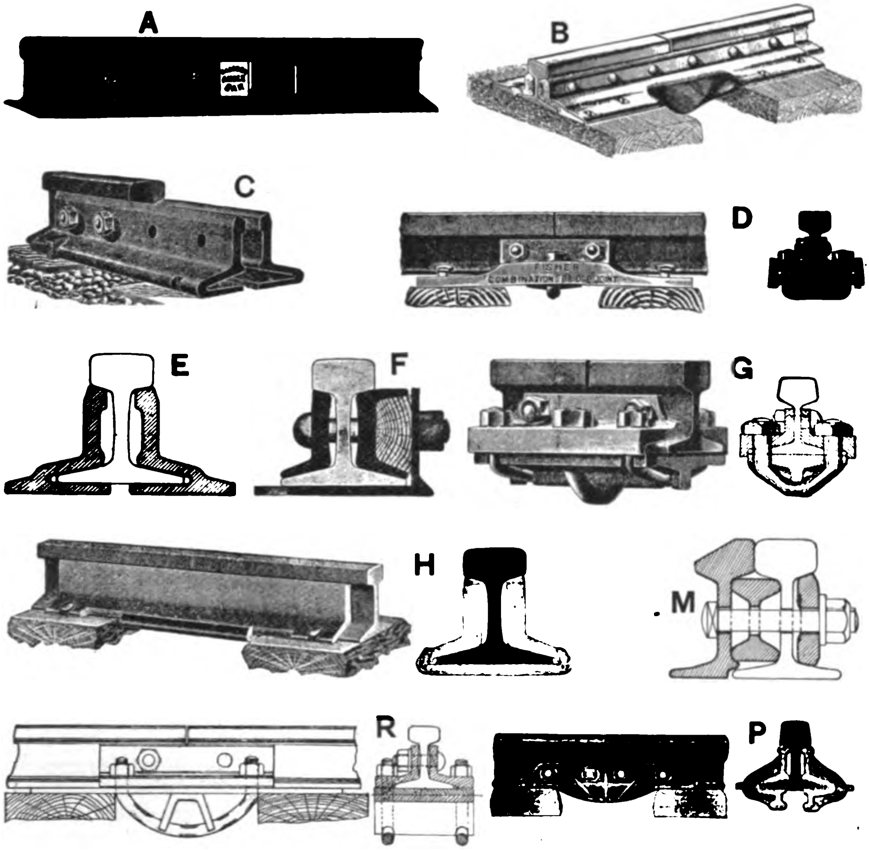
Lap Joints.—Another idea for carrying the wheel past the joint without permitting it to drop into the opening is found in the lap or scarf joint, which is made by halving or offsetting the rail ends on vertical planes to form an overlap, so that the joint opening does not extend entirely across the rail at one place. Some think that such a joint is better adapted to a rail with a curved top than a skew joint. As usually designed, the overlap is formed by halving the rail vertically through the web. While it would seem that the strength of the rail ends could be best preserved by a short scarf, say not to exceed 1 inch, as illustrated in Engraving *W*, Fig. 20, nevertheless where lap joints are being tried the long scarf seems to prevail, although the short scarf has been tried in a few cases.

Lap joints are not in service in this country, but on some European roads they are being tried to a considerable extent. Figure 17 shows a form of long lap joint that is being tried quite extensively, the lap in some cases being as long as $8\frac{3}{4}$ ins. This form of joint has been approved by the Prussian State railways, where it was being used on 124 miles of road in 1898, and it is also in service on the railways of Alsace-Lorraine and on the Austrian State railways. This joint enables the use of rails 49 ft. 3 ins. long on the Prussian State railways, without trouble from the increased opening necessary for expansion. The Haarmann-Vietor rail, named after two German engineers, who invented it, was designed with a view to form a lateral overlap or scarf at the joint without halving the web or weakening it in any manner. The rail is of unsymmetrical section, the web being non-axial, so that in forming a lap joint it is necessary to cut away only half of the head and base. The webs overlap at the joint and the rails are spliced with angle bars in the ordinary manner.

An eight years' trial of lap joints on the Kaiser Ferdinands Northern Ry. (1891 to 1899) proved a failure. A section of track about 3200 ft. long was laid with 86-lb. rails with joints lapping $9^3/_{16}$ ins. The thickness of the rail web was $^{11}/_{16}$ in. In a comparatively short time the lap ends became considerably battered and by the end of eight years, when all the rails were removed, 77 of them had broken at the lap. The splices were $21\frac{5}{8}$ ins. long and had four bolts.

Various Joint Splices.—It is hardly necessary to state that a great deal of experimenting has been done with joint-splice devices intended as improvements on the plain angle bar. Most of these splices have been patented and but very few of them have survived even a few years of trial. On general considerations some of the patented splices are clearly superior to the angle bar, because they embody all the principles of the angle bar, with additional features of apparent value, without multiplying parts. So numerous have been the trials of joint appliances, and so largely have experiments in this direction been disappointing, that sweeping statements favorable to this or that device are wisely regarded with some degree of misgiving. The joint-splice question has bothered railway engineers a great deal, and if there is any generality which is applicable to the matter it is perhaps best expressed in the following proposition: Practical men indulge in less and less talk about ideal splices, and more effort is being made in the direction of attempting some improvement or re-enforcement of the angle bar than in searching for some new-fangled appliance which might be expected to revolutionize things. It now seems to be quite widely conceded that some of the joint splices on the market, and others which are being tried by individual railroads, are giving better service than the plain angle bar. While a satisfactory test for a joint splice might be obtained in a few years, a period as long as the life of the rail must necessarily elapse before the ultimate worth of the device is demonstrated. Here follow illustrations and brief descriptions of some of the splices which have either received a long trial or are now being extensively tried, on the railroads of this country .

The ideas embodied in the so-called improved joint splices have for the most part taken three general directions: viz., in a stronger splice,



A, Sampson Angle Bar; B, Bonzano Splice; C, Continuous Splice (Old Pattern); D, Fisher "Bridge" Splice; E, Continuous Splice; F, Weber Splice; G. Fisher "Triple Fish" Splice; H, Permanent Splice; M, Barschall Splice; P, Price Splice; R, Long Splice.

Fig. 18.—Joint Splices.

either by thickening or deepening the section of the plain angle bar; in a firmer junction of splice and rail, usually by increasing the bearing surface of the splice, in one manner or another; and in attempts to overcome the drop of the wheel at the joint opening. The multitude of forms which inventions have taken includes many devices intended to combine two and sometimes all three of these features of improvement. One of the oldest ideas for increasing the bending strength of the splice was to thicken the angle bar in the middle. One form of splice embodying this idea is the Sampson bar, illustrated by Engraving *A*, Fig. 18, there being a protuberance of metal for the space of 4 or 5 ins. each side the joint opening, surmounted by another protuberance about 3 ins. long immediately covering the joint. Another direction in which this idea took form was in an angle bar of tapering section. Years ago such a splice was standard on the Chicago, Milwaukee & St. Paul Ry., the bars being rolled by eccentric rolls. For 67-lb. rails the splice was 40 ins. long, with 6 bolts, the thickness of the vertical leg being 0.597 in. at the ends and 0.875 in. at the middle. The experience which prompted this feature of design was the considerable number of breakages of angle bars on light rails under heavy traffic, it being clearly evident that the angle bar was, at least, lacking in strength at the middle. A great difficulty experienced in the rolling of these bars was to get them straight. The importance of having a splice of heavy cross section was early seen on the Lehigh Valley R. R., when rails not heavier than 52 lbs. per yard were used. With that weight of rail, it not being possible to have a heavy splice bar on the gage side, the outside angle bar was made about twice as heavy as the inside one, and the same depth as the rail, being grooved along the inside top corner, so as to fit against the side of the rail head.

The most usual, and in some cases the latest, scheme for strengthening joint splices is in the use of bars of deeper section, the typical arrangement being a deep bar depending below the rail base and between the ties of a suspended joint. About the simplest device of this kind is the Bonzano splice, which has been tried somewhat extensively on the Canadian Pacific, Pennsylvania, Philadelphia & Reading and other roads. This splice is shown as Engraving *B,* Fig. 18, being simply an angle bar with a horizontal leg of abnormal width bent down in the middle to deepen the section where the greatest bending stress comes. The bars are first rolled as ordinary angle plates, the intention of the wide flange being to give lateral stiffness and increased bearing surface on the ties. After being cut to length and punched for the bolt holes the bars are heated and the flange at the middle portion of the bar is bent down from the horizontal to a vertical position, to increase the depth and stiffness of the bar. The sectional area of the two splice bars is from 1.20 to 1.25 times that

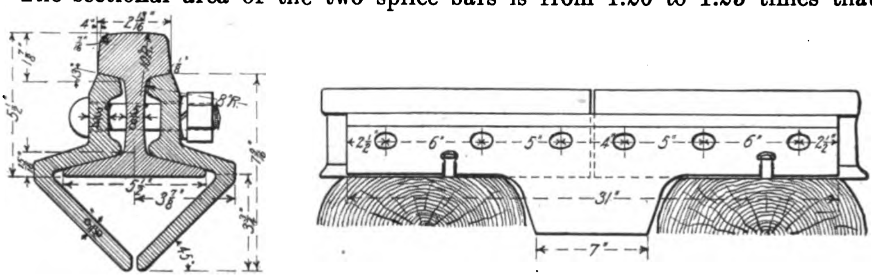


Fig. 19.—"M W 100 Per Cent" Splice and 100-lb. Rail, P. R. R.

of the rail to be spliced. Formerly this splice was made with a vertical camber of $\frac{1}{8}$ in., which, when the bars were bolted to the rails, gave the joint a camber of about $^1/_{16}$ in. It was expected that after a few trains had passed over the joint the scale of the metal would wear off at the center of the bars and the camber would be reduced to a straight surface. The advantage sought by the camber was to obtain a tight fit for the splice at the center, and although this feature seemed like an excellent idea, it had to be abandoned, for it was found that the camber put into the joint would not come out, even under the heaviest traffic and the heaviest wheel loads of locomotives. This splice is now made without camber.

Another splice of deep section, prominently known, is the "M W 100 Per Cent" splice of the Pennsylvania R. R., designed by the late M. W. Thompson, while principal assistant engineer. The name of the splice is intended to designate its relative bending strength, or stiffness, which is supposed to be equal to that of the rail on which it is used. The latest pattern of this splice, as designed for the standard 100-lb. rail of the road, is shown in Fig. 19. As is apparent, this splice is a development of the angle bar, having the very wide horizontal leg bent under at an angle of 45 degrees to the horizontal, so as to nearly meet the bottom leg of the other splice bar underneath the center of the rail. This splice is 31 ins. long, and all except a length of seven inches of the under portion of the bars is cut away, to clear for the joint ties. The total depth of the splice is $7^9/_{16}$ ins., of which a depth of $3\frac{5}{8}$ ins. depends below the rail base. The weight of both bars of the pair is 83.2 lbs., the moment of inertia is 53 for the pair and the sectional area of the pair at the middle is 13.94 sq. ins. The distance from the neutral axis to the lowermost fiber is 4.04 ins. The moment of inertia of the 100-lb. rail is 36.5, the sectional area 9.7 sq. ins., and the distance from the neutral axis to the lowermost fiber, 2.66 ins. The corresponding data for the ordinary angle-bar splice for the same rail, 34 ins. in length and weighing 75.4 lbs. per pair, is: moment of inertia for the pair, 8.06; sectional area of the pair 8.04 sq. ins.; distance from the neutral axis to the lowermost fiber, 1.71 ins. These data enable a comparison of the stiffness of the two types of splice. The bar shown is the development of four years of study and experiment, 60 miles of track laid with 85-lb. rails having been spliced with an older form of the bar, in which the extra metal in the horizontal legs of the splice, over the tie, was not cut away, but was extended out horizontally to form flanges bearing upon the ties. It is to be observed that the bottom flanges of this splice do not interfere with the action of tamping bars. The vertical axis of each bar of the splice is within the web portion that is gripped by the bolts, and as the vibrations of the lower flanges under stress are inward and upward, the tendency of the bars when the joint is loaded is to hug the rail. Another scheme for strengthening the joint splice in the middle was by means of a trussed support, usually including a bearing plate, with angle bars to hold the rail laterally. The Price and Long splices, Engravings *P* and *R*, respectively, Fig. 18, were of this form.

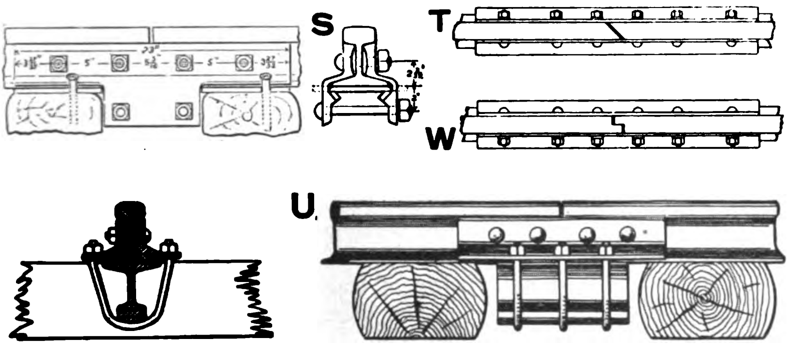
The idea of securing a firm junction of the splice and rail has usually led to the use of a base plate, primarily to support the rail ends at the base, thus affording bearing surface to relieve the top edge of the angle bars from wear, and incidentally to effect an equal distribution of the load upon the two joint ties, in the case of a suspended joint. The simplest device of this kind is a plain base plate used in addition to the ordinary angle bars. The standard joint splice of the Chicago & Northwestern Ry. is of this type, the base portion being a channel plate 24 ins. long, with $\frac{1}{4}$-in. flanges, the thickness of the plate under the rail being $\frac{1}{2}$ in. The rail ends (suspended joint) simply rest upon the plate and are not bolted thereto, but holes are punched through the plate for the spikes. One of the older forms of base-plate splices is the Fisher "Bridge" splice, which has been extensively tried. This splice, which is shown as Engraving *D*, Fig. 18, consists of a cambered channel or beam in combination with a pair of short angle bars bolted to the rails with two bolts through the web and with a U-bolt which holds the angle bars and rail firmly down upon the base plate. The corners of the rail are notched for the U-bolt and the angle bars are not permitted to reach the under side of the rail head, it being the intention to throw all the burden of supporting the rail ends upon the base plate. A later form of the Fisher device is known as the "Triple Fish" splice, shown as Engraving *G*, Fig. 18. This splice consists of a short base plate and pair of short two-bolt angle bars which "fish" only with the rail flange, the vertical leg of each bar not being quite deep enough to reach the under side of the rail head. There are three U-bolts holding the angle bars and base plate firmly to the rail flange, the idea in this splice, as in the case of the "Bridge" splice, being to support or stiffen the rail at the base and not at the head.

The simplest form of joint splice combining a base plate with an angle bar, and which also carries the distinction of having the fewest number of parts, is the "Continuous" splice, shown as in Engraving *C*, Fig. 18. This splice is in use on a large number of roads, and is so simple in construction that description is hardly necessary, any more than to say, perhaps, that it consists of a pair of angle bars with the horizontal legs widened out and doubled nearly half way under the rail base. Aside from the base-plate feature of this splice it will be noticed that it "fishes" with both the top and bottom faces of the rail flange. A later design of this splice, known as the "Extension Base" pattern, has tie-bearing flanges punched (not slotted) for the spikes (Engraving *E,* Fig 18). Another form of the base-plate type of joint appliance that has been extensively put into service is the Weber splice, shown as Engraving *F,* Fig. 18. It is composed of four parts besides the bolts, as follows: an ordinary angle bar and a channel bar fishing into the rail in the ordinary manner; a wood filler fitting into the channel bar, to act as a cushion against which the bolts are tightened; an angle plate, called the "shoe angle," the vertical leg of which bears against the wooden filler block and the horizontal leg of which serves as a base plate for the support of the rail ends.

The Heath splice, which was extensively tried on the Atchison, Topeka & Santa Fe Ry., was in one respect similar to the Continuous splice, in that it consisted of an angle bar with a wide horizontal leg doubled under the whole width of the rail base and extending some distance beyond the other side. In combination with this part there was a plain fish plate, the two being bolted together through the web of the rail in the ordinary manner. In one pattern of this splice the base portion was bulged downward under the joint opening, to afford extra stiffness. Strange though it may seem, a joint splice without bolts has been tried on main track under high-speed trains. This device is shown as Engraving *H,* Fig. 18, and is known as the "Permanent" splice. It consists of a pair of ordinary angle bars held to the rail by a base clamp or flanged base plate. The principle upon which the splice holds the rail ends firm is that, as the weight comes upon the joint the bars are made to gripe the rail all the tighter. At the center of the clamp there is a lug fitting into a notch cut out of the rail ends, to prevent the rail from creeping through the splice.

Of splices combining the two features of base support and bars of deep section there are at least two forms deserving of mention. The Churchill splice, used on the Norfolk & Western R. R., designed by C. S. Churchill, while engineer of maintenance of way of that road, consists of a pair of Z-bars fitting the rail as ordinary angle bars and depending about 3 ins. below the rail base for a length of 8 ins. between the joint ties. As shown in Engraving *S,* Fig. 20, there is a flanged base plate fishing with the lower legs of the Z-bars, which are held firmly to their work by means of two bolts. The "Crop-End" joint splice of the Michigan Central R. R., designed by the late Chief Engineer A. Torrey, consists of ordinary angle bars with an inverted piece of rail 11 ins. long, slightly cambered and placed base to base with the track rails, under the joint, as shown by Engraving *U,* Fig. 20. Two or three U-bolts are passed around the inverted piece and secured through holes in the horizontal legs of the angle bars, thus splicing the under piece of rail firmly to the ends of the track rails, the idea being to provide a strong splice by increasing the depth and also to prevent the rail ends from playing up and down and wearing the angle bars. This splice takes its name from the under piece of rail, which is obtained from the process of trimming rails with a rail-sawing machine, described in § 175, Chap. XI. In some cases in practice the middle U-bolt shown in the figure is omitted. An advantageous feature of this splice is that it can be applied to the rail while rail renewals are in progress without stopping to space the joint ties, which may be rearranged and the crop end applied at convenience. A somewhat serious objection against almost all other forms of deep-section splices is that the joint ties must be respaced while rail renewals are in progress, unless resort is had to the undesirable practice of making frequent cuts. The Crop-End splice was at one time the standard joint fastening of the Michigan Central R. R., and in 1900 was used on 390 miles of track. One feature of the device which was demonstrated was that it maintained a stiff joint—so stiff indeed that there was some question whether the rail ends did not suffer more where this splice was used than they did with a splice which permitted them to run away from the wheel. After a trial of six years the use of this splice was discontinued. The application of the crop end to joints on old rails generally improved the surface at the joint very much, particularly on rails where the traffic ran in one direction only. The serviceability of the crop end may be inferred from the use of some crop ends of 30-lb. rail under 60-lb. traffic rails, where it was found that the stress upon the joint splices bent the crop ends so that they sagged fully $\frac{1}{8}$ in.

There have been two ways of attempting to prevent wheels from dropping into the joint space, namely by cutting off the end of the rail in a manner to avoid an opening squarely across the same and by the use of wheel-bearing outer splice bars. The miter and lap joints have already been referred to. Splices designed to carry the wheels past the joint without jumping the opening were used as early as 50 years ago, and a number



S, Churchill Splice; T, Miter Joint; W, Scarf Joint; U, Torrey Crop End Splice.
Fig. 20.—Joint Splices.

of forms have been experimented with without permanent success. A late type of this splice consists of an angle bar or fish plate for the gage side of the rail and an "auxiliary" rail of suitable length, with the flange planed off one side to permit it to fit against the outside of the traffic rail in place of the outer splice bar. In the Barschall splice (Engraving *M*, Fig. 18) the fishing of the outer or "carrier" bar is obtained by means of a cast I-shaped filler placed between the carrier rail and the traffic rail, the bolts required being about 6 ins. long. The top of the carrier or "lifting" rail is on a level with the traffic rail and is beveled off at the ends to afford an easement in lifting the wheels. It bears direct upon the joint ties, usually on tie plates. A number of years ago some splices of this type were tried on the New York, Pennsylvania & Ohio (now Erie) R. R. with unsatisfactory results. It was found that the outer "flange" of guttered wheels would strike the piece of carrier rail heavily and that it formed an excellent anvil for guttered wheels to strike upon and pound down the joint ties. It was thought at the time by some of the people connected with this road that these trial splices might have been responsible for a noticeable increase in the number of wheels broken on the division where these splices were located. Such is the principal objection to this type of splice: a new wheel, by reason of the coning, will ride the traffic rail without touching the auxiliary, while a worn wheel will ride the auxiliary piece without touching the traffic or main rail. On the improved form of this splice, shown herewith, the larger portion of the head of the auxiliary or carrier rail is chamfered down to clear the "double flange" of guttered wheels. Of course this diminishes the bearing surface of the splice, but it removes, at least to some extent, the anvil-blow effect. It is intended particularly that this splice shall be suitable for use with long rails, one objection to the use of which is the wide joint opening necessary for expansion. On the Pennsylvania Lines West this splice is used on rails of 60-ft. length, and it is thought by the officials in charge that it has been the means of prolonging the life of rails under heavy traffic on double track, which had become badly worn on the drop side of the joint. These splices were manufactured in the company's own shops. As used on this road it is stated that no pounding from guttered wheels is noticeable. This form of splice originated in Germany, where it is known as the "Stossfangschiene."

A good way to test the merits of different kinds of joint splices is to put them in adjacent sections of track on new rails of the same weight. The roadbed and ballast conditions, ties, etc., should also be similar, and careful account should be kept of the cost of surfacing required to hold the track in smooth condition. In order to eliminate possible local influences each of the trial sections should be at least several miles in length. About 1899 the Pennsylvania Lines West began a systematic study of the joint question which resulted in the selection of six of the patented splices on the market and laying them in 10-mile stretches for trial. They were applied to 60-ft., 85-lb. rails of American Society section. These experiments also included tests of angle bars of standard section rolled from axle steel and from nickel steel (3 per cent nickel). The systematic observations made on the behavior of these splices should yield instructive data.

8. Bolts.—The standard sizes of track bolts are $\frac{3}{4}$ in., $\frac{7}{8}$ in. and 1 in. in diameter, the most usual lengths being 4 and $4\frac{1}{2}$ ins., although the proper length depends, of course, upon the design of the splice bar and the kind of washer or nut lock used. A few roads use bolts $^{13}/_{16}$ inch in diameter, but it is an odd size. There seems to be no uniformity of practice regulating the size of the bolt to the weight of the rail. On numerous roads $\frac{3}{4}$-in. bolts are used on rails as heavy as 80 and 85 lbs. per yard, and in a few instances on rails even heavier. About the lightest rail on which $\frac{7}{8}$-in. bolts are used extensively is the 75-lb. section; for heavier rails, except where $\frac{3}{4}$-in.bolts are used, the $\frac{7}{8}$-in. bolt is the common standard. On a comparatively few roads 1-in. bolts are used for rails weighing from 80 to 100 lbs. per yard, but in the most general practice the $\frac{7}{8}$-in. bolt is standard for the heaviest rails, which includes, of course, 100-lb. rails. Neither does there seem to be any uniform practice regulating the size of the bolt with reference to the number used in the splice. In numerous instances $\frac{3}{4}$-in. bolts are used on rails as heavy as 85 lbs. per yard, in 4-bolt splices, and just as frequently $\frac{7}{8}$-in. bolts are used on 75 and 80-lb. rails, in 6-bolt splices. It would seem that some standard might be recognized whereby the bolt would be sized according to the weight of the rail, say $\frac{3}{4}$-in. bolts for rails weighing 65 lbs. per yard or lighter; $\frac{7}{8}$-in. bolts for rails weighing 70 to 85 lbs. per yard, inclusive; and 1-in. bolts for rails weighing 90 lbs. per yard and heavier. It would then seem that in case of any question the 4-bolt splice should be given the benefit of the larger bolt.

The most common form of track bolt has a button head and an oval neck, the latter to correspond to the shape of the hole in the splice bar, so designed to prevent the bolt from turning. Other arrangements for holding the bolt from turning are referred to under the subject of "Splices," § 7. Track bolts and nuts should be carefully made. It is poor economy to buy cheaply-made goods of this kind. The wearing face or rim of the bolt head should be at right angles to the neck, to obtain an even bearing on the splice bar, and to avoid excessive wear it should be wide enough to catch a good bearing around the bolt hole. The neck of the bolt and the bolt hole should, for the same reason, be designed for a close fit. For strength the thickness of the nut should be at least equal to the diameter of the bolt, and the nut should be tapped at right angles to the wearing face, which should be flat. The thread of the bolt should fit the female screw of the nut truly and, except for two or three turns at the end of the bolt, at starting on, it should fit it snugly. The threads should be cut in oil. Dipping the bolt in oil after cutting the thread in water will not prevent rust. Much time is wasted in putting on and taking off nuts where the bolt is too long. The length of the bolt should be such that it will not extend more than ¼ in. past the nut after it is screwed home. Any extra length performs no particular service. The most convenient shape for the nut is hexagonal: a nut of that form is more readily caught by a wrench and much more quickly turned on or off than is a square nut.

In the use of bolts of the ordinary pattern it is not good practice to screw the nut up against the splice bar without a washer of some kind. The consequence of such practice is that the rails in expanding or contracting will force the thread of the bolt against the side of the hole in the splice bar and batter or destroy it, thus making it impossible to tighten the nut any further. An ordinary metallic washer alone gives no better results. In former years compressed fiber and wood blocks were much used for washers, a metallic washer being placed between such material and the nut. Fiber washers of good material, when properly handled, gave good satisfaction. They preserved the thread of the bolt intact next the bearing face of the nut, and the cushion-like bearing rendered the bolt less liable to break when very tightly screwed up. One serious trouble with these washers was that if they became wet or damp before being put to use they would soften, and when in that condition were not able to stand the pressure of the nut. The same trouble arose with washers soaked by rain when the nuts became loose. The wooden washer in most extensive use was a strip of oak about ⅞ in. thick bored to fit over two bolts. They were made of scrap pieces in the car shops, at small cost, and were sometimes soaked in oil. The principal trouble with these wood washers was that they softened after a few years' exposure to the weather, and split. If the nuts were tightened during wet weather (the time usually selected by trackmen for such work) they would crush. To overcome the trouble of splitting the Kansas City, Fort Scott & Gulf R. R. used a splice devised by Mr. J. M. Buckley, consisting of an angle bar for the gage side and a channel bar for the outside of the rail, with a strip of wood fitting in the groove of the channel, as with the Weber splice now. The bearing of the nut was received by an iron washer overlying the wood, but the rails (56-lb.) and splices outlasted the wood and it was gradually replaced with cast washers to fill up the space in the groove so that the nuts could be tightened. Although the principle of cushioning the pressure of the bolts against the splice bars seems like a good idea, the use of wood and fiber for the purpose has largely passed out of practice.

Nut Locks.—Nut locks are contrivances intended to prevent nuts from turning off or loosening when subjected to vibration or jarring. They are of three kinds: positive, or those which positively hold the nut from turning; spring locks, which are supposed to act constantly upon the nut with spring pressure, thus taking up any looseness which might come from wear; the third arrangement is a grip nut or bolt or "lock nut," of which there are several kinds. A common type of positive lock consists of a washer of sheet metal with a projecting corner or edge which can be bent up against one of the sides or corners of the nut. The Jones nut lock is of this kind. Another common form of positive lock consists in the use of a key. The Cambria angle bar is rolled with a rib on the horizontal leg, close by the vertical leg, forming a groove directly under the nut. By driving a tapering key into this groove and bending up the end the nut is held from turning and the key cannot slip out. The grooved bolt is another familiar type of a positive nut lock. The Stark pattern has a key seat on the bolt and corresponding seats in the nut, so that the nut need be screwed but part of a turn after it is tight, in order to bring the two seats together for the insertion of the key, which is a spring U-pin. The Champion nut lock is of the same general type but has a ring or rib of metal on the outer face of the nut which is punched down into the groove in the bolt when the nut is screwed home. A very simple method of locking nuts, sometimes employed to keep the bolts tight on crossing frogs, is to file a groove across the wearing face of the nut, outside the aperture, and then with a cold chisel cut a groove in the face of the splice bar to correspond with that in the nut, and drive in a split key after the nut is

screwed home. The position of the groove in the splice bar is found by first screwing home the grooved nut. As the splice becomes loosened from wear the keys may be temporarily withdrawn and the nuts tightened. On crossing frogs of the Michigan Central R. R. both the nuts and the heads of the bolts are held in this manner. Still another simple method of locking nuts positively is to burr up the metal of the splice bar behind a corner of the nut. To lock a track nut positively is a simple matter, but still inventors keep on studying.

Prevention of the nuts from turning does not by itself accomplish all that is desirable in nut locks for joint splices. The wearing down of the roughness and scale on the bearing surfaces of rail and splice bars, the elongation of the bolts and the wear from the bearing faces of bolt heads (especially badly fitting bolt heads), makes desirable some means for automatically maintaining the bolts in tight adjustment. A common type of elastic lock for this purpose is a spring washer, usually consisting of a coiled bar of one turn. A number of designs are shown in Fig. 21. Engraving *A* is the Excelsior single lock and Engraving *B* the Excelsior double lock. The double coil of the former prevents the device from being jammed into oblong bolt holes in splice bars, and its outline shape prevents it from turning with the nut. The double pattern is bent in the middle, to meet the splice bar convexly, and is coiled at the ends to fit over a pair of bolts. The National lock washer (Engraving *E*) fits the bolt closely, is made of hardened steel and has a rib around the edge of the aperture for the purpose of forcing some of the metal of the nut into the thread of the bolt, thereby locking the nut. The Verona nut lock (Engraving *F*) is a plain bar of square cross section spirally coiled. The improved Verona pattern (Engraving *G*) has a tail to engage with the lower leg of the angle bar and prevent the device from turning on the bolt. The Positive nut lock (Engraving *H*) is a variation of the old-style Verona, having barbs at the tips to cut into the nut and splice bar and lock the nut. The Standard nut lock (Engraving *P*) is a coïled and twisted bar with the ends turned out to keep it from getting into the elongated hole of the splice bar. The American nut lock (Engraving *C*) has twisted edges and the Harvey ribbed washer (Engraving *K*) has faces with ratchet-shaped ribs, to cut into the nut and splice bar and lock the nut when it is screwed up. The Eureka nut lock (Engraving *M*) is a square plate slit through to the aperture and spirally bent or warped with the edges of the slit upturned to lock the nut. The Automatic Rail-joint Spring or spring nut (Engraving *D*) is a heavy spring-tempered curved strap arched $^3/_{16}$ to $\frac{1}{4}$ in., according to size, tapped for the bolt and placed with the concave side against the splice bar. The aperture for the bolt is at a point about one-third of the length of the strap from one end, leaving an extending spring or tail longer on one side of the nut than on the other. The application of the spring to a rail joint is shown in the illustration of a 4-bolt splice, two of the bolts being put through the splice from one side and two from the other side; although all of the bolts can be put through from the same side of the rail if the spacing of the bolts permits. A square-headed bolt is used, and as the bolt is turned from the opposite side of the rail the spring is drawn down until it lies practically flat against the splice, as is the case with bolt No. 3 in the engraving. The primary action of the spring is to take up any wear of the parts of the joint and to compensate for any stretch of the bolts. Each spring or nut exerts an elastic pressure of 3000 lbs. The secondary action of the spring is to lock the bolt, since by the tendency of the spring to resume its normal shape the tail end exerts a pressure tending to give the bolt a sidewise twist or side bite, thus locking it.

Among lock nut devices one of the best known is the Harvey "grip thread bolt" (Engraving *R*). The bolt is made of soft steel and the threads are cold pressed in a manner to upset the metal and reduce but slightly the diameter of the bolt at the root of the thread. The threads are ratchet-shaped and undercut 5 deg. on the bearing side. In the nut the bearing side of the thread is at right angles to the axis of the aperture, so that when it is screwed up tight against the splice bar the threads of the bolt will give, to the extent to which they are undercut, and the metal will be pushed compactly into the outer recesses of the nut thread and hold the nut against turning off. The nut is square, with the corners chamfered next the wearing face to give a bearing which is approximately circular. On the bearing side the nut is recessed the depth of two threads to a diameter somewhat larger than that of the threaded bolt, thus housing and protecting that many threads against injury by chafing on the splice bar, as already explained. The National "elastic nut" (Engraving *S*) is split open on one side, being formed from a flat steel bar bent around into a ring to close by a lap joint. It is then pressed in a hexagon die and tapped slightly smaller than the bolt, so that when screwed on with the wrench it is distended and the joint opens about $^1/_{64}$ in., the spring action developing a grip on the bolt. The Oliver lock nut (Engraving *T*) is made some thicker than the ordinary nut and two or three turns of thread in the outer portion of the nut are cut at a slightly different angle from those of the greater portion of the nut and of the bolt. The locking of the nut is accomplished by the slight rupturing of the thread due to the gripe of the threads of differing angle. As this rupturing effect takes place on the outer end of the bolt no element of strength is sacrificed and the usefulness of neither nut nor bolt is destroyed by taking off the nut. The Young "gravity" lock nut (Engraving *N*) is an oblong jam nut tapped near one end. After the ordinary nut is screwed home the jam nut is put on and the overbalance of metal holds it against turning back. The nut-lock devices most extensively used are perhaps the double Excelsior, the National, the Verona and the Harvey grip bolt.

The devices above mentioned constitute only a small fraction of the nut locks which have been tried. Only a few kinds have been found efficient for the purpose, and none that has as yet come to general notice or into extensive service seems to have been entirely satisfactory. A number of years ago Mr. H. W. Reed, master of roadway for the Savannah, Florida & Western Ry. (now Atlantic Coast Line R. R.), found the average yearly expense for tightening bolts on 600 miles of track without nut locks to be $12.43 per mile, while with nut locks the average yearly expense for the same item was $4.00, labor at $1.00 per day. One trouble with spring nut locks, in numerous cases, has been the deterioration of the elasticity, in use, the device then becoming a dead flat washer. Another serious trouble with elastic washers of the narrow ring type, when used on splice bars with elongated bolt holes, is that they get jammed into the holes and their efficiency is lost for want of bearing. For the best results both nuts and nut locks should find an even seat all around the bolt. For this reason the bolt holes in the splice bar against which the nuts are screwed are frequently made circular and but slightly larger than the bolt, as already noted.

After all, the efficiency of track bolts depends largely upon the fit of the nut. A snugly-fitting nut, with or without a nut lock, will not work loose. In careful examinations of nut locks in service I have frequently found long stretches of track where all the bolts, provided with spring nut locks, had remained tight without attention, while on an adjoining piece of track, with the same nut locks in use, a large percentage of the bolts would be loose. The only explanation of the difference seemed to be that the tight bolts had snugly-fitting nuts, while the loose bolts had not, and that, apparently, the nut locks had played but little or no part in keeping the nuts tight. The production of loosely-fitting bolts and nuts is frequently due to the wear of dies and taps in too long service.

9. Spikes.—Track spikes should be made of good, tough material, so that the head will stand driving down upon the rail flange without breaking off. Both soft steel and wrought iron are the materials used, the latter principally for the reason that old iron rails are still to some extent being worked up into spikes. The Union Pacific R. R. owns a mill, located at Laramie, Wyo., in which a great deal of wrought scrap, including old iron rails, is made into spikes, bolts, angle bars and bar iron.

The standard size of spikes is $^9/_{16}$ in. square and 5 or $5\frac{1}{2}$ ins. long under the back of the head. For oak and other wood equally hard a length of 5 ins. is sufficient. The weight of a $5\frac{1}{2}$x$^9/_{16}$x$^9/_{16}$-in. spike is about $\frac{1}{2}$ lb. The head is usually made oblong, about $1^3/_{16}$x$1\frac{1}{2}$ ins., the under side of the same being inclined to correspond to the slope of the top side of the rail flange, which is usually 13 degrees. The standard spike point is wedge-shaped and its length varies from $\frac{3}{4}$ in. to $1\frac{3}{4}$ ins. The exact length, within these limits, is unimportant, so long as it is sharp on the cutting edge and not too thinly drawn out. For hard wood a point about twice as long as the thickness of the spike does very well. In seasoned white oak ties a long, slim point is liable to bend in driving and crook the spike. Spikes used in fastening rails to longitudinal timbers, as at pit cattle guards, have the point reversed, or turned quarter way around, so as to cut crosswise the grain and not split the timber. To strengthen the spike against wear from the rail, in the neck (a spike so worn is said to be "goose-necked"), it is the practice with some roads to slightly enlarge the cross section just under the head. Such reinforcement should not be made to the front or wearing side, because it would then operate to bend the spike outward when the head is driven down to the rail, and should the spike work up it would stand clear of the rail or permit the rail to spread slightly. If the reinforcement is made to the sides it interferes with facility of claw-bar operation. If reinforced at all the extra metal should be on the back side, but some object to any reinforcement to that side, on the ground that such would displace wood fiber which would remain out of contact with the spike, thus weakening its back support, should the spike work up.

The plain hook-headed spike of square cross section, above described, is standard practically everywhere in this country, and it is perhaps needless to say that for general purposes it is the best. Numerous attempts have been made to obtain greater lateral resistance, and increased adhesion, by the use of flat spikes, and spikes grooved at the back to give increased frictional surface, but all such experiments seem to have met with little success, and the spike of square cross section has held the field to the exclusion of all others. It was found that flat spikes were easily bent by the thrust of the rail, and spikes grooved to increase the adhesion cut open the fiber in such manner that water easily found its way into the fiber adjoining the back of the spike. Spikes of oblong section are difficult to catch with a claw bar and in hard timber they bend easily in driving.

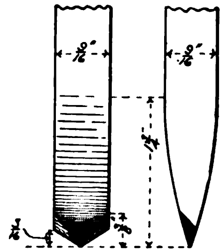

Fig. 23.

Fig. 24.

About the only improvement in the shape of the spike which has come into considerable use has been made in the shape of the point, the aim being to produce a point which will enter the tie without excessive injury to the fiber. The ordinary wedge point is formed in two ways: it may be cut with a die or it may be drawn out by rolling. When made by the former method the point is sharp, but frequently fins are formed on the corners which cause the spike to turn in driving. The rolled point is usually longer but dull or blunt on the cutting edge. The sharper the point the better is the satisfaction both as to ease of driving and in doing less injury to the fiber of the wood. The Goldie spike, made of soft steel, has a wedge point $1\frac{1}{2}$ ins. long, with corners beveled to sharp cutting edges, as shown in Fig. 22. The front side of the spike, as shown in the engraving at the left, is the wearing side. On this side the beveling extends $\frac{3}{4}$ in. above the extreme point and on the back side $^7/_{16}$ in. high. A side view of the spike is shown at the right hand in the figure. The standard spike of the New York Central & Hudson River R. R., for Carolina pine ties, is patterned closely after the standard spike of the Pennsylvania R. R., which is made of soft steel, is $5\frac{1}{2}$ ins. long under the head, $^9/_{16}$ in. square, in section, and has a rolled wedge point $1\frac{3}{4}$ ins. long, blunted on the extreme edge. The spike used by the New York Central company differs from that of the Pennsylvania company by being pointed at the tip on the Goldie style. The corners of the wedge on the front side are beveled for a length of $\frac{3}{8}$ in. and on the back side $^3/_{16}$ in., as shown in Fig. 23. In other respects the spike is exactly like the standard of the Pennsylvania road, having a neck enlarged on the side next the flange of the rail, the thickness front to back being $^{11}/_{16}$ in. The head is $1\frac{1}{4}$ ins. long and 1 $^5/_{16}$ ins. wide. The standard headblock spike of the Pennsylvania R. R. is like the standard rail spike except that it is 7 ins. long. The Diamond spike, shown in Fig. 24, has a gouge-shaped point, the face on the rail side of the point being convex, while on the back side of the spike (right-hand engraving) the face of the point is grooved. Screw fastenings are discussed in a later chapter.

10. Ties.—The selection of cross ties for track on roads of considerable length is a large and important undertaking. In this, much dependence may lie in the situation respecting the supply of timber in the locality. In timberless regions far removed from sources of supply there is usually a wide range for selection among timbers brought from a distance; while, on the other hand, where timber is abundant it is usually found to be more economical, all things considered, to use the best that can be obtained near at hand. It is between these two extreme situations, perhaps, that the most study is required in order to determine what particular kind of timber will be the most satisfactory. The cost of transportation, time required for delivery, and kindred questions increase the scope of investigation when ties are purchased at points off the railroad company's lines. The principal desideratum with ties is, of course, length of service at economical cost.

Conditions Affecting the Life of Ties.—The life of ties depends upon so many things that it is difficult of close estimation from knowing only the kind and quality of the timber. A good deal depends upon the season of the year in which the timber is felled. It is generally conceded that the proper time to fell timber is while it is free from sap. When timber is cut in the sap it will season leaving the sugar and albumen of the sap in the solid state, which will ferment and hasten decay when left to the action of water and variable heat, as is the case with timber used for ties. Also, when sap is in the timber the fibers are more open or porous than otherwise, which makes it more receptive of water from the outside than when the sap has declined naturally; and it is thought that when seasoned in this condition the pores do not close so tightly as with timber seasoned after the sap has declined. For this reason the holding power of spikes may depend to some extent upon the condition of the timber with respect to the presence or absence of the sap when it is felled. At all events it is commonly supposed that a mechanical change takes place in the condition of the fiber during the time the sap is out, which leaves the timber in a condition best suited to endure the action of the elements; and that at some particular time this condition is most favorable. On this time the opinions of good authorities vary all the way between the time just after the sap has declined until immediately preceding the time it starts again. Where some special use is to be made of the timber the determination of this particular time for the locality with some degree of exactness may be worthy of close study; but with ties it is hardly a practicable proposition to attempt to realize the desired condition so nearly as to specify a period as brief as a month or six weeks. It usually occurs, that, within reasonable limits, the time must be arranged to suit the convenience of the parties cutting the timber. In many localities a large portion of the ties are got out by farmers who own patches of wooded lands, and thus employ themselves during their spare time in winter. And then, too, the best time to cut probably varies with the kind of timber, and certainly with the climate or region. For the north half of the United States the time between late October and early March will include the tie-cutting season of perhaps all localities, and January is probably the proper time in most cases.

Ties cut during any month should be allowed time to season before they are put into the track. This rule is often repeated, but in practice it seems to be but little heeded. Those who profess to be authorities on the subject claim that at least six months is required to season timber well in the open air, and that a year is all the better. So far as ties used in renewals are concerned the most favorable time for cutting the timber and the most desirable time for placing the ties in the track are rather too close to admit of thorough seasoning of the timber, unless it is held over until another year; and such an alternative is, of course, out of accord with penny-wise policies regarding the investment of money. To let timber stand a year to season involves an interest charge of two to three cents per tie, which falls, of course, upon the railroad company, the matter being of no interest to the tie men. The tie-renewing season begins but a few weeks after the tie-cutting season ends and, as a matter of fact, a large amount of green timber is used in renewing ties. In building a new road it frequently occurs that any and all sources of supply are called upon, on short notice, and consequently much green timber and sometimes summer-cut timber, is used for ties. To aid the seasoning process the timber should be worked up into ties and peeled soon after felling. The hewing or sawing of the timber hastens evaporation of the moisture and the stripping of the bark prevents "souring" or fermentation. Timber experts say that bark should not be left on timber longer than two months after felling. The decomposition induced by leaving the bark on timber too long after felling, before the tie is made, is what the Germans call "suffocation."

In no case should ties be placed in the track before the bark has been removed. If they are not purchased with the bark peeled it will pay to have it taken off at the expense of the company. For such work a drawshave is a convenient tool, and track shovels and bark-peelers' spuds are also used. Ties peel easiest after being taken out of water, as when they have been floated in streams, or after a rain. The cost of peeling is 1 to 1½ cents per tie. With certain kinds of wood the presence of the bark after cutting favors worm eating; and with all kinds it is an absorbent of moisture, and will keep the sapwood of the tie damp as long as there is the least moisture in the ballast, thus hastening rot. Bark when dry is more inflammable than the timber in the tie and therefore renders the tie much more liable to take fire from sparks. After the tie becomes old the bark will loosen and mix with the ballast, much to its deterioration. It makes weed cutting between the ties more difficult, and, in short, it is so much of a nuisance that it should never be permitted in the track.

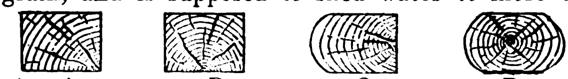
According to the general understanding the most durable timber is obtained from mature, but still sound and growing, trees, being superior to that cut from either young or very old trees. The disparity with the young timber is due to the relatively large amount of sapwood contained. It is also pointed out by authorities on timber that the location of the forest and the rapidity of growth have much to do with durability; that coniferous woods of slow growth (as indicated by narrow rings) on comparatively poor soil on high land, in dense forests, and hard or deciduous woods of rapid growth, from rich, deep, warm soil in the lowlands, but sparsely grown, yield the most durable timber of either class. The heavier and denser wood in the same species is the more durable. However much importance attaches to such conditions respecting the growth of timber, and even to the age of timber, for that matter, they have always been largely, if not entirely, overlooked in the selection of ties in this country. So far as age is concerned the "pole" tie or one faced on only two sides and made from a tree no larger than will yield one tie from a single cut, takes the preference. One reason for this is that the heart is in the interior of the tie and the sapwood on the faces occurs only at the edges of the same. Another reason is found with the advantages in the shape of the pole tie. The cheeks or rounded sides of the tie, from the center line downward, afford some bearing upon the ballast between the ties, and the weight of the filling material or ballast bearing upon these cheeks from above assists in holding the tie in position, making it more secure against being moved out of line or "churned" in the ballast than is possible with a tie sawed four-square. With some roads (one of which is the Buffalo, Rochester & Pittsburg Ry.) nothing but pole ties are standard, ties sawed on four faces, of whatever size or quality, being received only as second class.

Ties of any kind of timber resist decay longer in the colder countries, where the ground is frozen during several months of the year. For example, the average life of winter-cut white oak ties grown on high ground in Kentucky, Tennessee and Mississippi, and used on the Illinois Central R. R., is, by official statement, 7½ years on high ground in the states where they are grown, 10 yrs. in Illinois and 11½ yrs. in Northern Iowa. White oak ties grown and used in southern Arkansas last but 4 years, on the average, while ties of the same timber, grown in the same locality, when used in northern Illinois and Wisconsin, have an average life of 8 years. In the warm climate of southern Arkansas the timber is filled with sap at all seasons of the year, and ties cut therefrom are necessarily in sap. Under the continual action of the heat and moisture of the southern climate the process of decay is rapid, while in the northern states referred to, where the ground is frozen three or four months of the year, chemical change is entirely arrested during that time, and more or less retarded during other of the cooler months. Prolonged wet seasons shorten the life of ties, especially where the climate is hot. The life of ties varies with the kind of ballast used, to a large extent, being longer, for a usual thing, in those kinds of ballast which dry out most thoroughly and quickly. In loose material, like sand, gravel, broken stone or cinder, the exterior of the tie decays sooner than it does in compact material like clay, which is probably due to the condition respecting the exclusion of air. The chemical properties of the soil or ballast also have an influence on the life of ties. It is commonly understood that the effect of cinders is to shorten the life of ties. On the other hand, in 1901 there were ties in the track of the Central Pacific road, in salt and potash soils, in parts of Nevada and Utah, not the least bit decayed, which were laid when the road was built, in 1868. Ties of the same kind of timber in light, sandy loam roadbeds rot out in 3 to 4 years

Hard ties in stone ballast are hammered by the rail, and soft ties are rail cut, either action shortening the life irrespective of the destruction of the fiber by rot. The driving of many spikes into a tie, or a single spike redriven several times, mutilates and destroys the material of the tie just where it is put to the most severe service; so also does the grinding action of sand where it is habitually used, as on grades, near stations, etc. Ties of some kinds of timber check on the upper face from the heat of the sun and such open cracks get filled with sand or dust. Then when the tie gets wet the water gets in and is held by the earthy material to start decay in the interior sooner than otherwise. All these conditions, where they obtain, have to do with the life of ties. Good drainage lengthens their life.

A great deal of misleading data has been published on the life of ties. As a rule, the average number of ties placed in renewals per mile of track per year, reported by the railroad companies without qualification, is not a reliable basis for estimating the average life of the ties removed, because account is seldom taken of new road and sidetracks built within a back period corresponding to the life of the ties. When estimated on such figures the apparent life of the tie is too long, for it is clear that new track increases the mileage without increasing the renewals for a number of years. In estimating the life of ties from the renewals no track should be included on which renewals of ties have not been started, and, properly, no track on which the ties have not been renewed during at least three consecutive years, because during the first two or three years after the ties begin to fail the renewals are unusually heavy. On such grounds it would seem, therefore, that no track less than 7 to 12 years old, according to the quality of the ties, should be considered. As it is usually desired to know the average life of ties for main-track service, separate account should be kept of those used in side-tracks, where the timber is allowed to reach a more advanced state of decay before removal than would be safe for main track. In a general estimate on the life of ties, including all kinds of timber used for that purpose in this country, in its natural state, the average duration is usually taken at about 6½ years.

Manner of Cutting.—The advantages inhering with the pole tie have already been explained, and the same may be claimed for ties of any regular shape which conduces to anchor them in the ballast. In some of the European countries it is the practice to chamfer the upper corners of the tie, so as to narrow the face and reduce the supposed rocking motion claimed to be set up by the undulations in the rail. Such practice is badly advised, because under rolling loads the roadbed undulates with the rail and the rocking of the ties in the ballast is inappreciable; and besides, reduction in the width of the upper face without the use of tie plates removes fiber needed to resist rail cutting. Ties made from small trees are usually hewed, while from large trees they are sometimes split, but most frequently sawed. It is widely claimed that hewed ties last at least a year longer than sawed ties of the same quality of timber. One explanation for the inferiority of the sawed tie is that the faces are cut obliquely to the grain, exposing the ends of a great many fibers, which are roughened and started to a considerable depth, so that water is readily absorbed in wet weather. A hewn face is smooth, usually follows the grain, and is supposed to shed water to more or less extent



A B C D

Fig. 25.

for at least a year or two. For the purpose of smoothing the faces and making all ties exactly the same thickness (an unnecessary refinement), it is the practice in some mills to take the ties as they come from the saw and run them though a planer, surfacing two sides. Another objection to sawing, and one which is not overcome by planing, is that ties sawed out of crooked logs may be so crossgrained as to easily break in two under load or split in spiking. On split ties the faces naturally follow the grain of the timber, but some hewing is usually necessary to take out the wind at the rail seats. A sawed face affords an even bearing for both rails, which is not so liable to be the case with a hewed or split face. In ties sawed or split out of large trees it is not an easy matter to detect old timber, timber felled out of season, or even timber which was dead at the time of felling. In point of fact the timber worked up at saw mills, unless felled under contract at a specified time, is usually felled at any and all seasons of the year.

There are various conventional terms to denote the different ways of working up large timber into ties. When a log is sawed or split into four pieces, so that the heart is divided, each tie will have a piece of the heart at or near one of its corners, and is known as a "quarter" tie. When a log is sawed or split into two pieces each piece is known as a "slab" tie, if the heart comes in either top or bottom face, and a "half" tie if it comes in a side face. In Fig. 25, *A* is a quarter tie, *B* a slab tie, *C* a half tie and *D* a pole tie. Tie *C* is shown faced only three sides; if faced four sides it would still be called a half tie. The half tie is more liable to split in spiking than is a slab tie, for the reason that the spike enters the wood tangentially to the rings. Ties made from large timber should be laid heart side down, thus disposing the rings of the timber to shed water. The heartwood of most kinds of timber offers more resistance to rail cutting and holds the spike better than the sapwood, but it checks worse when turned up to the sun and the sapwood does not last so long in the ground. When the heart side is up the rings of the timber dip or open out, like troughs, and hold water. With pole ties the wider face should usually be laid downward. In cutting up large trees there is economy of lumber in sawing or splitting ties to rectangular section, and as an article of freight ties of that shape weigh less and occupy less space than pole ties having the same width of face. Under other considerations, however, it is inadvisable to face small timber four sides for ties, not alone because of the advantages already pointed out for the pole tie, but for the further reason that weight is a desirable property in track material, on account of the increased stability it gives.

Crooked timber should not be hewed into belly-shaped ties. With such timber it is better to make the faces straight, even though somewhat across the grain and though the tie be narrow-faced in the middle or at the ends. There is no particular objection to a crook in the tie horizontally, if not too much so. Ties, however made, should not be put into the track belly up, for a tie bulging upward in the middle of the track presents an ugly appearance and forms an obstruction to tear loose dragging brake rigging and pieces of car trucks; and such a tie is difficult of removal when it must be taken out. When a tie is put belly downward in dirt ballast its bed forms a sort of receptacle from which the water does not run freely after a rain.

Tie Dimensions.—The most common length of tie for standard-gage track is 8 ft., but since heavier rolling stock and heavier rails with wider bases have come into use many railway companies have increased the length to 8½ ft. For a tie of given thickness there is some certain length which conduces to a uniform distribution of rail pressure over the whole length of the tie. The experiments of Mr. A. Wasiutynski, permanent way engineer of the Warsaw-Vienna Ry., described under "Rail Deflection" (§ 181, Chap. XI.), show that such a length for white oak ties 6 ins. thick lies somewhere between 8 ft. and 8 ft. 10 ins. One of the general improvements carried out on the Prussian State and Imperial roads during recent years is an increase in the standard length for ties, both wood and metal, from 8 ft. 2½ ins. to 8 ft. 10¼ ins. (2.5 to 2.7 meters). In dirt ballast, where the ends of the ties must be exposed to insure proper drainage, a tie 9 ft. long seems to answer better than one of shorter length, since more support can then be given the track outside the rail and lessen the tendency to center binding, which is more pronounced with track in dirt ballast than in other kinds of ballast. Ties of such length are standard on a number of roads. Whatever the standard length, the specifications should be closely enforced. A variation of more than an inch either way ought not to be allowed, as there is no necessity for it. Where the ties are of uniform length the track is more evenly supported than is the case where the lengths vary. To give both rails equal support the middle of the tie should be at the center of the track, and if the lengths be not the same, or nearly so, either this condition cannot obtain or the ends will be out of line and cause a bad appearance. Still, where the ties are of irregular lengths it hardly improves the appearance of things to line one side, because then the track looks one-sided. The care usually taken to put the ends of ties to line on one side would, if the ties were approximately of equal length, secure fair line on the other side also, without extra trouble or expense. The habit of cutting ties to vary from 3 to 6 ins. from a standard length is slovenly and inexcusable, and the party who should pay for the consequences should be the individual who makes the ties, and not the railway company. The specifications of some roads require that ties more than 1 in. shorter than standard shall be rejected, on the first-class scale, and those more than 1 in. longer than standard length shall be cut off before they are received. The ends of ties should be cut with a saw, and reasonably square.

Besides being of equal length ties should be of uniform thickness, or nearly so. Ties varying much in thickness make an uneven rail surface for the outfit train to run upon during construction, unless considerable shimming or surfacing be done at a time when there is little opportunity to do it; and when not done there is danger of damaging the rails. The right thickness is about 6½ ins., and a variation of more than ½ in., at the most, should not be allowed. A tie much less than 6 ins. thick will be lacking in stiffness, and it is liable to be split when the spikes are driven, because the spike reaches so near to the under face. On the other hand a thickness of more than 7 ins., with ordinary tie spacing, interferes with facility in the use of the tamping bar. In pole ties extra depth narrows the faces, a difference of 1 in. in depth making a considerable difference in width of face. To allow for strength in the case of ties longer than 8 ft. and for both strength and for rail cutting in the case of soft wood ties, it is well to give such ties the benefit of the maximum allowable thickness. On a few roads soft wood ties are made as thick as 8 ins., but on a great majority of the roads the standard thickness of ties of all kinds of timber is either 6 or 7 ins., but perhaps more often 7 ins. than 6 ins. As touching the matter of strength a slight variation in the thickness of the tie makes a large difference. Since beam strength varies as the cube of the depth or thickness the relative strength of a 7-in. tie to that of a 6-in. tie of the same width, is as 343 to 216, or 59 per cent greater.

While there is neither difficulty nor reason why all ties should not be of the same length and thickness, it is not always so with regard to the width of face; neither is it so necessary that it should be. There is much said concerning the arrangement of ties in track with reference to uniformity of width of face that is to no great purpose. As long as there is no tie with a face narrower than a minimum acceptable, and the variation in width of face among all the ties is not greater than 50 per cent, it is hardly worth while to waste words with the tie maker or to consume time trying to arrange ties of the same width of face to go into the track together. Ordinarily about 40 per cent of the surface of the rail base rests upon tie face, and of course the same proportion of the surface of the ballast can be covered by tie face, be the ties large or small, so long as they are properly spaced. By spacing ties a certain distance apart in the clear (as they should be), and not a certain distance apart center to center, and increasing the width of the spaces next the largest ties, in case they are abnormally large, the bearing surface of the ties will be about equally distributed along the rail. A rough estimate in adjusting the spaces, by the eye, even where a considerable variation in width of face exists, will not appreciably depart from the proper proportion of bearing surface. Where the ties are small there are more, and where large, less, of them for a given length of rail, and consequently about the same amount of bearing surface in either case.

A 6-in face for pole ties and an 8-in. face for ties of rectangular section is the minimum allowable for main track. Smaller ties, bought at a reduction in price, may answer in side-tracks; but enough for this purpose may usually be had in culls from the whole lot offered for sale, because quite frequently a small tie must be made from the top of the tree in order to avoid undue waste of timber. But there is also such a thing as a tie too wide to give good results. Wide ties are seldom tamped as firmly as they should be; and it is somewhat difficult, also, to do it properly without using time much out of proportion to the size of the face. A tie having a face exceeding 10 ins. in width is too large for main track. The width of face giving best results all around is 8 ins. for pole ties, and 9 ins. for ties of rectangular section.

Kinds of Timber.—Oak, pine and cedar are now the timbers principally used for ties. White oak, rock or bur oak, post oak, chestnut oak and red oak are the varieties used. White oak is the timber which gives the best all-around results. Of the durable woods, when seasoned, it holds a spike the firmest, and, except under very heavy traffic, it supports the rail without being cut into until after it is well along in decay. Its life, stated in a general way, is from 5 to 10 years, depending upon circumstances, some of which have already been noted. A general average of the average life of white oak ties reported by 22 well-known railroads of the northern states, located both east and west of the Allegheny mountains, is 8¼ years. The figures taken into account in this average were supposed to represent the life of ties which had failed by natural decay and not by rail cutting. In the southern states the life of white oak ties seems to average 5 to 6 years. The weight of a 7x9-in. seasoned white oak tie 8 ft. long, sawed on four sides, is about 185 lbs.; of a 6x8-in. tie of the same length and sawed in the same manner, about 140 lbs.; of a white oak pole tie 8 ft. long, 6½ ins. thick, with 8-in. faces, about 175 lbs. The toughest and best quality of white oak, when green, takes on an inky blue color when cut across the grain. The other kinds of oak are not so good. Rock oak comes next best. It is hard, but not quite as tough as white oak, and its life is about the same. Red oak is more brittle and softer, not holding a spike nearly so well as either white or rock oak, and its life is not more than half that of white oak, sometimes lasting not more than three years. It makes excellent material for shims on account of its straight grain and ease of being split without shattering. It is subject to worm eating. Oak ties are used throughout the Allegheny mountains, in the middle Atlantic states, in the lake states, and in the Ohio and Mississippi Valley states. In 1900 it was estimated by good authorities that the different varieties of oak ties comprised about 50 per cent of all ties in service in this country; ten years earlier the estimate was 60 per cent.

In the south Atlantic and gulf states southern yellow pine ties are used extensively, and late years large numbers of them have been shipped into the middle Atlantic and New England states. The life in the South is 4 to 6 years and in the North 8 to 12 years. In the white sand ballast of some of the roads in Florida these ties last but 4 years and on the Isthmus of Panama but 1 to 2 years. In western Texas, New Mexico and Arizona a mountain pine is largely used for ties, but it is inferior to the southern yellow pine, lasting only 4 or 5 years when laid in the natural condition; when treated with zinc chloride such ties last 8 to 12 years or longer, as witnessed by the experience of the Atchison, Topeka & Santa Fe Ry. (§ 168, Chap. XI). California mountain pine is of better quality. In the gulf states black and red cypress are used to a considerable extent. It is a soft timber, requiring tie plates for best results. The natural life, as reported by some roads, is 10 to 12 years.

The most durable timber for ties, so far as resistance to decay is concerned, is cedar. Both red and white cedar are the varieties available, but the supply of the latter is much the more abundant. It is a very soft timber and is cut into by the rail so rapidly that it is sometimes taken out, turned over, and put back long before there is any sign of decay. It is used to best advantage on straight-line track under light traffic. Under heavy traffic it does well on tangents if tie plates are used, the life of cedar ties, when so protected, being 15 to 20 years, and even longer. In fact the natural life of cedar ties seems not to be widely known, if known at all, because in nearly every case where such ties have failed the cause has been either rail cutting or spike killing. On the Saginaw division of the Michigan Central R. R. there are large numbers of cedar ties which have been in service more than 19 years, and the ties are still in sound condition and expected to last 10 years longer. Tie plates were not used on these ties until after they had been in service 18 years. On the Buffalo division of the Buffalo, Rochester & Pittsburg Ry. there are cedar ties in the track which have seen service for 17 years and are in condition for further use. There is on record the case of a red cedar tie which did service in the track of the Boston & Providence (now New York, New Haven & Hartford) R. R. from 1834 to 1876 or 42 years. Sound, dead cedar gives just as satisfactory service as live, green cedar, which is a fortunate circumstance, for the bark of cedar trees is thin and over large areas of cedar forests which have been swept by fires the trees have been killed. The supply of cedar ties in this country is obtained largely from Canada and from states along the Canadian border, such as Maine, Michigan, Wisconsin, and Washington. Cedar is light in weight and is carried farther for ties than any other timber. When used with tie plates it is considered to be a very economical tie timber. On the behavior of cedar ties under traffic, and the use of tie plates with the same, the reader is referred to a comprehensive article entitled "Cedar Ties in Service," written by Mr. Moses Burpee, chief engineer of the Bangor & Aroostook R. R., and published in the Railway Review of March 13, 1897. Spikes hold best in cedar ties when driven in the sap, or as close to the edges of the tie face as good practice will permit.

The average life of chestnut ties is about 7 to 9 years. Chestnut timber is medium in hardness and holds a spike quite well. It is found quite abundantly in the middle Atlantic and New England states and is there much used for ties, telegraph poles, and fence posts. It is disposed to check badly in the sun. In the northern states east of the Mississippi river hemlock is used to a considerable extent for tie timber. It is soft, but holds a spike tolerably well. It usually rots from the outside in, and it will hold the spike quite firmly, sometimes, when so rotten on the outside as to be of no further use. The life of native hemlock ties is 4 or 5 years, but hemlock ties brought from Canada and used in New England last a year or two longer.

In California, redwood is extensively used for ties. It is soft but durable, and when green it is heavy. Redwood ties are usually split out of large timber. On the Southern California Ry. (Santa Fe System) redwood ties, used with tie plates, have been found in good condition after a service of 14 years. Without tie plates the life of this timber is measured by the traffic carried rather than by time. There are records of redwood ties in side-tracks on the Southern Pacific road, perfectly sound after 40 years of service. Farther up the coast, in Oregon and Washington, fir and white cedar are used. Fir, if first allowed to season, holds a spike well, and lasts 6 to 8 years in gravel ballast. In Montana ties are principally tamarack and cedar. In the Ohio valley wild cherry, honey locust and black walnut are used to a small extent for tie timber, and each lasts about 8 years. In Canada cedar, oak, tamarack, hemlock, spruce and fir are the tie timbers largely used, the average life of all except cedar and hemlock being about 8 years. Tamarack is a variety of larch (American or black larch) and in some localities is called hackmatack. Its durability is quite variable, for in some parts of Canada and the United States the average life is only about 4 years. On the Duluth, Missabe & Northern Ry. it lasts 6 years. In Canada the average life of hemlock ties is 6 years.

It is an easy matter, and useful as well as interesting, to so mark a tie when it is put into the track that at any time its length of service may be known. This can be done by simply cutting a notch in the edge of the tie face, in a certain position fixed for each year of a decade. Say the road runs north and south: then let the odd numbered years be marked on the north edge of the face and even numbered years on the south edge. Starting at the east end of the tie, let successive notches toward the west end thereof indicate years increasing upwards to ten. As distinct positions for the notches points can be taken outside the rail, just inside the rail, and at the middle of the tie, making positions for five notches on each edge of the tie face. With ties thus marked the foreman is able to take note of the ages of the ties removed when making his report on renewals. A system of notching something similar to that above described has been used on the Allegheny Valley Ry. On some roads, including the Southern Pacific and the Lake Shore & Michigan Southern, the ties are stamped when put into the track with a cast iron hammer having a raised figure on the striking face denoting the year. The figure is quite large and is raised about $\frac{1}{8}$ in. The usual practice is to stamp the tie in the end, on the line side, and sometimes also on the top. At the end of each year all the hammers bearing dies for that year are called in and scrapped and new ones are cast for the new year and issued to the section foremen. A better record, and one which has now come into extensive use, is a galvanized iron or copper nail with the last two figures of the year of laying stamped on the head. The nail is usually $\frac{1}{4}$ in. in diam. and $2\frac{1}{2}$ ins. long and the head is $\frac{5}{8}$ in. in diam.

11. Tie Plates.—Tie plates, or "wear plates," as they are known in Europe, are metal bearing pieces placed upon the ties to protect them from being cut by the rails. Rails cut into the ties by crushing down and abrading the fiber. The crushing action is due to direct pressure or impact and the abrasion takes place by the infinitesimal creep or sawing action of the rail in its wave motion under the traffic. The presence of grit on the ties, where it can work in upon the rail seat, as on grades or in yards where sand is used freely, augments the rasping or cutting action of the rail. Some students of the question ascribe the principal cause to the abrasion, while others go so far as to claim that it is the sole cause, of rail-cut ties. The symptoms, however, clearly indicate that rail pressure has considerable effect in cutting the ties; otherwise a thin sheet of metal would suffice for their protection. The fact that tie plates $\frac{1}{4}$ in. thick buckle in service disproves any assumption which ignores the effect of rail pressure. It is further to be noticed that the rail cutting of ties is most rapid at the joints, where the rail is weakest and rail pressure the most intense. The point is sometimes raised that tie plates do not greatly increase the surface over which rail pressure is distributed, and at first consideration this fact would seem to nullify the importance of rail pressure. It should be understood, however, that the ribs or under projections of tie plates assist materially in the support of the plate. It is a matter of common observation that tie plates placed upon the ties without being seated resist the pressure of the traffic for some time before they become fully settled into the timber.

As the object sought in the use of tie plates is to make the ties last during the natural life of the timber, the necessity for the same arises only where the ties would fail by rail cutting or spike killing sooner than they would become unserviceable from decay. Generally speaking, the conditions which decide this matter are the hardness of the wood and the intensity of the traffic. Thus, hardwood ties usually fail by decay rather than from wear, and, as a rule, the use of tie plates on such ties is not sanctioned in practice. In rare instances, where the traffic is very heavy, as in busy yards, but seldom on main track, the use of tie plates on white oak ties may be justifiable, but such cases are the exception. Under light or medium traffic softwood ties may give satisfactory service without tie plates, but under heavy traffic they usually need protection against rail wear, especially on curves. In this connection, however, it should be said that a great deal depends upon the weight of rail used. Increase in weight of rail lessens the tendency to cut the ties, in several ways: the increased hight and greater stiffness of the heavier rail distributes wheel pressure over more ties, and the wider base covers more tie surface, thereby reducing the unit pressure in two ways; while the decrease in wave motion, due to the increased stiffness, lessens the creeping of the rail and its rasping action on the wood fiber. Reflection upon this fact will account for the excessive cutting of ties in some busy yard tracks. The rails in such places are usually of light section and of second quality, or too badly worn for use in main track. Under these conditions the rail deflects heavily under the wheels, bringing excessive pressure upon the narrow bearing, and this pressure is further augmented by the hammering action of the wheels on the roughened running surface.

The natural life of the ties is also an important consideration in tie-plate economy, for it is clear that nothing is gained in applying tie plates to timber which rots out as soon, or nearly as soon, as it would cut out under the traffic without them: if only a year or two can be added to the life of the tie by their use it may not be worth the while to bother with them. The possibilities in the use of tie plates are greatest with soft timber which resists decay for a long time, such as cedar, redwood and cypress. Without tie plates such timber may not hold out half its natural life. Between these extreme cases there is opportunity and occasion for study, for while the use of the tie plate may add something to the life of a tie which, unprotected, can carry the traffic imposed without being badly cut until it is well along in decay, the question as to whether the saving so made will pay for the cost of the plate and the labor spent upon it is worth looking into. It is, however, a question easily determined, for if there be any doubt concerning the advisability of using tie plates, in any case, it is a matter of but slight trouble and expense to put them in the track for a few hundred feet and give them a trial.

The strictest sense of the limitations on the use of the tie plate, hitherto remarked upon, is intended to apply only to straight-line track, or to track laid with white oak ties or other ties equally as hard. For curved track laid with any but the hardest ties some exceptions to, or qualifications of, these statements may in cases be necessary. On curved track, especially where the curvature exceeds 3 or 4 deg., tie plates can sometimes be used to advantage, though the same ties on tangents would bear up well without them. As the tie plate ties the outside and inside spikes together the two or more spikes driven through the plate act in combination with the resistance of the plate against the spreading of the rail, whereas the spike driven on the inside of the rail where a plate is not used is of no effect in holding the rail against spreading. Tie plates, then, if of proper design, may serve as rail braces; and in fact they are frequently used in lieu of rail braces. The tie plate can also perform important service by preventing the inside rail of curves from canting. Where the ties on the curve are soft or where hard ties have become somewhat decayed, heavy, slow trains will sometimes cant the top of the inside rail outward (The cause for this action is fully taken up in a later chapter). While there is just the same tendency to cant where the tie plate is used, the outside edge of the rail flange cannot cut into the tie and thus tilt into a position in which the tendency for canting is increased. So far as curves are concerned it may be said that, as a general proposition, wherever trouble is had from spreading or canting rails the use of the tie plate is to be recommended. On a number of roads it is the practice to use tie plates on curves, regardless of the quality of the ties, but not on tangents. The idea is, of course, to maintain the gage and preserve the upright position of the rails. On other roads the use of tie plates, if at all, is restricted to curves of 3 or 4 deg. and over. When used on curves it is customary and also the best practice to plate every tie. It is the practice of a large number of roads using tie plates on tangents to place them on joint ties only.

The early idea of a tie plate was that it should be thick and heavy, and it was usually made smooth on the under side. Experience has developed changes in these respects, for economy of material compels a minimum of weight consistent with strength, and one of the most important considerations is to obtain a plate which will unite firmly with the tie; otherwise it will pound the tie and wear into it under rail vibration and afford no lateral resistance to spreading of the rails. As such a requirement cannot be met by a plate with a smooth under side, practically all tie plates are now made with under projections, in the shape of claws or flanges, which enter the tie and hold the plate fast. The claw type of under projection enters the wood crosswise the grain and the flange or rib type enters the wood longitudinally with the grain. In the former case the lateral displacement of the plate is resisted by an abutment against a section of the fibers, while in the latter case the displacement is resisted by the friction of the flanges in the wood, the idea being that the seating of the plate crowds and compresses the fibers of the wood in between the flanges, thus giving the plate a firm hold in the tie. One advantage with the longitudinal flange is the facility of moving the plate for an adjustment of the gage of the rails, since by striking the plate on the end the flanges may be made to plow their way through the wood. After a plate having claws (or other under projections) cutting crosswise the fiber is once seated it is not an easy matter to change it to a position slightly removed and seat it again firmly.

Respecting the wearing surface or rail seat of tie plates, various patterns are flat, grooved, corrugated and shouldered or provided with lugs. The advantages intended for the grooved top are economy of metal and provision for the escape of sand and dirt, which may work under the rail and, if not removed in some way, lead to undue wear to both rail

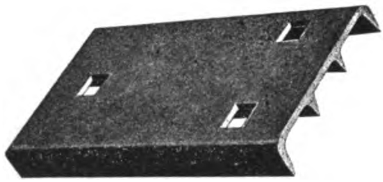


Fig. 26.—Servis Tie Plate.

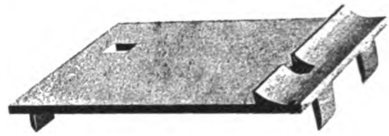

Fig. 27.—Goldie Tie Plate.

and plate. On the latter point of design authorities disagree, for there are those who claim that a groove or depression in the face of the plate serves to hold the grit and cause it to accumulate in larger quantity after once it begins to collect there, whereas the undulation of the rail over a flat-top plate will blow the grit away. The purpose of a lug or shoulder on the top of the plate is to receive the lateral thrust of the rail and save the neck of the spike from direct pressure and wear. With such an arrangement the lateral thrust of the rail is opposed by the resistance of the plate in the wood before the spikes begin to act, thus relieving the spikes of that much side pressure. There is also the further advantage that the pressure against the spike is received at a point nearer its bearing in the wood, thus acting at a shorter leverage than is the case where it is received above the plate; in other words a spike can hold more firmly against a tie plate than against the flange of a rail placed on top of the plate. One fault found with shouldered tie plates is that they do not permit shimming to be done crosswise the rails. For curved track the largest practice seems to favor a tie plate with a shoulder, and a shoulder extending across the whole width of the plate has the preference, as it stands wear better than a narrow lug. Shoulders or lugs not being required for the gage side of the rail are provided for the outside only.

One of the oldest and best known of modern tie plates is the Servis pattern, Fig. 26. It is made with or without lugs on the top, and the bottom has three or four longitudinal flanges, according to the width of the plate. It is rolled to a thickness of $^3/_{16}$ to $^5/_{16}$ in., and in widths varying from $4\frac{1}{4}$ to 6 ins. Another very well-known tie plate is the Goldie pattern, Fig. 27. It has a shoulder running the width of the plate and the under side has four claws set on the end edges, 1 in. inward from the sides. These claws are 1 in. wide and $\frac{7}{8}$ in. to $1\frac{1}{4}$ ins. long, as ordered, and have a sharp cutting edge. On the latest pattern the claws have a Goldie spike point (Fig. 22) and the claws are rolled to stand in under the body of the plate, thus protecting the opened fiber from the entrance of water. It is rolled of steel, $4\frac{1}{2}$ to 6 ins. wide, and $\frac{1}{4}$ to $\frac{3}{8}$ in. thick, according to demand. Another design, bearing a close resemblance to the Goldie pattern, is the Churchward, or better known as the "C. A. C.," tie plate. Like the Goldie plate, it has a shoulder about $\frac{1}{4}$ in. high

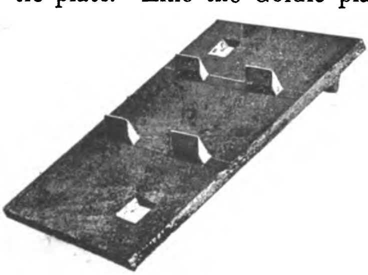

Fig. 28.—C. A. C. Tie Plate.

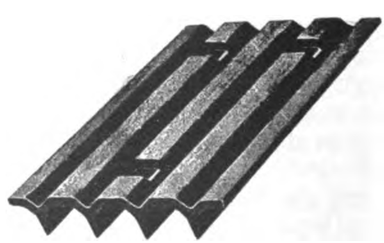

Fig. 29.—Wolhaupter Tie Plate.

and as wide as the plate, and on the under side (Fig. 28) there are four chisel-edged holding lugs or claws set in directly underneath the rail seat, where they receive the bearing of the traffic direct and where the fiber is well protected from the entrance of water. The plate is steel, about $\frac{1}{4}$ in. thick, and is rolled either flat or beveled, as desired, the intention of the latter style being to give the rail an inward cant, the purpose of which is explained under the subject of "Rail Design." The Wolhaupter tie plate (Fig. 29) is of rolled steel, with four longitudinal flanges on the under side and a corrugated top surface, the grooves of the corrugations coming over the flanges. The side flanges are set in under the edges of the plate and the spaces between the flanges are arch-shaped, so as to compress the fibers and hold firmly to the tie. The plate is made either with or without lugs to take the thrust of the rail. The metal is $^3/_{16}$ to $^5/_{16}$ in. thick. Another tie plate of an earlier pattern is the Fox, shown in Fig. 30. It is a flat plate with segments stamped down to form longitudinal flanges and provide holes for the spikes, and the top has a lug to take the thrust of the rail. It is in use, but not extensively.

Among tie plates of more recent design the prominent patterns have longitudinal flanges on the under side, and in all essential respects they are but variations of older forms, the chief aim being to distribute a

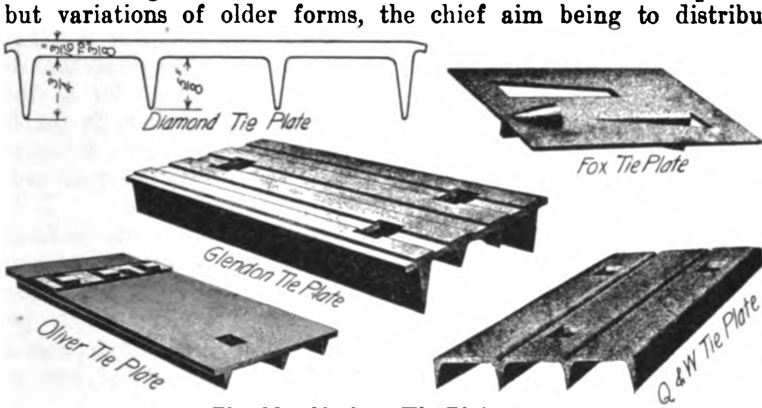

Fig. 30.—Various Tie Plates.

minimum of material to effect a desired strength or stiffness. On the Glendon "Flange" tie plate (Fig. 30) the top is grooved and the rail rests on bearing surfaces immediately over the flanges, the intention being to apply the load over the strongest parts. There is no rail bearing surface extending beyond the outer flanges. The plate is made in sizes from $4\frac{1}{4}$ to 6 ins. wide and $^3/_{16}$ to $\frac{3}{8}$ in. thick. The Q. & W. tie plate (Fig. 30) is a combination design, borrowing the side flanges of the Servis plate and the corrugated top of the Wolhaupter. The advantages sought are the economy of metal characteristic of the latter pattern and the adhesion of the former. The Oliver tie plate (Fig. 30) has short longitudinal flanges on the under side, a flat rail seat without depressions, and a transverse rib or shoulder extending across the whole width of the plate, to serve as a rail brace and prevent the rail from "necking" the spikes. The thickness of the metal is $^5/_{16}$ in. The Diamond tie plate (Fig. 30) has a plain flat top without depressions, the intention of the designer being to avoid the collection of cinders and sand. The plate is rolled in widths of $4\frac{1}{4}$, 5 and 6 ins. and in thicknesses varying by $^1/_{16}$ in. from $^3/_{16}$ to $\frac{3}{8}$ in., the $^3/_{16}$ and $\frac{1}{4}$-in. plates being the ones in largest demand. The $4\frac{1}{4}$ and 5-in. plates for intermediate ties have four flanges, as shown, the outer flanges being $\frac{3}{4}$ in. deep and the inner ones $\frac{5}{8}$ in. in depth. As with the Glendon plate, both sides of the flanges have the same inclination from the under surface of the plate, the intention being to equalize the pressure of the wood fiber on both sides, thus avoiding any tendency to distortion of the flange as the plate is driven to its embedment. Plates 5 and 6 ins. wide, for joint ties, have only three flanges, such being commonly in use where the specified punching would interfere with the inner flanges of the four-flanged plates. The sides of the plate have small hood projections extending beyond the outer flanges. The upper surface of this projection is beveled down, to prevent bearing from the rail outside the flange, and the under side is fluted to prevent water from reaching the opened fibers.

The distinctive features of the Hart tie plate, another of the later designs, are a cambered top and a corrugated top surface. The top of the plate is crowned or cambered without cambering the plate as a whole, which is done by increasing the thickness of the plate at the center. The corrugations begin near the median line of the plate and extend obliquely across the top surface, growing gradually wider and deeper as they approach the outer edges of the plate. The purpose of this feature of design is: First, to prevent the accumulation of sand on any part of the plate's surface; second, to carry off water, brine, acid or other drippings from the cars; and third, to add strength without destroying the fiber or grain of the metal, or causing crystallization of the metal in the process of manufacture. The bearing of the rail comes at the central portion of the plate, bringing the bearing upon the center of the tie, with the idea of avoiding any tendency to loosen the plate in the tie, or rock the tie from the undulations in the rail. The under surface of the plate is provided with longitudinal flanges, similar to those of ordinary design. It is illustrated in Fig. 549, Supplementary Notes.

It may be of interest to state further that some of the railroads of France are using a tie plate made of tarred felt, costing 1.6 cents and lasting from six to ten years. These, however, are being superseded by tie plates made of creosoted poplar wood, cut from the gnarly portion of the tree. These plates are about the thickness of a shingle, cost about .8 cent each and are said to be more economical than either iron or felt tie plates. The claim for these tie plates of soft material is that they take all of the wear, whereas the iron tie plate, in time, wears both the rail and the tie. The fact that tie plates of such material are serviceable might seem to belittle the importance of rail pressure as one of the causes of the rails cutting the ties, but it must be considered that in France, and in Europe generally, the rails are heavier and the wheel loads much lighter, as a rule, than they are in this country.

The most common width for tie plates is 5 ins. and the most common length 8 ins., 5x8 ins. and 6x8 ins. being the sizes most frequently found. A length of 9 ins. is not uncommon, and greater lengths come to notice occasionally. The minimum width in extensive use is 4½ ins. For softwood ties the plates should afford generous bearing surface and 5x8-in. and 6x9-in. plates are none too large for rails of heavy section, the latter size being preferred except where the face of the tie is too narrow to afford a good seating for the plate. In any case the plate should be somewhat narrower than the face of the tie. For pole ties an assortment of plates of both the widths stated works well. The tendency of practice is to reduce the length of tie plates to such dimension that there will be only ½ to ¾ in. of metal outside the spike holes. The experience with long plates is that they buckle and do not stand the service as well as shorter ones.

Tie plates are usually punched for two or three spikes, but for use on sharp curves they are sometimes punched for four spikes. If the margin outside the spike hole is wider on one end of the plate than on the other the plate (there being, of course, no alternative with shouldered plates) should be laid to bring the wider margin outside the rail. This arrangement assists the plate to oppose the canting tendency of the rail. In some designs the plates are punched that way purposely. The spike holes should be punched to allow for a close fit of the spike to the rail flange. To provide for this the holes are usually made large enough for $^1/_{16}$ in. play. In order to bring the spikes at the right edges of the tie on both rails it is necessary to punch two-hole plates as rights and lefts. In some cases plates are punched with four holes, so that they can be used on either side of the track; or they are sometimes punched with three holes for the same purpose—two holes on one end of the plate and one hole on the other end, in the center of the plate. The latter arrangement is not a good one, for ties, especially pole ties, should not be spiked in the center of the face. For joint ties the plates must be punched with reference to the width over the splice bars (supported joints) or to correspond to the slotting of the bars for suspended joints or long splices extending over three ties. It is often desirable to punch plates with two sets of holes, so that when new rails of different base width are laid it will not be necessary to move the plates. When such is done the margin of metal outside the outer spike hole should be such that after the change the projection of the plate outside the rail will not be less than that on the gage side. Further instructions regarding the punching and handling of plates intended for rails of two different sections are to be found in connection with "Laying Tie Plates," § 106, Chap. VII.

12. Ballast.—Ballast is material placed upon the roadbed for the embedment of the ties, and the following are its functions: (1) to drain water from the ties; (2) to provide a firm and even bearing for the ties and to distribute the pressure from the ties over the roadbed; (3) to provide against heaving by frost; (4) to supply filling material between the ties, to hold them in place, and against their ends to hold them in line; and (5) to impede the growth of grass and weeds in and near the track. Some essential properties of good ballast are that it shall not change to a miry consistence when wet, and it should not disintegrate upon exposure to the elements. A desirable property of the filling material is that it may be readily worked in renewing ties and surfacing.

Broken Stone.—The material which most nearly fulfills all the requirements of ballast is broken or crushed stone, commonly called "stone" or "rock" ballast. Some of the advantages to be gained by its use are: It distributes the pressure better than any other kind of ballast, the pieces of stone acting much like bricks in a wall. The area of support widens with depth, and at a less depth than with any other ballast the pressure from the ties is distributed uniformly over the roadbed. Being the hardest material (considered in the aggregate) used for ballast, it secures the track best against settling. It does not hold water, and if the roadbed is properly drained it does not heave in freezing weather. Clean stone ballast can usually be handled and worked in winter, or in wet weather, and it is not wasted by rain or wind. It is the cleanest material used for ballast, and when carefully dressed presents the neatest appearance; for which reasons it is usually preferred to other kinds of ballast by railway companies which depend largely upon summer travel for business. As long as it is kept clear of dirt, such as sand, dust, loam, cinder etc., it will not grow grass or weeds. Where such growth does get started, however, it is a difficult matter to get rid of it, for practically it must be pulled by hand.

While broken stone answers so well the many requirements of a good ballast, nevertheless in some respects it compares unfavorably with some other kinds of ballast. Its first cost is high and the cost of putting it under the track or of handling it in any manner with the shovel is much higher than the cost of similar work in gravel. It is more severe on ties and rails than gravel, and unless the track is kept in smooth surface stone ballast is hard on rolling stock. While it affords good drainage the sharp corners of the stones cut into the ties, and after the ties begin to decay they deteriorate by impact more rapidly than they do in gravel ballast. The cost of tie renewals, surfacing, and all repairs where the ballast must be handled over is high, running from 50 to 100 per cent higher than the cost of the same work in gravel or like ballast. At a convention of the New England Roadmasters' Association, in 1897, it was voted as the sense of the convention that the average cost of renewing ties in gravel ballast was 15 cents each and in rock ballast 21 cents each. In a low lift of the track in surfacing, broken stone ballast is not so easily or as satisfactorily tamped as is gravel or other ballast of finer aggregation. Wherever the lift in stone ballast is not as high as the thickness of the stones the ties cannot be properly tamped without breaking up the old bed, whereas in ordinary gravel or cinder ballast the ties may be tamped under a lift as small as $\frac{1}{4}$ in. without disturbing the hard bottom of the previous embedment. On this consideration, it is widely claimed that smoother surface can be maintained with gravel and some other kinds of ballast than with broken stone. Where ballast is not tamped to a uniform solidity the tendency for the rails to cut into the ties is much increased over that which obtains under normal conditions, and such is an objection sometimes raised against broken stone ballast. Referring to general practice, it is probably true that on stone-ballasted track there is a natural inclination to let minor defects in surface run longer without attention than is the case on gravel-ballasted track. It is also claimed that in lining track in stone ballast some difficulty is experienced in holding the rail to the exact spot, especially when it is lightly thrown, the reason being that the stones crushed into the bottom and sides of the tie will roll and carry the track some distance back when the first train goes over it.

The stone ballast most commonly in use in this country is broken or crushed to a size which will pass a ring of 2 ins. inside diameter. There is, however, a wide diversity in the sizes known to practice. One class of maintenance men, who think that the size stated is too retentive of fine material, causing the ballast to become dirty and compact, prefer a size as large as $2\frac{1}{2}$ or 3 ins., and there are a few who use it as large as $3\frac{1}{2}$ ins. On the other hand there are many who think that 2-in. stone is too coarse for even tamping, smooth surfacing and easy working, and with them the $1\frac{1}{2}$-in. and 1-in. sizes are in favor; in fact a good deal of experimenting is being done with stone broken to a $\frac{3}{4}$-in. ring. A general principle which governs to some extent is that the harder and tougher the stone the smaller it may be broken, as such material is not so easily crushed and reduced in size by working. The most usual size with European roads is that broken to a $3\frac{1}{8}$-in. (8-centimeter) ring, but $1\frac{1}{2}$-in. and 2-in. stone is frequently used.

Rock ballast broken in a crusher contains more dust and small pieces than that broken under the hammer, and the proportion of fine material increases with decrease in the size to which the ballast is broken. It is customary, therefore, to pass crusher-broken stone over a screen and take out the dust and finer particles. In some cases the product from the crusher is run over a series of screens, one or more to take out the fine material and another to separate pieces larger than the specified size. Thus, at a certain railroad plant the stone from the crusher passes through three revolving screens formed of perforated steel plate, the first having holes ½ in. in diam., the second 1 in., and the third 3½ ins., in diam. The size of stone used for ballast is that which will pass through the 3½-in. holes but not through the 1-in. holes. As a matter of information it may be said that the supervisors who are using this ballast think it entirely too coarse, being of the opinion that ballast of this size would be improved by omitting the 1-in. screen, or by using everything which passes over the ½-in. screen and through the 3½-in. screen. The stone broken up at this crusher is flint and limestone, and it screens out in the following proportions: 70 per cent 1-in. to 3½-in. ("No. 4") ballast; 17 per cent ½-in. to 1-in. ("No. 2") ballast; and 13 per cent stone dust, dirt, etc. passed through the ½-in. screen. It is understood, of course, that in all broken stone ballast the specified size refers only to the largest pieces, a large portion of the material in all cases being smaller than that size. In some specifications it is required that the largest stones shall go through the ring "any way they are put," which means that the specified size refers to the largest dimension. Some are opposed to screening out the small clean particles of stone more closely than is necessary in removing the dust and sand-like residue, claiming that ballast may be too open, the tendency in which case is to gradually sink into the roadbed and become mixed with earth.

To meet an important and stated requirement of ballast broken stone should not disintegrate under atmospheric influences or crumble in working. The most suitable rocks for the purpose are trap, granite and limestone. Sandstone is used occasionally, but the ordinary class of material does not make good ballast, as it crushes under the tamping pick and grinds out under the traffic, the tendency being to wear round. The other varieties of rock named break off angularly. Sandstone containing over 95 per cent of silica is said to give satisfactory results. The Norfolk & Western Ry. has in use a quality of sandstone that is very hard and makes first-class ballast. The Seaboard Air Line Ry. is using a quartz ballast, in crystallized form, obtained near Statham, Ga. Among the limestones the hard bastard varieties are preferred to that which will burn into lime, as the latter goes too largely into screenings at the crusher and breaks up considerably in tamping. Magnesian limestone is recommended.

In former years stone ballast was largely hand broken, with napping hammers, sometimes at the quarry but more frequently in or at the side of the track, the unbroken stone being unloaded from the cars in sufficient quantity to supply the required amount of ballast. During recent years such practice has largely been superseded by the use of machine-crushed stone produced in a plant at the quarry and hauled out along the road in ballast cars, like gravel. There is one scheme, however, sometimes employed in ballasting new track, whereby a portable machine with power to operate it and move it slowly forward, crushes the ballast and drops it upon the track. The unbroken rock is first distributed along the track, and then picked up and thrown into the crusher as it moves along.

Crushing Machinery.—Rock Crushers are made in many patterns, but in general there are only two types—jaw crushers and gyratory crushers . In the jaw crusher the rock is broken by being squeezed or pinched between a strong casting and a heavy lever or jaw hinged at the upper end and reciprocated at the lower end by means of a connection with an eccentric on the shaft of a fly wheel. The gyratory crusher consists of a stationary heavy cast shell or casing, with a conical aperture, within which revolves a heavy vertical crushing spindle reversely coned. At its top end this spindle turns in a fixed bearing, but at its bottom end it is journaled into an eccentric, so that, aside from its revolution about its own axis, it is given a gyratory motion, causing it to advance and recede, or wabble, within the stationary casing. To give the machine a biting action on the rock the surface of either the revolving cone or the interior of the casing is fluted or corrugated. The rock is dumped in at the top and is gradually broken up as it settles down between the casing and the wabbling, whirling cone, until it finally passes out at the bottom into a chute. A ballast crushing plant consists of an installation of one or more crushers, with screens for assorting the sizes and means of conveyance for loading the material into the cars. If the crusher can be located some distance above, and near, the track, as at a quarry opened up in the face of a hill, the discharge of ballast into the cars can take place by gravity; otherwise the material usually passes from the crusher into a belt conveyor which elevates it into the screens, whence it slides into the cars through chutes. One arrangement for screening is to have the material slide over a perforated incline, but preferably through a series of revolving screens, or through a single revolving screen with successive sections having perforations of varying size. The cars which receive the various sizes of stone and screenings stand upon parallel tracks under the discharge chutes. The loading tracks should preferably be laid to a grade, so that the cars may be spotted by gravity.

The arrangement of one of the typical rock crushing plants of the Pennsylvania R. R. includes a gyratory crusher having a capacity of 40 to 50 cu. yds. of broken granite rock per hour, with an auxiliary crusher of smaller capacity. The rock is dumped into the large crusher, the discharge from which passes to a belt conveyor and is elevated into a revolving cylindrical steel plate screen 12 ft. long and 4½ ft. in diam. The screen is set at an incline and is divided into three sections, the first and uppermost being closely perforated with 1-in. holes, the second with 2-in. holes and the third with 3-in. holes. Outside the first section there is a concentric wire screen dust jacket of ½-in. mesh, which permits the dust and stones smaller than ½ in. to drop through into a subjacent bin, but carries the ballast from ½ in. to 1 in. in size and drops it into another bin. The second section of the screen drops stones from 1 in. to 2 ins. in size into a third bin; and the third section drops stones from 2 to 3 ins. in size into a fourth bin. The rejected material passes into an extension of the screen at its lower end perforated with slots 6 ins. wide and 12 ins. long, through which it drops into a chute running to the auxiliary crusher, where it is reduced to proper size and again spouted to the conveyor and discharged into the revolving screen. The products which drop into the four bins are of the following proportions: 17 per cent of screenings, from dust to stones of ½ in. size; 8 per cent of stones in sizes from ½ in. to 1 in., commercially known as ¾-in. ballast; 33 per cent of stones in sizes from 1 in. to 2 ins., commercially known as 1½-in. ballast; 42 per cent of stones in sizes of 2 to 3 ins., commercially known as 2½-in. ballast. The four bins discharge through chutes into cars standing upon three parallel tracks, the cars to be loaded with screenings and ¾-in. ballast, respectively, being spotted upon the same track at different times. The grade of the loading tracks is 1 per cent. This plant is operated by an engine of 150 h. p. and the cost of the entire installation was $16,000. The labor required to operate the plant includes one engineer, one fireman, one oiler and four laborers, the wages of all seven men amounting to $1.19½ per hour. The renewal of the principal wearing parts of both crushers costs about $500 for each 400 working hours.

The means for conveying stone from the quarry to the crusher may consist of dump cars, run by gravity or by cable or pulled by horses, or it may consist of an aerial cableway or other power driven conveying machinery. At the plant of the Stewart Contracting Co., Columbia, S. C., ballast contractors for the Southern Ry., the quarry is in a deep pit

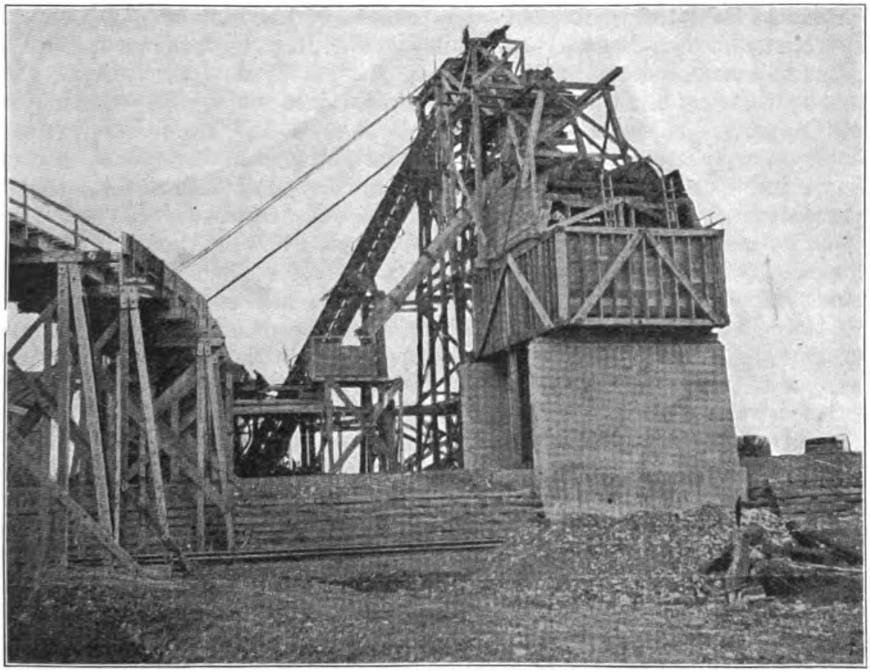

Fig. 30 A.—Ballast Crushing Plant, North Leroy, N. Y., Lehigh Valley R. R.

excavated below the level of the crusher. Rock is fed to the crushing plant in small cars hauled up an incline, and also by means of an "apron" suspended from a trolley running upon a cableway between two towers. At the tower on the opposite end of the cable from the crushing plant there is a hoisting engine which raises the apron out of the quarry after it has been loaded with rock, and then pulls the trolley over the suspended cable to the crusher plant. In 1901 this material (hard granite), broken to 2½ ins., was costing the Southern Ry. 60 cents per cu. yd., on board the cars. At North LeRoy, N. Y., the Duerr Contracting Co. operates a stone crushing plant to supply the Lehigh Valley R. R. with ballast. The stone is quarried and brought to the crushers in tram cars on two tracks, one on each side of the crushing machinery, so that the material may be fed from both sides. As this is one of the largest plants of its kind the general arrangement is interesting. There are three crushing machines with openings 2x6 ft. in each. As the material is dumped from the cars (on the trestle shown at the left in Fig. 30 A) it falls into large hopper bins from which it is fed to the crushers. From the crushers the broken product is delivered to an incline elevator, shown in the center of the view, which conveys it to a hight of 83 ft. and delivers it to a heavy revolving screen. The product from this first screen is delivered to two other screens below, the tailings being returned by a belt conveyor to one of the crushers for recrushing. The product passing from the second screens is delivered into three large bins holding several car-loads. Under the bins are two switching tracks, so that two trains of cars can be loaded at the same time. The elevator and revolving screens are driven by a rope drive. The elevator is of the Common Sense type, with buckets 4 ft. long by 2 ft. wide. The plant is operated by a Corliss engine of 250 h. p., and the capacity is 440 tons of crushed stone per hour.

Some railways operate crushing plants of their own, but it is quite customary to purchase broken stone ballast of contractors, delivered on the cars. An inspector is sometimes detailed for duty at the crushing plant to see that decomposed rock from the top of the quarry is not put in and that the dirt and dust are properly taken out by the screens. In wet weather the screening must usually be watched more closely than during dry weather. In hauling broken stone to a distance it shakes down and there is a considerable shrinkage in volume, amounting to 10 per cent in some cases for a haul of 100 miles. Owing to this fact it is largely the custom to purchase such ballast by weight, the price per ton being determined in relation to the weight of a cubic yard of crushed stone measured in a box freshly filled. In a report to the International Railway Congress, in 1900, Mr. A. Feldpauche, principal assistant engineer of the Philadelphia, Wilmington & Baltimore R. R., put the average weight of a cubic yard of 2½-in. crushed granite at 2450 lbs., and of crushed trap rock of the same size, 2624 lbs.

The cost of broken stone ballast delivered on the track varies widely, according to the expense for quarrying, crushing, hauling and unloading. The cost of putting the ballast under the track and dressing it up also varies considerably, according to the lift of the track, the size of the stone, the price for labor, amount of room available for unloading ballast on the shoulder, etc. For machine crushed stone ballast 45 to 75 cents per cubic yard on board cars, 60 cents to $1.00 per cubic yard delivered on cars, 75 cents per cubic yard unloaded beside the track, 15 to 25 cents per cubic yard for labor of placing under the track and tamping, and 75 cents to $1.25 per cubic yard, in place, in track completely ballasted, lined and dressed, are figures which have been quoted, but not by the same road in every case. During the year 1899 one of the trunk-line railways operating in Ohio purchased from a contractor in that state large but limited quantities of 2-in. crushed limestone ballast for 28 cents per cubic yard, o. b. c., and in 1900 the contract price between the same parties was 33 cents. These extremely low prices were due to the fact that the contractor was stripping quarries to be worked mainly for building stone, and the material disposed of for ballast would otherwise have been wasted. For crushed stone ballast in place, in track completely surfaced, lined and dressed, 85 cents to $1.00 per cubic yard seems to be the average total cost on a number of roads, for a haul not exceeding 200 miles. In 1902 one of the large railway systems running west and northwest from Chicago paid 45 cents per cu. yd. for broken stone ballast, o. b. c. The average cost of putting this ballast under the track, tamping, lining, filling in and dressing off (the track was generally raised 9 ins. and in dressing off but little ballast was placed at the ends of the ties) was 37 cents per cu. yd., train service 10 cents per cu. yd. additional.

The screenings from crushed rock ballast are used in yard and side- tracks and as paving for station platforms, highway crossings and sidewalks.

For stone ballast broken by hand, 10 to 45 cents per cubic yard (no cost for quarrying in the former case) for the unbroken rock placed on the car; 25 to 35 cents per cubic yard for breaking with hammers; 22 to 40 cents per cubic yard for putting it into the track, surfacing, lining and dressing, are figures obtained from official records; also 57½ cents per cubic yard for rock distributed along the road and broken to 2½ ins. in the track, by hand, not figuring the cost of quarrying or hauling; 67 cents per cubic yard for stone unloaded and broken upon the shoulder to a 3-in. ring, counting all costs except hauling, and 30 cents per cubic yard additional for putting it under the track; $1.15 to $1.20 per cubic yard for stone broken on the shoulder and then put into the track, not counting the cost of hauling. On roads where there are rock cuts, the rock being of suitable quality for ballast, it is usually advantageous to quarry the ballast stone in such places; especially if it is broken by hand, as the section men can be employed at such work at odd spells during the winter, and the ballast is convenient for loading. The widening of the cuts is also another consideration of importance, particularly where a second track is in contemplation.

Where broken stone ballast is used to good depth it is sometimes the practice to put in a bottom layer of coarsely broken rock—about the size of cocoanuts, say—for a depth of 6 ins. or so. For soft or wet ground, at least, the use of such stones is not advisable, for the mud will ooze up through the open spaces between the large stones and cause the track to heave in winter. In fact broken stone ballast of ordinary size, placed over soft spots in the roadbed, will settle and gradually become filled with loam or mud which rises through the voids. It is therefore the practice, to some extent, to underlay the ballast in such places with a stratum of cinders or fine gravel or with flat stones, if they can be procured.

Slag.—In regions convenient to blast furnaces slag is cheaply procurable and is much used for ballast. In many or most instances the furnace people are pleased to be able to dispose of it gratis, in order to get it out of the way. Those who have studied the character of the material closely prefer the hard, glassy or vitrified slag that is clear from, or contains but little, free lime; and to secure a uniform product it is coming to be the practice to arrange with the furnace authorities to have the hot material so poured that it will spread out into thin layers. In this way it is rendered hard and brittle and easily broken, whereas if it cools in thick layers the top portion will be vitreous, but the interior and under portions will be porous and difficult to break up. Sometimes this spongy material becomes pulverized in time by the traffic and the repeated action of the track tools, and in cases the dust will cement together again and form a hard layer under the ties that is extremely difficult to work. The properties of slag ballast of good quality are very similar to, or practically the same as, those of broken stone. It is handled in the same manner as broken stone, and in general is perhaps somewhat the cheaper material of the two. It is sometimes broken into large lumps, and thus rendered more easily broken into finer sizes, by throwing cold water upon it while it is cooling from the molten state. It softens, however, when broken in this manner and is not so good, so it is claimed, as when broken in a crusher or by the hammer. At the furnaces it is sometimes broken up by blasting and loaded by steam shovel. Some think that the life of the ties is somewhat shortened by the chemical action of the slag.

One of the roads of the country which makes extensive use of slag ballast is the Southern Ry. The minimum depth under the ties is about 8 ins., except on some of the lines where traffic is light, where 6 ins. is found to be sufficient. In wet cuts it is found to be advantageous to place a layer of cinders on the roadbed before the slag is distributed. The ballast is unloaded from double hopper-bottom cars, the bottom doors being opened just wide enough to allow the slag to come out in quantities required. The cars are hauled slowly over the track, and at the end of the train there is a plow which levels the material off even with top of rail. On this road an average day's work in surfacing track with slag ballast, placing it in good surface and line and dressing off, is 17 ft. per man. The slag is loaded with steam shovels at a cost of 5 to 5½ cents per cubic yard. The material weighs 2700 lbs. per cubic yard and about 24 cu. yds. are loaded upon each car. In order to handle the material with steam shovel, it is necessary to blast it. The material is found to be cheaper than broken stone but is not considered quite so good, although it can be worked somewhat more rapidly. It pulverizes under the tamping pick to some extent, and on account of the acid contained in the material the life of the ties is not as long as in broken-stone ballast.

Gravel.—Gravel is found in large deposits widely distributed and is the universal ballast material. All things considered, gravel of good quality is probably the most efficient material for ballast. As compared with broken stone it is inferior in but few respects, while in some ways it is superior. Its area of support is not so diverging as that of broken stone; still it is firm, and when used in sufficient depth it holds track to surface satisfactorily. Where it can be obtained in desirable quantities the ease with which it can be handled in loading and in working makes it the cheapest of all materials for ballast which are of unlimited supply. It seems to be the opinion of the largest number of track maintenance officials, including those having experience with broken stone, that track in good gravel ballast can be put into first-class condition and be maintained in that condition at less cost than in any other ballast. It offers good drainage for water and, if of fair quality, is not heaved by frost. As a mass it is more elastic than broken stone, is easier on ties and rolling stock and is not so noisy under train operation. It is easily handled in tie renewals, frequently without the use of the pick, and is easily worked in tamping. Weeds and grass do not grow readily in clean gravel (free from loam), and such vegetation as does get started when the gravel becomes dirty is more easily subdued than is the case with such growth in broken stone and some other kinds of ballast.

Fine gravel, or that which will all drop through a sieve of 1½-in. mesh, is considered the best, although a few prefer a coarser size. Gravel much coarser than this may give good satisfaction providing a sufficient quantity of sand or finer gravel is mixed with it to fill the voids or interstices. The proportion of sand and small pebbles contained in the gravel determines very largely its worth for ballast. Thirty to 45 per cent of sand (preferably coarse, sharp sand) is considered about the right proportion. Gravel containing more than 50 per cent of sand is considered dusty and inferior in holding qualities as the proportion of sand grows larger. Material containing as much as 75 or 80 per cent of sand would probably be classed as sand, for ballast purposes. The qualities of gravel ballast in relation to the proportion of sand might be expected to depend a great deal upon the character of the sand. Gravel containing a given percentage of coarse sand might be better material to hold track than another grade containing a smaller percentage of fine sand. The distinction between coarse sand and fine gravel, in this connection, might be drawn at such material as is used for sand in ordinary building purposes, like masonry work.

A considerable quantity of soil or loam mixed with gravel helps the growth of weeds and grass and makes the ballast soft when it gets wet. For this reason the soil which overlies a gravel bank should be stripped off in advance of the loading of the cars, for although the amount of soil mixed with the gravel may be comparatively small, yet it takes but a little earthy material to fertilize the gravel sufficiently to enable vegetation to take root. The stripping of gravel pits is usually done with teams and scrapers. In case it is desired to replace the soil after the pit has been worked out the soil is usually scraped into long heaps at a distance apart which corresponds to the width of a cut with the steam shovel. Each time the shovel makes a cut through the bank the soil lying along the brink is thrown down and spread over the bottom of the pit.

Screened gravel ballast is being tried on American railways to some extent. On the Pennsylvania Lines West, where such material is being used in an experimental way the screening is done in a machine consisting essentially of an elevator and a revolving screen, which deposits the sand and clean ballast in separate cars. The cost is intermediate between that of broken stone and gravel. The length of time during which screened gravel has been on trial has been too short to ascertain its value decisively, but experience on the Grand Trunk Ry. with beach gravel washed almost free from sand is officially reported to have been disappointing. The track is free from dust and vegetation, but the ballast does not seem to bond well, and it does not hold the track in line and surface as well as does ordinary gravel. "Washed" gravel is a term applied to material washed by both natural and artificial means. The former is usually obtained from creek or river beds and is used in limited quantities on a number of railways in this country, one of which is the Kansas City, Pittsburg & Gulf R. R. (Kansas City Southern system). Several of the railways of France wash gravel ballast artificially, to remove loam or clay, and sometimes to remove part or all of the sand where no earthy material or clay is contained. A typical washing machine consists essentially of a steel cylinder or barrel about 20 ft. long and 3 ft. in diam., perforated with holes $\frac{3}{8}$ to $\frac{5}{8}$ in. diam., to permit the egress of water, mud and other fine particles. The cylinder is inclined to the horizontal and within it there is a revolving shaft armed with steel blades helically arranged. The supply of water enters through passageways attached to the revolving shaft. The material to be washed enters the cylinder at the lower end and is driven by the blades toward the upper end, where the clean stones fall into a chute which conveys them to the ballast cars. The muddy water and small debris drop into troughs underneath the washing cylinder and are conveyed away. The operation is quite similar to that of some of the iron ore washing plants in central Pennsylvania. In differently constructed plants the material to be washed is run over a riddle or through a revolving screen with a copious intermixture of water. If it is desired to retain a portion of the sand or small gravel a screen is used which has a smaller number of openings, so that it cannot pass the finer material freely.

One of the most undesirable properties, peculiar to gravel in some locations, is a cementing action due to the infiltration of calcareous material or iron oxides. Such material is known among railroad men as "cementing" gravel, and is usually avoided, even at the expense of hauling freely mixed material a long distance. Cementing gravel is as difficult to work as is broken stone ballast, and sometimes even more so, the work of removing it from the track reminding one very much of picking frost. Gravels containing a large proportion of flat or angular-edged stones, formed principally by disintegration, are the worst to contend with, for in such material the vibration set up by the traffic and the settling action of rains causes the mass to become compacted by the overlapping and dovetailing of the parts, independently of any chemical action due to infiltration. Similar results are also promoted by the presence of angular sands. A remedy which has been suggested for such material, in cases where it forms the chief available ballast, is to prevent the mechanical process by mixing with it water-worn or loose material in the proportion of $\frac{1}{4}$ to $\frac{1}{3}$ of the entire mass. By unloading both kinds of ballast at the sides of the track the mixing can be done roughly as the material is shoveled into the track, without extra expense for handling. A desirable way of utilizing cementing gravel, where some proportion of better gravel can be obtained, would be to raise the track and tamp it to surface with the inferior material and then level the ballast down even with the bottoms of the ties and fill in the track and dress it off with the material of the better class.

The cost of gravel ballast in place in completed track varies between wide limits, owing to the diversity of conditions attending the loading, hauling and unloading of the material and the hight to which the track is raised when ballasted. Limits of cost commonly met with are 15 to 40 cents per cubic yard, with figures between 20 and 30 cents per cubic yard occurring most frequently. In one instance the official records of a season's work show that fine gravel ballast was placed in the track at a total cost of 23 cents per cubic yard, including the loading (by hand), the hauling out and placing under the track, which was raised an average of 6 ins.; tamping was done with shovels. In these costs 10 to 15 cents per cubic yard is the usual proportion of expense due to handling the gravel after it is delivered on or at the side of the track, which includes the labor of placing it under the track, shovel tamping, filling in and dressing off.

Combination Ballast.—As broken stone ballast is conceded all the desirable properties respecting stability and drainage, and as gravel is usually cheaper in first cost and in cost of working, it is considered good practice to combine the two, using broken or crushed stone for a foundation, with gravel above it for tamping immediately under the ties and for the filling material. One method that can be followed when ballasting new track is to lift the track about 6 ins., ballast it with broken stone and then wait for the roadbed to settle. The track may then be raised $1\frac{1}{2}$ or 2 ins. and ballasted and filled in with gravel. Where this method is contemplated, at the first ballasting the track need not be filled in full or dressed off; in case it should be, however, the ridges between the ties should be leveled down at the second ballasting. A perhaps better method for new roads is to ballast the track with broken stone and immediately level the material even with the bottoms of the ties and fill in with gravel. As the track settles out of surface owing to roadbed shrinkage it will be raised and tamped with the gravel, and in time will have the desired depth of gravel for support. Sometimes, to economize in cost, the reverse process is carried out; that is, gravel or cinders is used at first, and after the roadbed settles and becomes compacted the track is raised about 6 ins. and rock ballasted. The former method seems the better, since, for ease of working, it is desirable to have loose material for filling.

The plan of using broken stone or equivalent ballast for bearing and some easier working material, like gravel or locomotive cinders, for filling between the ties has been practiced to a considerable extent. The use of broken stone above the bottoms of the ties in preference to gravel is of no advantage except as it prevents dust from rising. The Chicago, Rock Island & Pacific Ry. has used cinder filling on broken stone ballast quite a good deal, particularly where the stone has been of an inferior quality, and good results have been obtained. At one time the Lehigh Valley R. R. ballasted main second track at various places and the "Mountain Cut-off Line," near Wilkes Barre, Pa., with a foundation of broken slag topped out with anthracite engine cinders in a light layer under the ties and for filling between them. Experience showed that the cost of track work was much reduced (compared with work in stone ballast) and the results were generally good. On the Chicago, Milwaukee & St. Paul Ry. the use of sandy gravel on top of coarsely broken rock ballast did not give satisfaction. The broken-stone ballast had been in service for some years and had settled to a firm bed, when the track was raised about 2 ins., the stone filling between the ties was leveled out on the shoulder, and the track was then carefully surfaced with gravel and filled in with the same material. After a little time the section men began to complain that the track was not holding well to surface, and after five years of this experience it was concluded that the combination had not worked satisfactorily. The gravel contained more than the usual proportion of sand for ballast of first quality, but still it was what might be considered fairly good material for ballast. The broken stone was slightly above medium size. The principal difficulty arose from the working of the stone up through the gravel, somewhat as clay is liable to do in a wet cut. It seems that through the jarring of the traffic the sandy part of the gravel settled down through the stone, and that nowhere between the surface of the filling material and the original roadbed could a line be drawn between the gravel and the stone. The two kinds of material had become quite generally mixed together. On the Kansas City line of this road burnt clay ballast has been used on worn-out stone ballast with splendid results.

Cinders.—Cinders makes splendid ballast, and is too frequently consigned to side-tracks or used for filling up hollows and old excavations near the roundhouse when ballast of inferior material is used in main track. Cinders should always be saved for ballast. Under the subject of "Ash Pits" (§ 178, Chap. XI.) several arrangements are considered for cheaply handling and loading into cars the cinders dumped at roundhouses. Even when loaded by hand cinders is very cheap material for ballast, for it is easily handled in scoop shovels. By good rights the cost of loading cinders and laying it down at the side of the track should not be chargeable to the ballast account at all, for it is a waste product, and the ash dumps at the terminals must be loaded into cars and hauled off at more or less frequent intervals, in any case, in order to get them out of the way. On such considerations cinders is a very economical ballast, so far as it goes, furnishing, in fact, the cheapest material available for ballast renewals; and in a convenient manner, for the loaded cars may be shipped daily by local freight trains to points where ballast is needed or else allowed to accumulate for a few days at a time to be handled in the work train. The dumpings from locomotives contain very little ash proper, since the ash, for the most part, goes out through the smoke stack with the exhaust, leaving behind cinders, clinkers or slag, burned rock, slate etc. Cinder soon slakes, like lime, and makes a uniformly compact mass well adapted for ballast. The remarkable feature about coal cinder is its capacity for absorbing water. A heavy rain can be taken up and held within two inches of the top surface of a pile of cinders. In track ballasted with cinders comparatively little water reaches as far as the bottom of the tie, but is held near the surface until evaporated; and evaporation takes place quickly when the material is exposed to the sun. Except when the rains are prolonged this ballast keeps the roadbed in better condition than does either rock or gravel ballast. It is fine material to handle and is proof against weeds; it keeps track in even surface and does not heave in winter more than a slight bulging on the top surface. Like broken stone its area of support diverges rapidly with depth, and for use on wet or soft roadbeds it is the best material that can be obtained.

The principal objections against cinder ballast for main track are the dust, in dry weather, and the fact that it wears away more rapidly than gravel or broken rock. It is also generally conceded that the life of ties is slightly shorter in cinder than in stone or gravel ballast. This fact is usually attributed to the action of the sulphur in the cinders, which is supposed to be most pronounced during the occurrence of light rains. Locomotive engineers complain that at such times a lubricant is formed on the rails where the track is cinder ballasted, which greatly impairs the adhesion of the drivers, but whether such lubricant is due to moistened cinder dust on the rail or to the chemical effect on the brightened rail top of gases set free by the action of the water on the cinders, has not been well established. At any rate cinders is not considered good ballast material for heavy grades. Notwithstanding these drawbacks, however, the value of cinders for ballast is not to be lightly considered.

Sand Ballast.—Sand is inferior to either gravel or cinders, for ballast, but is much used, for the simple reason that it is widely distributed, and over extended districts it is the best material available. As a matter of fact gravel easily grades off into sand, and much of so-called gravel ballast is sand with stones or pebbles few and far between, so that it is practically sand ballast. It is retentive of water to some extent and, while it does not usually become plastic when wet, it is heaved by freezing. It cannot be worked when very wet, and it cannot be worked to best advantage when very dry. It is easily handled, and while weeds will grow in sand of ordinary quality they can usually be kept down without difficulty. Where the drainage is good and rains are infrequent it holds track to surface quite well. In southern California, Arizona and parts of Mexico, where the climate is generally dry, adobe sand is much used for ballast, and with fair satisfaction.

Sand ballast is of fugitive character, being, like old cinder ballast, considerably wasted in dry weather by winds and by breezes stirred up by fast trains. In dry weather the dust from fast trains running over sand ballast is a "fright." It is injurious to rolling stock, causes trouble from hot boxes and makes uncomfortable traveling, which passengers will avoid, if they can do so, by taking another route the next trip. In France, Russia and India it is quite commonly the practice, where fine sand ballast is used, to cover the roadbed and track filling with a layer of broken stone or gravel, to keep down the dust and prevent the sand from blowing away. The same plan is followed on the Mexican Southern Ry. When repairs require the removal of the ballast the broken stone is first raked off into a pile and kept separate from the sand. In France small brick tiles, manufactured for the purpose, are sometimes used in lieu of broken stone for covering up sand ballast.

As a measure for keeping down the dust on some of the sand-ballasted railways of the South, Bermuda grass is permitted to grow over the track. This grass does not generally grow higher than the rails and consequently does not interfere with locomotive traction. It grows in the form of a mat and springs up rapidly after the sod has been disturbed in the renewal of ties. Sand which is entirely free from loam will not support this grass. The Louisville & Nashville R. R. has had satisfactory experience with it, for the purpose here stated, on some of its sandy divisions, but on the Pensacola & Atlantic division the effort to cultivate the grass was not successful, owing to the infertility of the sand. It is used in the southern states all the way from the Atlantic coast to points in Texas, and is found very effectual in preventing soft banks from washing. As elsewhere stated, it is set out in squares on embankments, and eventually covers the whole ground surface. It is a jointed grass, the joints being a few inches apart, and as it creeps along it puts down new roots at each joint. Under favorable conditions the roots penetrate the earth 3 to 5 ft. and form a compact mass. It is then next to impossible to eradicate it. A blade of the grass dropped on the ground will take root and grow. When it gets into the track it is a waste of time to try to cut it out. In Florida, where it grows larger than in the states farther north, it stands 4 to 6 ins. high, but ordinarily the blades are only about 3 ins. long, and it does not interfere materially with track work. Except during long periods of drouth it is green the year round. On the east coast of Florida it is called "St. Lucie" grass, although the botanists claim there is a slight distinction.

Dirt.—If there is anything that will depress the spirits of an old trackman who has been accustomed to rock or gravel ballast it is a change to track ballasted with dirt, often called "mud" ballast (and very appropriately, too, during certain seasons of the year). Still, where it must be done, track can be kept up in dirt ballast, for a very large mileage of track in this country is dirt ballasted. Dirt or mud ballast is the common earth, of almost any kind at hand, usually thrown up from within reach of the track. It can often be improved by casting aside the top layer of the ground, or the soil which would grow weeds most readily, and using only the subsoil. Earth varies so much that it is difficult to classify the varieties of dirt ballast, but it gets better the more sand it contains. Argillaceous earth bakes hard in dry, hot weather and at such times it is difficult to work. Generally speaking, it may be said that it is the very opposite of broken stone or gravel, so far as answering the requirements of a good ballast, for it answers none well. It settles easily under load and, if drainage be defective, becomes literally a mud puddle in wet weather. It heaves badly during freezing weather and usually grows grass and weeds as abundantly as a garden, in summer. It goes without saying that it should not be used in any place where it is feasible to get better ballast. On some roads carrying light traffic there may be circumstances which make its use expedient, if not economical. It is always cheaply procured and is easily handled, which compensate in some degree for the labor expense of keeping it up. Good drainage makes dirt ballast a possibility, and good judgment and experience teach methods of work which render its use practicable. Happy ought to be the foremen who have never had occasion to know anything about it!

Burnt Clay.—In the Mississippi Valley a "patent" (but not patented) ballast is manufactured extensively by depositing gumbo or clay and coal slack in layers and burning the two together. The product is a dry material bearing a close resemblance to broken brick. It makes good ballast, can be handled and worked as easily as gravel, and costs less than broken stone. It has a marked affinity for water, surpassing any other ballast in this respect, absorbing ordinary rainfall and keeping the roadbed dry. When well burned it does not return to the original condition of the clay. It does not grow weeds readily, being similar to cinders in this respect. The manner of its preparation is something like the following: A side-track is laid over the ground where the material is found and, parallel to this track at a convenient distance for loading, old ties or cord wood are placed in a long pile about 4 ft. wide and 3 ft. high. Coal slack is sprinkled through the wood and the pile is covered over with a layer of clay about 12 ins. deep. To give draft while burning the first layer of fuel and clay, or while the kiln is being heated up, an open space is sometimes formed underneath the fuel, in the bed of the kiln, by throwing up two ridges of earth with material excavated from a shallow trench between them, and the wood is piled crosswise these ridges. After setting fire to the ends and at intervals the heap is closed and alternate layers of coal slack, 6 to 8 ins. thick, and clay, 12 ins. thick, are added as the heap burns down. The heap keeps sinking and burning away and, when finally burned, the pile may be something like 10 ft. in hight and 20 ft. wide.

It is said that the best quality of ballast is produced from tough "gumbo" or "black wax" clay, which is fatter material than would be used in burning brick. The presence of sand, which is desirable in brick clay, is detrimental to the material for the purposes of ballast. The clay should be burned hard, even to vitrification, as it is easily broken up. In dry weather one ton of slack will burn from 4 to 5 cu. yds. of ballast. The cost ranges from 25 cents per cubic yard upward, for the finished product in the pile, depending upon the price of labor and fuel, the depth at which the layer of suitable material is found, cost of laying side-track to the pit, the amount of stripping in order to get at the raw material, the draining of the pits, etc. The burning of clay ballast is frequently undertaken on a large scale, the kiln being ½ to 1 mile in length. On work of this magnitude the clay is usually excavated and placed upon the kiln by some machine of the steam shovel or belt conveyor type, running on a track on the opposite side of the kiln from the loading track. The ballast material is excavated from a trench between this track and the kiln, the trench being sometimes dug to the depth of 8 ft. It is desirable that the material to be burned should be excavated in lumps and placed upon the fire without being much broken up. The burned clay may be loaded by steam shovel or by hand, throwing the track in to the heap as it becomes shoveled away. It is customary to let the forming and burning of the kiln out to experienced contractors, who furnish the machinery and the labor, while the railway company supplies the land, the tracks and the fuel, the last named purposely to insure that a sufficient quantity will be used to properly burn the clay. Contract prices for handling the clay and burning the kiln have been made as low as 19 cents (and perhaps lower) per cubic yard of ballast, the railway company supplying the fuel. The usual prices in the vicinity of the Missouri river range from 20 to 25 cents per cu. yd. Coal slack or refuse, for burning, is sometimes bought as low as 25 cents per ton, at the mine. Almost any quality of coal may be used, but the quality of the ballast is said to improve with the quality of the coal used in burning it. In some cases a small percentage of nut coal, with a considerable quantity of mixed coal, has been mixed with the slack. In wet weather a little run-of-mine coal is sometimes used to bring the fire up. In the experience of the Chicago, Milwaukee & St. Paul Ry. the use of an excess quantity of coal in the burning of clay ballast is detrimental to the properties of the material. The large proportion of ash resulting from too much fuel causes the ballast to soften when it becomes wet.

When first put into the track this ballast is very dusty, owing to the ashes intermixed, but after a good rain it becomes clean and remains in that condition. The material is light, weighing only 1500 to 1700 lbs. per cu. yd., according to the character of the raw material and the thoroughness in burning. In some records it is found as heavy as 1800 lbs. per cu. yd., and as a rule the poorly burned ballast is heavier than that which is well burned. It is said that burned clay ballast of good quality does not wear out faster than gravel or stone, although in time it becomes somewhat finely broken up and settles down. So long as this ballast does not become mixed with foreign material it will not grow weeds, but dust blown upon it from plowed fields will in time so contaminate it that it will support vegetation. On the Chicago, Burlington & Quincy, the Atchison, Topeka & Santa Fe, the Chicago, Milwaukee & St. Paul, the Wabash and other western roads it is in extensive service. The first that was used in this country was burned in Iowa, in 1880, for the Chicago, Burlington & Quincy Ry.

Mr. W. Shea, roadmaster on the Kansas City line of the Chicago, Milwaukee & St. Paul Ry., speaking from an experience of 12 years with both burnt clay and broken stone ballast, has made the following comparison: "For ordinary traffic I prefer burnt clay ballast to rock ballast, as I consider that track can be maintained in better condition for less money with the clay ballast than with the rock, and the life of the burnt clay ballast seems to be about as long as the rock. Weeds can be cleaned out of the burnt clay ballast for one-quarter the cost that they can out of rock. Ties can be renewed in burnt clay ballast for forty per cent less than in rock ballast. The life of a tie in burned clay ballast is ten per cent longer than in rock. I account for this on the ground that the clay is porous and dries out quicker, so that it draws the dampness out of the tie, not waiting for the common elements to dry the tie out after being wet. We dress and shoulder our track in burnt clay ballast the same as in good gravel ballast."

Miscellaneous Ballast.—The foregoing kinds of ballast are in common use, and, except in the case of burnt clay (which, however, is in use over a large extent of territory), each is found in many and widely separated parts of the country. Nevertheless the expense of transportation is so large a factor in the procurement of suitable ballast at economical cost, that local conditions of supply assume importance as the source of supply of a desirable ballast becomes farther removed. The result is a considerable list of miscellaneous ballast materials, both natural and artificial, used in practice, each being identified more or less distinctively with some particular locality. Mention will be made of the best known of these materials. In eastern Pennsylvania anthracite coal dust or culm from the breakers is used to some extent on several roads in the vicinity of the mining regions. It is a mobile substance, and for the best results must be confined at the sides of the roadbed. It is particularly serviceable on wet roadbed, as it is not softened by water and does not heave by freezing. So long as it remains unmixed with foreign material it does not harden or become compact and make a firm support, but it settles evenly when of uniform depth.

It is very easily worked—in fact, too easily, being too untenacious for bar tamping. It does not grow vegetation.

Decomposed rock is used for ballast on several roads in the West and South. On the Southern Pacific and Union Pacific roads the material of this description is decomposed granite, which makes pretty good ballast; in fact, that used on the Union Pacific R. R. is first class. This material is from Sherman hill, the summit of the road. It is a disintegrated mica granite and the aggregation of the material is similar to that of a fine quality of gravel. It is gritty, does not grow weeds, and is dustless. It is used to a depth of 9 ins. under the ties. From the pits near Sherman this material has been excavated for ballasting the road all the way from Council Bluffs, Ia., to Green River, Wyo., a distance of 827 miles. The haul from Sherman to Council Bluffs is 550 miles. It is loaded with steam shovels, much of it being excavated without blasting, but, generally speaking, more economical results are obtained by the use of some powder. Under favorable conditions this material has been excavated and loaded for about 6 cts. per cu. yd., which included all the expenses in the pit. Decomposed shale is used on some roads, to small extent, but is not as good as decomposed granite. It becomes very compact and firm and hard to work, when dry, but churns into mud during long spells of wet weather.

Another material used on a few railroads is "chatts," or the tailings from lead and zinc mills. It is the residue from quartz rock after the ore has been separated by crushing, and is in grains about the size of kernels of wheat. It is heavy material, easy to work and free from dust. On the St. Louis & San Francisco it is used extensively for ballast.

On its lines in Arizona the Atchison, Topeka & Santa Fe Ry. uses large quantities of volcanic cinder for ballast. It is excavated from pits with steam shovels and in character bears a close resemblance to burnt clay ballast. In ballasting track it is first tamped with shovels, surfacing up later with tamping bars. At various points on the Kansas City branch of the Chicago, Milwaukee & St. Paul Ry. extensive use is being made of burnt shale, or mine cinder, for ballast. This material in its original condition consists of shaly rock or slate, being refuse from soft coal mines, and is piled up in large heaps to get it out of the way. It takes fire spontaneously, and, with the considerable amount of coal unavoidably mixed with it, burns down to a material possessing some of the properties of burnt clay ballast, but is unlike it in several respects. In places where too much coal has become intermixed with the shale the large quantity of ash has a deteriorating effect on the ballast, causing it to take on a muddy consistency when it becomes wet. This material is giving good satisfaction as ballast.

In the Chesapeake bay region a considerable mileage of track is ballasted with oyster shells, costing about 21 cents per cu. yd. on the cars. The material is dustless, but too light for the best results, and the admixture of animal matter with accumulated dust encourages the growth of vegetation.

CHAPTER III.

TRACK-LAYING.

13.—Track-laying, in American countries, signifies the placing of the ties, rails and fastenings and the spiking of the rails. It includes only such temporary work in lining and surfacing as is necessary to enable the track to carry the construction train safely, and without permanently bending or kinking the rails. To meet this requirement the alignment of the track need conform only approximately to that of the center stakes; quite frequently the alignment as it is left by the spikers is sufficient for this temporary purpose. As to the surface requirements, there should be no abrupt humps or short sags, causing several ties in succession to be suspended from the rails without support from the roadbed. The work of placing track in smooth surface and alignment is a part of the operation of ballasting. In cases where the ballasting is to be delayed for some time after the operation of the road is begun the track is usually surfaced with earth to temporarily carry the traffic.

The fact that the necessities of construction do not require completed work in line and surface apparently conveys to some railroad men inexperienced with track maintenance an impression that the workmanship of track-laying is necessarily crude; hence it has become quite customary to sacrifice skillful work for speed in construction. In typical cases of railway building it has seemed that both the officials of the road and the contractors have regarded track-laying a good deal as a large class of farmers do the season of haying and harvesting—a time for rushing all work through at utmost speed, by an outlay of human strength to the utmost limit of physical endurance, and by working from daylight to dark every day until the job is finished. The scheme of building a railroad is often decided upon suddenly, and, with some object or other in view, usually to accommodate a rush of settlers, to hasten the time of earning dividends on the investment, or to head off a rival project, the circumstances seem to require the greatest possible speed in construction. In building new roads it has frequently happened that engineers have been so crowded for time that they have been unable to give proper attention to location, earthwork, etc.; still in no part of the work of railway building do men sometimes get so wild as in track-laying. Patience is lost as soon as the wheels of the construction train begin to turn. A time limit—or what amounts to the same thing, a minimum length of track to be laid per day—with a contractor seems to justify him in his belief that almost any measures or methods which can operate to his advantage in pushing things forward will be overlooked by the railway company, so long as he fulfills the all-important requirement of speed. Consequently the really most important matters connected with track-laying are too often left to the men the least interested—the laborers; and when it comes to pushing a disinterested party beyond reason it is not to be expected that he will very much care how he does his work. Speed in construction is sometimes a subject of much boasting, but less frequently considered in its bearing upon maintenance work. Unless some great interest or issue be at stake anything gained in speed by laying track in the careless manner so prevalent in the past is soon lost many times over in the poor track and early repairs which must stand as the result of the undue haste. In order to accomplish the best results in track maintenance, from the start, the work of track-laying must be done carefully and in a substantial manner. It requires the exercise of good judgment, under the conditions at hand, and no part of the work should be left uncompleted. In ordinary cases the question of speed in construction should be deemed of secondary importance. A continual cry for haste invites every man concerned to slight some part of the work. Now that track-laying is being done more largely by the railroad companies and less by contractors than formerly, there is less excuse for that sort of thing.

Center Stakes.—For the purposes of track-laying it is not necessary to set center stakes closer than 100 ft. apart on tangents and 50 ft. apart on simple curves. The practice of setting center stakes 50 ft. apart on tangents is useless and makes unnecessary expense. In order to stand firmly center stakes should be of good size, say about 2x2x18 ins., for ordinary ground in its natural state, and 6 ins. longer for made ground, such as embankments, and for soft roadbed. The stakes should be of tough wood, like oak or hard pine, and sawed stakes are the most convenient to handle. One of the reasons for this brief reference to the subject of center stakes is the fact that small stakes of soft wood are sometimes used, and with evidently poor satisfaction, not penetrating the ground far enough to stand firmly, or else being so soft that the stake splits and breaks up in driving. In order that the stakes may remain for service when the track is being ballasted they must be driven firmly enough to withstand slight knocks, such, for instance, as when stubbed against by the toe of a boot. A number of disturbing causes may be avoided by driving the stake to a good depth, so that it stands not more than 3 or 4 ins. out of the ground.

14. Outfit Train.—Where there is much track to lay the first thing to get ready is the outfit train. It should consist essentially of bunk or sleeping cars, kitchen car and dining cars, for the men; a tool car, a supply and office car, a locomotive, car-load of fuel; a water tank car, if needed; and a caboose for the train crew. Where the grades are not steep the best arrangement is to put the dining, kitchen, bunk and office cars to the front, as then they do not have to be handled by the locomotive in running back after material; it also gives the cooks better opportunity to do their work, and the dining cars are always on hand at meal time. The office and bunk cars should be ahead, followed by the dining car, with the kitchen car coupled in next behind. If there are two dining cars the kitchen car should be between them. Next behind may come the tool car, which is usually a flat car with large boxes, but sometimes a box car. On this car may also be placed some water barrels, fuel, etc., for the cooks. There should be end doors in all the cars, so that one may walk through the train from end to end. Next behind come the cars loaded with rails, then the car carrying spikes, bolts and splices, and after that the cars loaded with ties. Behind the ties should be put the fuel car, if carried, and behind this the locomotive, turned backwards to the direction in which the work is progressing. It should be provided with sand pipes which can be used when running in either direction. In any case the fuel should be next the tender, and the water car next to it, if used, and provided with a piece of hose long enough to reach the tender around the fuel car. Where streams are plentiful along the route the water car may be dispensed with by providing a steam siphon for the locomotive. The locomotive should be the heaviest one available, especially if track is to be laid on mountain grades. On work of considerable magnitude it usually pays to have a blacksmith, with a car carrying a portable set of tools, accompany the outfit train, and if the contractors do a mercantile business with their employees there are store cars also, carrying supplies of workmen's clothing, provisions, tobacco, etc.

In laying track up heavy grades or through a broken country where the construction of bridges interferes with the track-laying, it is impracticable to keep the outfit cars at the front. In such cases they are side-tracked a few days at a time at convenient points as the work progresses. This is easily and quickly done by disconnecting the track and throwing it over to a temporarily built piece of track or spur and afterward throwing it back to main line, thereby leaving the cars standing on the isolated piece of track. When it becomes necessary to move the outfit ahead again the main track is disconnected and thrown over as before, the cars hauled off, track thrown back to place, and the temporary piece taken up, all in a very short time. On level track or easy grades an ordinary locomotive can handle the outfit cars besides the material for a mile of track, in one load. Material for a mile of track includes about eight ordinary car-loads of ties, five car-loads of rails and a car-load of fastenings. Where possible, a whole day's supply of material should be carried in one train load, except perhaps when close to the base of supplies.

On roads where the track-laying lasts but a season or two the outfit cars usually consist of box cars temporarily converted for the various uses, but for longer service or for the service of contractors it is usual to make use of specially built double-deck cars. An ordinary arrangement is to have cars with a dining room on first floor and sleeping quarters overhead. The office and supply car, or store car, usually has a sleeping apartment on second floor. Such specially built cars usually have a cellar or box suspended underneath for carrying the tools. The water car is sometimes an ordinary oil-tank car and sometimes it is a flat car having a wooden tank over each truck, with a pipe connection between the tanks. A more detailed description of the construction and arrangement of boarding cars is given in § 143, Chap. X. The health of the crew requires that attention be paid to cleanliness around the kitchen and dining cars, and for both health and comfort the sleeping cars should be thoroughly renovated occasionally. A sleeping car is easily and effectively cleared of bedbugs and like inhabitants by putting it on a side-track and, after closing it tightly, turning live steam into it by hose from the locomotive until the pressure is as great as the body of the car can stand. After this the old bunk straw should be thrown out and the car thoroughly scrubbed.

15. Material Yard and Side-Tracks.—In starting out to lay track for any considerable distance it is necessary, in order to keep the work going continuously, to lay in a good-sized stock of material at some point conveniently situated for forwarding to the front. To provide room for the accumulation of this material and facilities for expeditiously handling the same there should be a systematically arranged yard, even if such must be built for only temporary use. All the material for the front is then shipped through this yard. Of course, after track-laying has begun, shipments of material received are forwarded direct to the front, as far as it is practicable to do so, without unloading or transferring at the yard; but such transferring as must be done, as, for instance, the changing of rails from box to flat cars, is done in the material yard. The material yard is then the storehouse where the reserve stock is kept on hand and the point where the supply of material for the front is regulated. In building a long line the material yard must be moved forward, from time to time, being usually kept within a day's run of the front. In building long lines the laying out of the material yard in such a manner that the material can be unloaded properly and reloaded quickly and cheaply is a very important matter. The delaying of the track-laying force for an hour now and then costs a good deal in the end. For information on material yards in further detail the reader is referred to §198, Supplementary Notes, by Mr. John Smith, a railroad contractor of long experience.

In order to keep supplies of material within convenient distance of the construction train it is usual to lay side-tracks from time to time as the work advances. On new lines in the West these side-tracks are usually put in about 10 miles apart, seldom farther, and sometimes as close as six or eight miles, the aim frequently being to select such points as seem likely to become future stations or town sites. The ordinary length of such side-tracks is about ½ mile, and in event the supply of material is short, or if there is no prospect that the side-track will remain permanently, it is usually only half tied, half bolted, etc. At such sidings the construction train exchanges its empty cars for loaded ones brought thither from the material yard by the "swing train," as it is commonly known. According to the usual custom in track-laying on long lines the swing train brings the material up to the farthest side-track in trains made up in proper order for the front, so that the train which handles the material at the end of the track need not run farther back than the first side-track in the rear, and no switching of the cars is necessary. Such sidings as are to remain permanently, for passing tracks or other purposes, should be built double ended, or with a switch at both ends, as then if the engine of the construction train is able to push a whole day's supply to the front it can leave its empties on main track, run in at the rear of the siding and push the loaded cars straight ahead to the front; while the engine of the swing train as it approaches the siding may first push the empties beyond the siding and then enter it with the loaded cars, cut loose, run out on to main track and return with the empties—all without switching the trains. It is usually the case, however, that the front end of the side-track is occupied by the boarding train, cars loaded with bridge timbers, etc. In such event the engine of the "swing" train is usually run around to the rear of the train at the next to the last side-track, pushing the train from that point to the last side-track.

The proper time to lay side-tracks is as soon as the desired points are reached, and not to first go by them two or three miles. If the boarding outfit is kept in the side-tracks, the sooner each side-track is built the sooner can the boarding train be moved up so as to get the benefit of the short run from camp to the end of the track, in taking the men to and from the work. It is the usual, in fact nearly the universal, custom to take out a half day's supply of material to the end of the track in the morning and return for dinner, and then take back the material for the afternoon's work. If the speed of track-laying is only a mile or 1¼ miles per day the supply or swing train can, if the grades are not steep, take out the whole day's supply in a single trip.

As in most parts of the West it is necessary to take out water cars to supply the locomotive of the construction train and the boarding camp, it is seldom that material for more than the length of track named is hauled in a single trip, and usually the side-tracks will not hold much more, with the boarding train, bridge material cars, etc. When track is laid at the rate of two miles per day or faster it is usually necessary for the supply train to make two trips between the material yard and the farthest side-track, bringing a half day's supply at a time. It should be timed to get out to the siding as early as 11:30 a. m. and again in the evening.

16. Unloading Material.—If the outfit cars are not placed ahead the cars loaded with rails will then be at the front and one or two carloads of rails can be unloaded directly to the rail car by pulling them ahead on dollies, over the end of the head car. If, however, the outfit cars are in front, the rails must be unloaded from the sides of the cars. The unloading point should be selected where there is clear space beside the track, and as near as may be to the end of the track. The rails should not be thrown off the car bodily, as they are liable to be bent by such usage. It is a better plan to slide them off on skids, using for this purpose two pieces of rail, each about 10 ft. long, with a piece of the web and base cut away at the end and the projecting head bent over to hook into a stake pocket. To keep the rails off the ground, so as to make it easier to pick them up when loading the rail car, a tie should be laid at the foot of each skid, and if the ground is higher than the track it may be necessary to grease the skids. Four men able to handle themselves—two men working with rail forks (Engraving E, Fig. 295) and two with small pinch bars about 3½ ft. long—can slide off a carload of rails in about half the time that twice as many men can pick them up and throw them off the car, and, besides, no harm will be done the rails. If the rails are loaded upon gondolas the unloading force must be large enough to lift the rails over the side of the car. Wherever it is practicable the rails should be unloaded from both sides of the car. Rails for the far West are often shipped in box cars and must, therefore, be unloaded through the end of the car. In such cases it saves time to transfer the rails to flat cars before taking them to the front. This transferring can be most easily done in the yards, and the work can be much facilitated by first coupling the box cars alternately with the flat cars to be loaded.

Ties shipped long distances are usually loaded in box cars. They are more convenient for unloading if shipped on flat cars, and even cattle cars are more convenient for this purpose than box cars. As in the case with rails, the ties are unloaded from both sides of the cars wherever the ground is favorable. Unless the surroundings, such as grades, narrow embankments, etc., determine otherwise, materials sufficient for ¼ to ⅓ of a mile of track should be unloaded in a place. As soon as the material is unloaded the train is hauled back out of the way, but just before meal time, at noon and at evening, it is customary to run the train close up to the workmen.

17. Organization of Forces.—The work of track-laying may be analyzed into two distinct operations, namely: That of forwarding materials and laying them down at the front; and the work of joining these materials together and building the track structure. The methods pursued in the former operation have to do principally with the speed and cost of track-laying, and in the latter with the excellence of the track, for, on general principles, good track can be laid just as cheaply as poor track, if intelligent labor be employed and placed under competent supervision. In the organization of a track-laying crew there is usually a superintendent of construction, assisted by a clerk and three foremen. There is a foreman over tie distribution, a foreman with the rail car, and a foreman over the strappers and spikers. The clerk keeps the time of the men and looks after ordering and accounting for the camp supplies. Circumstances sometimes demand both a clerk and a timekeeper. If the work is done by contractors the railway company has its own superintendent or engineer, who is usually assisted by a clerk and an inspector or two, to see that material is not wasted and that the work is done properly and according to contract specifications. The number of inspectors required always depends a good deal upon the honesty and reliability of the contractor. There is also a receiver of material employed by the railway company, through whose hands all the track material must pass and be accounted for by the time it reaches the front.

The superintendent of construction usually gets about on horseback, and for convenience of communicating with headquarters it is a good plan to build the telegraph line as fast as the track-laying progresses. When this is done the superintendent of track-laying usually has a clerk who is a telegraph operator, and the line is temporarily connected with the office car and put in working order as often as the car is side-tracked, or every evening at the end of track if the outfit train is kept moving with the work. Usually there is a night watchman to take care of the locomotive, and sometimes another to look after the train and outfit. On extensive work, however, particularly when some distance out from the base of supplies, there is usually a night train crew to make up the material train for the following day's work and bring it to the front. The baking for a large crew, and sometimes part of the cooking, is done during the night by an extra force in the kitchen car.

18. Placing Ties.—The rapidity with which track can be laid depends, more than on anything else, upon the facilities for distributing the ties on the roadbed ahead of the men laying the steel. The most favorable conditions are to be found in a wooded country, where the ties can be got out along the route. In such case the ties should be delivered along the line and left in piles of a wagon-load each at about the proper distance apart to supply the required number. In a prairie country where hauling is good alongside the roadbed the best method is to distribute the ties with teams as they are unloaded from the train. If this cannot be done, and it is desired to rush matters, it may be found profitable to haul out along the roadbed each night enough ties to keep the steel men busy the following day. In order to keep the roadbed clear for hauling when following this plan the teams should haul to the far end first and work backwards toward the train, not attempting in any case to lay the ties to place during the night. The foreman in charge of the tie distribution can estimate nearly enough the number needed; and if not quite enough should be delivered a space can be left now and then to be filled after the track-laying is brought up. It will usually be found cheaper to distribute the ties with teams, if there is good opportunity to work them, than by any other method. Ten teams in one day can haul out the ties for a mile of track. The wagons should be coupled up short and provided with a sort of rack, so that a full load may be put on in a single pile. A V-shaped affair built on the order of a hay-rack is sometimes used. It saves much labor of handling to unload the ties from the cars to the wagons direct. A plank chute, with rollers, attached to the door posts, with the outer end slung from the top of the car, is sometimes used for passing the ties from the car to the wagons.

The usual method of distributing ties where teams are not employed is to haul the ties ahead on rail cars and carry them around to the front by hand. Eight or ten rails, base down, are placed upon the rail car and upon these are loaded 200 to 300 ties, crosswise the rails. This car-load of ties is hauled along close behind the car which is distributing the rails, so as to make the distance they have to be carried around as short as possible. If the ties are heavy this is a slow and expensive way of laying track, but if the ties are of light wood, not requiring more than one man to carry a tie, it does quite well, but never so well as the method of hauling them out with teams under fair conditions of wheeling. A modification of this method which has been practiced to some extent is to carry the rails, and ties enough to lay them, on the same material car. Ten rails are placed side by side on the rail car, and over the rails, and separated from them by side timbers on the car, are placed ties enough to lay the track as far as the rails will reach. In this way the rails may be unloaded regardless of the ties and the ties need not be carried farther than a rail's length in advance of the car.

The foreman of the tie distribution should see that the ties are distributed with some regard to the quality. For instance, if some of the ties are of harder wood, than others, it should be arranged to unload the harder ties for use together, and on the curves, as far as they will go, while the softer ties should be distributed on the tangents. It has sometimes occurred that cedar ties have been laid on curves and ties of fir or harder timber on the adjoining tangents.

As to the preparation of the roadbed for laying the ties, it is nonsense and a waste of time to smooth down the surface with planks or boards, after the manner of making an onion bed in a garden, or to set grade stakes every few feet and bed the ties to a straightedge laid across their upper faces. If the graders have done their work properly further attention is not usually required; but if the surface happens to be a little humpy or has been badly furrowed by wagon tracks a lively man or two working with pick and shovel can go in advance of the tie men and make the surface smooth enough for all practical purposes. If the ties vary much in thickness it is a good plan to have two men follow the spikers, one on each side of the track, to block or roughly tamp the ties to an even bearing before the outfit train comes on them. At such work as this it is well to detail lively men who are possessed of a little genius for grading; otherwise a great deal of time may be spent on the roadbed to but little purpose.

The ties are thrown down and then lined and spaced. If the faces of a tie vary in width the wider face should be placed downward, thus taking advantage of a larger bearing surface for the ballast. In lining the ties two men are given a stout cord or small rope about 1000 ft. long, called the tie line, which they stretch out and wrap around stakes set opposite every center stake at a distance of half the standard tie length. On curves the tie line should be staked about every 25 ft. On some roads it is the rule to line the ends of the ties on the south or east side of the track; on other roads they are lined on the side of the track on which the mile posts are located, and on many roads the inside of curves is always taken for the line side; but any question as to which is the proper side to line is of comparatively little consequence. On double track it conduces much to the appearance of things to always line the ties on the outside of both tracks. As the ties are laid down they are dropped approximately to the tie line, and the two men referred to, one working at each side of the track with a light pick, one end of which has been cut off near the eye (commonly known as a "picaroon"), pull the ties to the line and space them at the same time. It saves time to have a man with a sort of T-square gage turned down at the end so as to reach over and catch the end of the tie, measure from the long corner and mark across the face of each tie, on the line side, with a large plumbago pencil, a gage line for the edge of the rail base. This can be done rapidly, and it saves the spikers the trouble of gaging each tie to a notch on the hammer handle, as it is usually done. Among track-layers this man is known as the "fiddler." In some cases his tool consists of a piece of 6-in. board with a cleat across one end, to catch over the end of the tie, and a car door handle screwed on top, with which to carry it.

19. Spacing Ties.—It is economy to put plenty of timber under the rails. Within recognized limits of spacing an increase in the number of ties affords the track better support against deflection and against permanent settlement, the track is more easily maintained in alignment, the rails cut into the ties less and they are held to gage better on curves. Any increase in the number of ties provides a firmer support for the rails when the ties become old and begin to decay, and hence may slightly increase the life of ties in some cases. The application of these principles is independent of the weight of rail. Tie bearing surface will compensate to a considerable extent for deficiency in the size of rail section, or decrease in the number of ties when laying a heavier rail may lose to the track the advantages to be expected from the heavier and stiffer rail. There should be enough space between the ties to allow a shovel to be used to advantage, and this distance is at least 11 ins. in the clear. In the case of pole ties reference would be had to the distance between the cheeks or bulging sides. Such a spacing provides for about 17 pole ties of 6 to 8-in. face and 18 squared ties of 9-in. face, per 30-ft. rail. For main track it is now the standard practice with a number of roads to use 18 ties per 30-ft. rail, and a few roads use as many as 19. In numerous instances, however, the standard number is only 15, and on a comparatively few roads (where the average width of tie face is about 10 ins.) it is only 14, per 30-ft. rail. The number of ties used per rail length should depend upon their size and the spacing adopted. In the case of squared ties, all of which are usually of the same size, the number per rail length may be uniform and the spacing may be expressed as a certain distance measured from centers. In the case of pole ties, however, which are bound to vary in width of face, the number per rail length need not necessarily be constant, and a uniform center-to-center spacing does not afford the best distribution of the timber. As pointed out in discussing the size of ties (§ 10, Chap. II), the ideal distribution of rail support is a uniform proportion of tie bearing surface to rail length. Wherever the ties faces vary in width this equality of bearing surface is much more closely realized by a uniform spacing in the clear (regardless of the size of tie or the number per rail length) than by a uniform spacing between centers; and by making the spaces somewhat wider next the largest ties the desired distribution of rail support may be secured. If each tie separately had to bear the whole weight of the load passing over the rail then those parts of the rail resting upon the largest ties would be the better supported; but from the fact that the weight on the rail at any point is always distributed over several ties, and that as ties get smaller, if properly spaced, there are more of them for a given length of rail, the total amount of bearing or supporting surface for a given length is not after all very greatly affected by slight differences in widths of tie face.

No great heed need be given to the matter of spacing ties. Calculations or actual measurements need not be made. Men a little accustomed to the work will rapidly place the ties about the right distance apart, by the eye, without hardly taking thought. Ties should be placed squarely across the track, and never obliquely to suit joints which do not come exactly opposite. On curves it is usual to put the butt or wide end of the tie to the outside of the curve. It is the practice to some extent, however, to vary this arrangement to suit the class of traffic. Thus where the curve is to be elevated fully for fast passenger traffic the larger end of the tie would be placed under the inner rail, so as to give more supporting surface to resist the additional weight of freight trains thrown to that side of the track by reason of the slower speed. But if the freight traffic is the more important and the curves are elevated for a compromise speed, the larger ends are placed under the outer rail, so as to better resist the additional weight thrown upon that rail by passenger trains running at higher speed.

The spacing of ties at joints is a subject which seems to receive a great deal of attention—in some cases too much attention, so to speak, as in practice the matter may be overdone. In the first place there is nothing gained by crowding ties together at joints so closely that tamping, with bar, pick or shovel, cannot be freely done between them; in fact, such a congestion of support may amount to a weakness, by reason of inferior tamping. In the case of a suspended joint it is considered good practice to space the two joint ties as close as may be permitted without interfering with the use of a raising jack and the effective use of tamping tools, which is about 8 ins. in the clear. The shoulder ties, however, should not be spaced so close to the joint ties as to interfere with the free use of a shovel between them. At supported joints it is quite commonly the practice to space the two shoulder ties as close to the joint ties as is practicable without interfering with the free operation of tamping tools. Outside of these three ties, however, spaces too narrow for free shoveling should not be allowed: the extra bearing secured will not compensate for what is lost through inconvenience in removing the ballast when renewing the ties. In connection with the use of long splice bars (the so-called "three-tie joint") one may frequently find the three ties under the splice spaced too close for effective tamping. One object in spacing so closely in such cases is to bring the two shoulder ties (sometimes, but improperly, called joint ties) entirely under the splice bars for the purpose of slot spiking. To follow out this plan under splice bars less than 42 ins. long makes the spaces on either side of the joint tie too narrow. On some European roads where it is the practice to reduce the spacing of the ties in the vicinity of the joint to the smallest practicable limit, room for the use of tamping tools is provided for by chamfering off the upper corners of the ties, outside the rail seat. Where rail creeping is not bothersome some advantage may be derived by selecting the widest ties for the joints, as in that way the proportion of bearing surface to the minimum allowable spacing may be increased. For the same reason the butt or wider end of joint ties may be turned to the joint side, on broken-jointed track. At suspended joints on double track it is largely the practice to put the largest tie under the shoulder at the receiving rail end or "facing" end, as it is sometimes called. On some of the European railways the same object is aimed at by an unsymmetrical arrangement of the ties at the joint, whereby the support for the receiving rail end is brought closer to the joint than that for the leaving rail end, so as to better meet the greater stress.

In American practice it is customary to space intermediate ties evenly or as nearly uniform as may be permitted by the variations in the size of pole ties. Theoretically the spaces should vary to gradually increase the ratio of tie bearing surface approaching the weakest points of the rails, which are the joints. This principle is extensively followed in European practice, the spaces being gradually increased from the joints into the quarters. Thus, in one case the center-to-center spacing increases from 16 ins. at the suspended joint, to 22 ins. for the shoulder ties and 33 ins. for the remainder of the intermediate ties. In another case the spacings run 19½—26½—31½—33½ ins. centers; and in another 19½—21½—21½—31½ ins. c. to c. of ties. It is understood, of course, that any advantages obtainable by varying the tie spacings near the joints apply only to square-jointed track, or where the joints come opposite. The bunching of ties at and near the joints on broken-jointed track bunches them likewise at the centers and quarters of the rails opposite, so that the intermediate portions of the rails get the same extra support as do the joints, and no advantage is gained. The same considerations have a bearing upon the question of sorting out the largest ties for the joints—on broken-jointed track they strengthen the support for the rail center as much as for the joints.

In order to space the ties with reference to the joints, in advance of the laying of the rails, a light pole as long as the standard rail is trailed along over the ties and the proper locations for the joint ties are measured off. In laying the Columbia & Western branch of the Canadian Pacific Ry. a piece of band iron 30 ft. long, with a ring on the front end, to pull it along, and copper rivets at intervals corresponding to the tie spaces, was used for this purpose. The use of a spacing pole or line requires the attention of two men and gives a good deal of bother. Where the rails are laid broken jointed, requiring the arrangement of two sets of joint ties in each rail length, it is better to let the tie spacing go, except roughly, until after the rails are laid down—and it is perhaps the better plan in any case. Two men working with picks and two men with bars to lift the rails, can then space the joint ties and divide up the other spaces to conform thereto. Owing to variation in rough measurements the joint ties should not, in any event, be located far ahead of the rails. To avoid discrepancies and the necessity for rearranging the ties at intervals the pole measurements should be checked occasionally by referring back to the rails.

20. Supported or Suspended Joints?—Properly speaking, the term joint, as applied to track, refers to the junction or meeting point of two rails; at ordinary temperatures it is usually an open space. There are two ways of spacing ties with reference to the joint. A supported joint, as understood among trackmen, is one where the rail ends meet upon a tie; a suspended joint is one which hangs in the clear between two ties. All joints are therefore either supported or suspended, but it is usually the aim in spacing joint ties to have the joint come approximately over the middle of the tie, in the case of the supported joint, and about midway between a pair of ties, in the case of a suspended joint. Since long splice bars have come into use the term "three-tie" joint has gained currency. Such, however, is only another name for a supported joint, the "three-tie" idea arising from the fact that the splice extends over three ties. Strictly speaking, the two outer ties of such a group are not joint ties, because they lie neither under the joint nor adjacent to it. For the sake of accuracy the terms joint and splice should not be used interchangeably; nevertheless their use in this manner is pretty general.

As already pointed out, a scientific investigation of the supporting strength of joint splices is perplexed with so many practical difficulties that recognized theories fail of application. Such is also the case with the question as to the merits of supported and suspended joints. So far as concerns the matter of support, observing trackmen are about evenly divided in their opinions as to results. It is a fair supposition, therefore, that any advantages one way or the other must be small. Aside from the question of support, however, there are other considerations deemed to be more or less important which have weight in determining practice. One of these is the facility of suspended joints to the slot-spiking of the splice bars against creeping rails. At a suspended joint it is always practicable to provide for slot-spiking two ties, whereas at a supported joint the splice bars must be long enough to extend over three ties in order to slot-spike at all, unless resort be had to the objectionable practice of slotting or punching the splice bars near their middle. These facts will very likely account for the predominance of the suspended joint on American railroads. At any rate it appears significant that where short splices are in service the suspended joint is generally standard. A summary of the practice of 50 representative American railroads, from data on angle-bar splices collected in the year 1900, shows that the suspended joint was standard on 39 roads and the supported joint on 11 roads. Out of the 39 roads referred to only seven had standard splices longer than 30 ins., and the average length of the standard splices of all these roads was 27.4 ins. Of the 11 roads on which the supported joint was standard only three had standard splices less than 36 ins. long, and the average length of the standard splices of all these roads was 34.2 ins. It is commonly the case, therefore, that the splice bars of supported joints are long enough to permit of slot-spiking the two shoulder ties, whereas the average length of splice bar at suspended joints is not sufficient to permit of slot-spiking at its ends if used with a supported joint.

The stock arguments for and against either type of joint under consideration are quite widely known, but for the sake of completeness a few more of them may bear repeating. Those who stand for the supported joint claim that the rail is supported at its weakest point, but, since the support is yielding and not a permanent one, by any means, all know that it is depressed when the load comes on; still it seems like getting the support, such as it is, at the right place. In the case of a joint splice broken at the center (which is equivalent to a broken rail) the supported joint is undoubtedly the safer at any season of the year, and particularly so in the winter, when splice bars are most liable to break. When the ballast is frozen up solid a tie directly under the joint should afford much better support to the rail ends than the two ties as arranged for a suspended joint. A suspended joint with the splice bars broken at the center is equivalent to a rail broken between two ties, which is always considered very dangerous.

It is claimed for the suspended joint that the rail ends are supported at the middle of the splice, which distributes the load upon the joint to two ties, instead of one, and when the joint is depressed both rail ends are carried down evenly. It is readily seen, however, that these advantages do not obtain with a loose or badly worn splice; besides, the distribution of the load upon a joint does not fall entirely upon the joint ties, being partly carried by the shoulder ties, and we have no means of ascertaining just what portion of the load is sustained by the ties which take part in the support of the rail ends at either a supported or suspended joint. A worthy attempt at a mathematical determination (approximately, of course) of the "Relative Strength of Suspended and Supported Angle-Bar Joints" is recorded in a paper prepared for the Association of Engineers of Maintenance of Way of the Pennsylvania Lines West of Pittsburg, in 1896, by Mr. J. C. Bland, then principal assistant engineer of the Pittsburg, Cincinnati, Chicago & St. Louis Ry. It is further claimed for the suspended joint that, hanging clear as it does, it does not permit the collection of dirt or other material to hinder the proper expansion of the rails.

In my private opinion most of the labor and care of spacing joint ties symmetrically with respect to the joint amounts to nothing in the end. As the joint is the weakest part of the rail the heaviest pressure on the ties occurs at this point, in the case of a supported joint, and in the vicinity of this point in the case of a suspended joint. The idea in the symmetrical arrangement of the ties is, of course, to equalize the rail pressure on ties occupying corresponding positions on either side of the joint. If we could solve the rail joint problem on the theory of continuous beams, cantilevers and solid supports we could then figure out the distribution of rail pressure to a nicety; but when we come to consider that the shoulder ties, as well as the joint ties, have some part in the joint support, and that the rail under each wheel load is depressed over a distance extending several feet each way from the joint, the aspect of the situation is then not so precise. If the ties are properly spaced, any hit-or-miss location of the joint cannot depart more than 5 ins. from a symmetrical position with reference to them; that is, it cannot be more than 5 ins. from the position of either a supported or a suspended joint. This possible difference (which would not occur in every case if ties were spaced irrespective of the joints) is such a small fraction of the span of depression that any variation of the distribution of rail pressure due to this cause, when the splice is holding properly to its duty, must be indeed small, particularly in the case of a long splice. If the splice be loose or worn, so that it cannot perform its function, the joint is necessarily a shaky affair, in any case, and a choice as between a symmetrical and nonsymmetrical arrangement of the ties then falls between "six for one and a half dozen for the other." Coming to actual practice, what is the usual condition of things, even where the ties as originally laid were arranged very carefully with respect to symmetry with the joint? Where splices are slot-spiked the creeping of the rail crowds the joint and shoulder ties together on one side of the joint and pulls them apart on the other, leaving the bearing surface badly distributed. If the ties are moved back to their proper spacing their position with respect to the joint is necessarily changed. In this way joints which were originally supported "get suspended," or vice versa, and it is mere luck and chance if the new arrangement brings the ties into positions symmetrical with the joint—such can occur only where the rail happens to creep a distance corresponding to half the spacing interval. If the splices are not slot-spiked the creeping of the rail will soon carry the joints out of any prearranged position with respect to the ties, and leave the big joint ties behind on the shoulders. This matter of rail creeping, wherever it occurs (and it occurs pretty generally), renders it impracticable to maintain any desired arrangement of joint and shoulder ties without continually respacing them or pulling the rails back. It is actually a fact that thousands of miles of track in this country would be in much better condition to-day if the ties in the first instance had been spaced without reference to the joints and no attempt had been made to pick out the largest ties for the joints.

21. The Rail Car.—From the point where the materials are unloaded from the construction train the rails, and in some cases the ties, are hauled ahead on strongly-built cars known as "rail cars," also commonly called "iron cars" and "steel cars." The car is usually about 8 ft. long, with 4x8-in. side sills and four cross pieces, and it should carry a load of 15 to 18 tons, or say, forty or forty-five 80-lb. rails. On both ends of the car, near each corner, there should be a roller, for use in unloading the rails. Planks are sometimes nailed to the under side of the frame, between the two middle cross pieces, to form the bottom of a box for carrying tools and small supplies. The wheels are usually about 16 ins. in diam. and the treads of the same should be 7 or 8 ins. wide, so that the car may be safely run over loosely-lying rails, before the track is spiked. If the wheel treads are narrow in a case of this kind it requires a great deal of care to keep them from dropping between the rails on curves. A rail car off the track, with a load of rails aboard, is often the cause of serious delay to the whole work. The axles should be as large as 2¾ or 3 ins. in diam., and the wheels should be spoked, so that they can be spragged in emergency. For hitching the team to the car there should be a large ring eye-bolted to each side sill at the middle. For hauling rails it is usual to have a team of two horses hitched in tandem, the driver riding the hind horse and driving the one ahead. In this way they pull close beside the track, on a rope 25 to 30 ft. long, and are driven at a trot when returning with the empty car. A man with brake stick should always ride the car and be ready to unhook the rope in case the car should get the start of the team.

22. Placing Rails.—As the limit to the length of track that can be laid in a day, after the ties have been placed, is fixed only by the rapidity with which the rails can be laid down, much depends upon the skill acquired by the rail car gang in handling rails. The succession of movements in laying the rails to place is about as follows: There is a man with a wheel chock to stop the car at the right place at every move ahead. There is a squad of five men (more or less, according to the weight of the rail) near the head end of the rail who seize it in their hands and carry it ahead as soon as the car stops; after a little practice they pull the rail off so as to drop it almost to place. Two men, known as "heeler" and "hip heeler," at the rear end of the rail, move it in line with the rail behind; the heeler inserts an expansion shim; the men at the head end give the rail a pull backwards, to close up on the shim; one man who watches the rails for lip carries a bar, to hold the end of any rail in line, in case of necessity, and the car is pushed ahead. A clamp gage is sometimes used on the rails ahead of the car to keep them from spreading, especially on curves. Where quick work is desired there are two parties handling rails, unloading from both sides of the car at the same time. The opportunity to do this is not so favorable if the rails are laid broken jointed, which is the reason that contractors prefer to lay them square jointed. On track with but few curves greater speed can be made in laying rails square jointed than when laying them broken jointed, because there is not so much starting and stopping of the car.

One rail car can handle the rails for laying a mile of track per day. In fast work two rail cars are used. One of the cars is loaded while the other is being unloaded, and in order to get the loaded car past the empty one, when pulling the loaded car to the front, the empty car is turned up on its side, on the ties, outside the rail, and held there or tilted back and propped in a leaning position while the loaded car is passing. A portable turntable has sometimes been used for this purpose. The men with the rail-laying car come back with the empty car each time as far as the point where it is passed by the loaded one coming out, but if the work is properly managed they should pass near the front, thus delaying the rail-laying crew as little as possible. The crew at the rear should be large enough to unload the material, curve the rails, if necessary, load the ties and the rail cars and keep things moving at the front. In some cases where the ties are hauled ahead by teams the rail cars are loaded by the rail-laying crew. Where such is the practice it pays to load up two cars with rails, before starting out, and take them both to the front. After the first car has been unloaded it is taken off the track and the second car is run forward and unloaded. This arrangement saves the time that would otherwise be lost in taking the crew back to load and return with the second car, and it gives the material train a chance to run back and do switching. On every car-load of rails hauled ahead enough splices, bolts and spikes are taken to lay the rails. The splices are thrown off at every joint passed and spikes and bolts, in the original kegs or boxes, at such intervals as they are needed. In some instances the heelers attend to dropping off the fastenings.

In laying track around curves the inner rail gains upon the outer rail at the rate of about 1.03 ins. per 100 ft. per degree of curvature. Provision should therefore be made to lay enough short rails on the inner side of the curve to compensate for this gain. In practice such rails are seldom shortened more than 1 ft., but a shortening of about 6 ins. is considered preferable, as then the relative position of the joints on the two sides of the track need not change so much. It is most convenient to crop the rails with a view to save one or two bolt holes, which will usually shorten the rail about 6 ins. If 29½ ft. is the length of the short rail used each one so laid should be placed when the inner rail has gained 3 ins., instead of waiting until it has gained all of the 6 ins., as then the joints on opposite sides need not get more than 3 ins. out of the desired relative position. If the tangent beyond the curve is laid square-jointed, the last short rail laid in the curve (or the only one in a short curve) should be cut to such length that it will bring the joints even at the end of the curve, whether it comes the standard length for the short rail or not. The short rails for use on curves are usually loaded with the rest and are designated by some mark, such as a band of white paint around the rail or by painting the end of the rail white, or both.

It is not considered standard practice to lay in main track a piece of rail shorter than 14 ft. Gaps shorter than this are closed by taking out a rail of full length and using two cut rails as "closers" for the whole distance. As an example, suppose that a gap of 10 ft. is to be closed. Taking out a whole rail leaves a gap of 40 ft., which is closed by laying two 20-ft. pieces or two pieces of other convenient lengths, neither being shorter than 14 ft. On the outer side of curves it is not desirable to use short lengths at all, especially pieces shorter than 20 ft. On short curves it is an easy matter to avoid the use of a short piece by slipping the rails back to carry the gap ahead to the tangent. Short lengths of rail laid on either side of a curve should be curved before laying, whether the rails of full length laid on the curve are so prepared or not. To secure a proper fit for the splice bars the ends of any rails which may have become burred, by sawing or other cause, should be filed smooth on the fishing surfaces. For this purpose sharp cold chisels and large bastard-cut files are useful. The same treatment should be applied to splice bars burred at the ends.

23. Square or Broken Joints?—There are two ways of laying rails with reference to the relative position of the joints on opposite sides of the track. When the joints are directly opposite, or nearly so, the track is called "even jointed" or "square jointed;" when the joint on one side comes opposite the middle of the rail on the other side, or thereabouts, the track is said to be laid "broken jointed." Of course, track not laid even jointed would be broken jointed whether the joint on one side came opposite the middle of a rail on the other side or not, but broken-jointed track is usually laid in the manner stated. Practically, it is immaterial whether the joint on one side comes exactly opposite the center of the rail on the other side or not. If joint splices performed their duty to entire satisfaction it would not matter which way rails were laid—square jointed or broken jointed—but under conditions as they exist some question arises as to the merits of the two ways of arranging the joints. With broken joints the track structure possesses a greater continuity of strength to hold it in alignment than is the case with square joints, because at all points there is a solid rail on at least one side. Track, especially on curves, will hold in line better if it is laid broken jointed, and the necessity for curving rails on curves of long radius is then not so great. Where it is intended to keep the road in first-class order there can be no doubt but that broken-jointed track is the easier to maintain in good condition.

Even or square-jointed track is found principally in the West. It is a familiar argument that on long lines where the traffic is light and where it is considered unprofitable to maintain track surface in first-class condition, square joints are preferable; since the roughest parts of the track are found at the joints it is better to have them opposite, so that both wheels on the same axle drop at the same instant, thus avoiding the swinging motion to the car which occurs where the low places alternate, as on broken-jointed track. On the other hand the necessity for raising low joints on square-jointed track may be so far lost sight of that the surface will become excessively bad and the cars go hopping over the line. The motion is a teetering one, unpleasant to passengers, destructive of draft rigging and severe upon the track, for if both sides of the car truck pound the track at the same time the track is struck a heavier blow than is the case if the action is alternating from side to side. Low joints on broken-jointed track, if not excessively out of surface, become less noticeable as the speed of the car increases, owing to the fact that the car body has not time to make a full oscillation to one side before it is under a tendency to swing the other way. One explanation for the existence of a great deal of even-jointed track on roads that are comparatively straight, is that the contractor for the track-laying understood his business better than the railway official in charge knew the company's business, for as heretofore explained, it is somewhat cheaper, under these conditions, to lay the joints even than to lay them broken; and on straight line contractors prefer to lay them that way—it is one of the measures in track-laying which makes for haste. Where curves are numerous it is cheaper to lay the rails broken jointed, as otherwise a good deal of time is lost in squaring the joints. On broken-jointed track it is not necessary to keep the joint on one side exactly opposite center of rail on the other side, and hence on curves the inner rail may be permitted to run ahead until the short rail of standard length (28 ft., 29 ft. or 29½ ft.) will compensate for the difference. On square-jointed track this could not be done. Square joints are standard on but comparatively few roads. There are some who think that on new lines not well ballasted square joints are preferable while the banks are settling, and others claim to prefer square joints where the track heaves badly in winter. On the Atchison, Topeka & Santa Fe Ry. even joints are standard for track on earth filling and broken joints for track on ballast.

The superior arrangement of broken joints for holding the alignment on curves has been recognized in the practice of a number of roads where a double standard is maintained—broken joints for curves and even joints for the tangents. Where this practice is followed the matter of keeping the joints on the curves directly over against the centers of the opposite rails is not always insisted upon, and on short curves the joints on the inner rail are allowed to run ahead of their regular positions until the tangent is reached, where a cut rail is laid to square the joints. In passing from even to broken joints in entering a curve, or vice versa, upon leaving the curve, the work need not be delayed to await the cutting of a rail, for the changed arrangement of the joints may be started and the connection made temporarily by turning out the end of a whole rail and laying a switch point. A rail may then be cut at convenience to fill the gap, and the spare piece from the rail so cut should be taken ahead to the other end of the curve, or else to the next curve. If the curves are only a short distance apart (say less than 1000 ft.) it is usual, where the practice of changing the relation of the joints at curves is followed, to continue the broken joints throughout the intervening tangents.

Touching the question of square or broken joints for double track, arguments are presented both ways. Some prefer square joints in order to keep the joint ties square when the rails creep. If the rails creep on broken-jointed track the joint ties are slewed out of square and the rails are pulled out of gage and alignment. This difficulty may be overcome, however, by putting anchor splices or anti-creepers on the solid rail opposite the joint. Others prefer broken joints for the reason that, with traffic in one direction, one rail will generally creep more than the other, and if the joints are laid even to start with, it is only a little while until the joint ties become slewed out of square, making it necessary to drive one of the rails back, to bring the joints opposite and straighten the ties around.

24. Curving Rails.—The rules of various roads require that the rails for curves of 2 to 4 deg. and over (most frequently 3 deg. and over) shall be curved before laying. In practice, however, it is quite frequently the case that rails for curves much sharper than 4 deg. are laid without curving. As to the limit of curvature up to which rails may be laid without curving there is a simple experiment which I think may serve as a rough guide to practice, and that is to ascertain what curvature the rail will hold of its own weight. For instance, a straight 60-lb. rail 30 ft. long resting loosely upon the ties, simply by its own weight, will lie to a curve having a middle ordinate of 1 in., without spikes or other means to hold it in place. The 1-in. middle ordinate corresponds to a curve of 4¼ deg. Such being the facts there would seem to be no question but that 60-lb. rails spiked to ties would hold considerably more curvature, or lie to a curve of say at least 6 or 7 deg., without being curved. As the work of curving rails is expensive, costing, by the usual methods, $35 to $60 or more per mile of curved track, the necessity for the same should be carefully considered.

The conditions which have a bearing upon the question are the length of rail and the weight per yard, the efficiency of the joint splices in the way of lateral stiffness, the manner of laying the rails with respect to the relative position of the joints, the weight of the ties and the manner of filling in and dressing off the ballast. The longer the rail the less the necessity for curving, for obvious reasons. In practice it has been found that 45-ft. and 60-ft. rails could be laid without curving, on the same curves where it had always been considered necessary to curve the 30-ft rails laid thereon. Increase in weight of rail increases the necessity for curving, other conditions the same. The tendency of uncurved rails to straighten when laid on sharp curves would not necessitate curving were it not for the weakness of the rail at the joint. A rail sprung to the curve is more rigid than one curved or bent so that it will lie to place of itself; and if such rigidity could be maintained continuously the track would be better able to hold its shape or alignment against

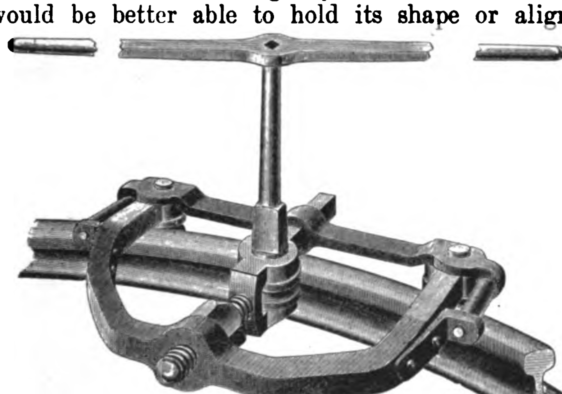

Fig. 31.—Rail-Curving Machine.

side pressure from wheel flanges; that is, if it was practicable to make rails continuous it would be better not to curve them for track of any degree of curvature. A bow pulled to the point of shooting the arrow is more rigid than it is when not strung up, and the same principle applies in some degree to rails laid on curves. If, however, the splice fails to perform its duty properly, as is usually the case with short splices, splice bars of light section or with splices which have become loose, the rail will bend at this point and relieve itself of stress, and uniformity of curvature will not be maintained. For reasons made clear in the previous section the superior alignment conditions of broken-jointed track will permit uncurved rails to be laid to sharper curvature on such track than is the case with track on which the joints are laid opposite. It is unnecessary to explain how heavy ties and the filling of ballast around the ties, especially against the ends of the same, assist in holding the track to the proper curvature, regardless of any question of curving the rails.

Rail-Curving Devices.—A rail-curving machine consists essentially of three rolls so positioned that the rail is made to pass between two rolls on one side and a roll on the opposite side placed midway between the other two. By tightening down on the middle roll, which is adjustable, the rail is bent uniformly to a curve as it passes through, the desired curvature being obtained by properly setting the middle roll. The best results are to be had by the use of rolls shouldered to fit against both the head and web of the rail. On some roads these machines are placed in the shops and operated by steam power, but the use of hand machines is more extensive. A hand machine of this description is shown as Fig. 31, being what might be called a traveling jim-crow. It has a heavy forged yoke or frame carrying three grooved curving rolls, the middle one being adjustable by means of a screw and provided with means whereby it may be revolved—in this case a heavy box wrench and a lever. The rail stands workwise, with a plank alongside to support the frame, and as the middle roll is turned it travels along on the rail, curving the rail as it moves. Two to 6 men, depending on the weight of the rail and the amount of curvature given, are required to operate it; and, working in this manner, about 50 rails can be curved in 10 hours. In the proceedings of the New England Roadmasters' Assn. for 1896 it is stated that 20 men working with a machine of this kind curved one hundred 100-lb. rails in 10 hours. To expedite matters the machine is sometimes made stationary by chaining it to the ties, in the middle of the track, and the rails are hauled through with a locomotive and switch rope. In one instance of this kind there were two gangs of men—one carrying rails to the machine and another carrying them away as fast as the locomotive could pull them through. By this method the

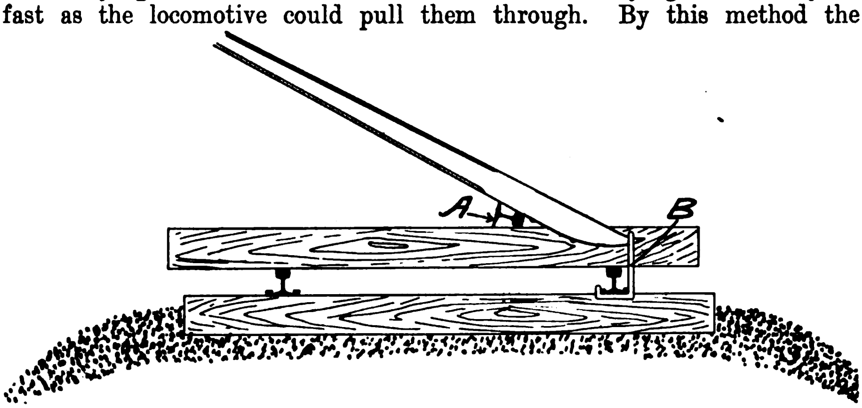

Fig. 32.—Lever and Hook Arrangement for Curving Rails.

rails were curved at an average rate of one each minute. The machine may also be fitted with a horse-power attachment intended for heavy work. It consists simply in a 7-ft. lever fitting the square shaft of the middle roll, the horse traveling around at the end of the lever.

The most rapid method of curving rails by hand is by the use of levers and sledges. The crew for this work should be large enough to pick up a rail and carry it easily in the hands—say ten men for 80-lb. rails. The rails are unloaded onto skids alongside some side-track. Two ties are then placed on and across the rails of the side-track a rail's length apart, and the rail to be curved is placed upon these two ties, on its side. The rail to be curved is then put under strain by bending it downward with two levers placed at about the quarter points and secured to the track rail by means of an inverted U-shaped iron with a hook on the lower end of each leg to fit under the base of the track rail. Figure 32 shows the arrangement, *A* being the rail to be curved and *B* the device for anchoring the lever, known as a "curving hook." In the absence of this hook a piece of chain is substituted. In lieu of a side-track for anchoring the levers two rails may be thrown down loosely across some ties. The rail is curved by striking it a few times, in its strained position, on the side of the head, just outside where the two levers are resting, with two 16 or 18-lb. sledges. The rail is then turned workwise and a string is stretched to see if the middle ordinate corresponds to the proper curvature. In case the rail should be curved too much some curvature may be taken out easily by turning the rail on its side, curve up, and springing down upon it with a teetering motion a few times; this is called "shaking" out the curvature. Rails can in this manner be cheaply and well curved. If the curvature does not seem to be uniform throughout the length of the rail the position of the levers should be slightly changed. After ascertaining the proper positions for the levers, and by always bearing down upon them with the proper amount of force and striking firm, steady blows, men can soon become so skillful that a certain number of blows each time will curve the rail so nearly right that it will not be found necessary to measure the middle ordinate every time; but the foreman should measure one occasionally to correct his eye. Sometimes only one lever is used, at the middle of the rail, but this arrangement does not give as good satisfaction as that of using two levers and two sledges in the manner stated. The curvature of the rail may be tested for uniformity by measuring the quarter ordinates, which should be three fourths the length of the middle ordinate with the string in the same position; that is, stretched the whole length of the rail. Another way to test for uniform curvature, best adapted to rails curved to a short radius, is to stretch a string over each third of the rail to see if the middle ordinate is the same in every case.

The lever-and-sledge method of curving rails is widely in disfavor, owing to the "barbarous treatment" which the rail is supposed to receive. On this point it is pertinent to inquire how a rail liable to injury by a side blow from a sledge hammer can be expected to stand the heavy alternating stresses imposed by fast locomotives and the heavy pounding of

flat car wheels. The fact is that rails are made for heavy duty, and drop tests under sudden blow from a hammer weighing a ton are required of full-size rail specimens to show that the metal will bend before it will break. It being known that rails take permanent set under the gag and that the stock rails of split switches are bent cold, and yet are considered safe, why should the blows from a sledge hammer in curving be regarded severe treatment? The fact that the lever-and-sledge treatment, properly administered, curves the rail uniformly its whole length, and without kinking it, proves that the blows received are only moderate; if they were otherwise the rail would be bent most sharply at the points where it was struck. If any man has seen rails break while being curved in this manner he should regard such incidents in the light of fortunate discoveries, for it is quite evident that the rails were unfit for service in the track. Rails cannot be curved satisfactorily with a jim-crow. This tool is intended for bending rails to an angle, but not to a curve. Any attempt to employ a jim-crow in rail curving will result in very slow progress and a series of angular bends in lieu of a curve.

Table IV. gives middle ordinates for rails 10 to 30 ft. long, to the nearest 64th of an inch. It is not necessary to be so exact as this in curving rails. It is sufficiently close to work to the nearest ¼ in. or even to the nearest ½ in., for heavy curvature. It will be noticed that the middle ordinate of a curved 30-ft. rail is approximately ¼ in. multiplied by the degree of curve. This rule is sufficiently exact for any work of rail curving, and may be used in preference to consulting the table, and also for curves of higher degree than are provided for in the table. The middle ordinate of a curved 33-ft. rail, which is now the standard length on a number of roads, is (nearly enough) $^3/_{10}$ in. multiplied by the degree of the curvature.

Handling Curved Rails.—In handling curved rails it is well to so arrange the work that the rails may be taken from the curving blocks or machine and loaded directly onto the cars; otherwise the expense of handling is considerably increased. After rails are curved they should be handled with special care and should not be thrown.

In laying track where curves are numerous the rails should be curved in the material yard or before they are shipped to the front. A man from the engineering department is usually given charge and supplied with a note book giving the location and lengths of the tangents and curves of the line. This man has charge of loading the rails and the ties (in case the ties are of different kinds, so that a harder quality may be had for the curves) and he is supposed to so arrange the shipments that cars loaded with material for the curves are forwarded in their proper order. By a little calculation the cars can be arranged to come exactly in the order needed. To avoid confusion, cars loaded with rails for certain curves should be labeled by marking, on a shingle or card tacked to the side of the car, the station numbers of the P. C.'s between which the material is to be used. In building the Columbia & Western branch of the Canadian Pacific Ry. each car was marked with the initial station for any curved rails carried, and the first and last rails of each curve had the station number painted on them. Rails curved for different degrees of curvature should not be mixed, or carelessly loaded on the same car. To avoid inconvenience the curved rails for different curves should be placed in separate piles, divided, if necessary, by pieces of board. It is also customary in loading curved rails not to place rails for more than one curve on the same car, the balance of the car-load, if there is room to spare, being finished out with straight rails.

On the question of curving rails for spiral or easement curves it would of course not be expected to curve them for that portion of the easement the curvature of which does not exceed the limit governing the curving of rails in the usual practice of the road. From information published in the committee report on "Track," to the American Railway Engineering and Maintenance of Way Association, in 1901, it appears that a number of maintenance-of-way men prefer to curve the rails of the spiral to correspond to the curvature of the spiral at the position of the rail; that is, that each rail should be curved to that middle ordinate which will fit the degree of curve at the point where the middle of the rail lies when in position on the spiral. As already seen, however, there is no necessity for any great precision in rail curving as, if the rails are curved within 2 or 3 deg. of the stated curvature, they will not be subjected to appreciable strain when spiked to that curvature. In all ordinary cases it would seem sufficient for practice to follow a method suggested by Mr. Jerry Sullivan, which would be to use on one side of the easement the rails curved for the regular curve, with straight rails on the other side. By way of illustration, for an easement at the end of a 6-deg. curve, the rails curved to 6 deg. might be used as far out on the easement as the point where the curvature decreases to 3 deg., with straight rails on the inside of the curve to offset the strain due to the excessive curvature of the rails on the outside. This method would obviate the necessity for curving rails to different ordinates for the same curve, where spirals or easement curves occur, and undoubtedly answer just as well as if every rail was curved for the position in which it lies on the spiral.

25. Allowance for Expansion.—For every degree, Fahrenheit, change in temperature steel is supposed to change its dimensions about .0000065 of itself, or about 1 part in 150,000, the change varying slightly according to the chemical composition of the metal. As steel rails are subject to the extremes of atmospheric temperature allowance must be made for the resulting change in length, according to the temperature of the rail at the time of laying it. The correspondence of the temperatures of the rail and the atmosphere does not seem to have been thoroughly investigated. It is commonly understood, however, that the rail comes to the same temperature as the atmosphere except, perhaps, while the sun is shining, when it may become hotter. In that case it is considered good practice to take the temperature by holding the thermometer against the rail, on the shady side. On the other hand the ground is supposed to have some considerable effect on the rail temperature, by way of radiation, usually in the nature of a compromise of both extremes, but it remains to be demonstrated whether this effect is reasonably constant for such conditions as have to be taken into account. Temperature tests on 100-lb. rails in the track, by Mr. P. H. Dudley, by means of a "companion" rail with a hole drilled in the head for the insertion of a thermometer, showed that when the thermometer registered 135 deg. F. in the sun the highest temperature obtained in the head of the rail was 120 deg. F. and the base of the rail, as a rule, was 2 to 4 deg. cooler. At the other extreme, careful observations taken by the late Mr. A. Torrey, chief engineer of the Michigan Central R. R., showed that between 20 deg. F. and —20 deg. F., or over a range of 40 deg. of temperature, the length of rails was unchangeable. Changes of temperature between these limits produced no movement, but above 20 deg. F. the rail was quite sensitive to temperature changes. The rail on which the observations were made was 500 ft. long, built up by rigidly splicing 30-ft. lengths together as one. Further details are given under the subject "Longer Rails," § 172, Chap. XI.

Such observations are not reconcilable with the customary basis for computing allowance for expansion, which assumes a uniform change of length throughout the whole range of temperature. Unfortunately, observations of the kind noted have been too few to cover conditions in general, and so practice abides by the safe side, providing for the full effect of atmospheric temperature within the extremes registered by the thermometer. Carelessness in not properly allowing for change of temperature usually results in harm from the expansion of the rails in hot weather, and frequently as much from contraction during cold weather. To make no more provision for change of length in a long steel bridge than is sometimes made for track rails would soon result in trouble either for the bridge or the coping of the abutments.

It is safe to assume that there are but few localities where a rail will change in temperature, between the extremes of winter and summer, more than 180 deg. F., which corresponds to a change in length of $^7/_{16}$ in. for a 30-ft. rail, or a change of $^1/_{16}$ in. in length for each 25 deg. change of temperature. As the extremes of temperature in different localities may vary widely it is not feasible to arrange a table of expansion allowances suitable for universal application. In the northern part of the Mississippi valley the extremes are something like —40 deg. and + 140 deg. F. in the sun, while in parts of Arizona they would be more like + 20 and + 150 deg. F. in the sun. In a general way, however, it might be said that for most places in this country the range of temperature between coldest in winter and hottest in summer (in the sun) is about 150 deg. F. This change in temperature would produce about $\frac{3}{8}$ in. variation in the length of a 30-ft. rail. In some parts of the coast of California the variation between extremes is probably not more than 60 deg. F., thus requiring but little more than $\frac{1}{8}$ in. for change of length in a 30-ft. rail. It is highly desirable that no more space than is really necessary be left at the rail joints, and in localities where the extremes do not vary widely but little allowance need be made. A general rule for expansion allowance in laying 30-ft. rails, at any temperature, at any place then would be: Ascertain the lowest temperature to which the region is subject, and also the highest, in the sun, and take the difference in degrees, Fahrenheit. Divide this difference by 25 and multiply by $^1/_{16}$; this will be the opening in inches when laying at the lowest temperature. Then to find the opening to be allowed when laying at any other temperature, decrease from the opening for the lowest temperature at the rate of $^1/_{16}$ in. for each 25 deg. above the lowest temperature. For rails of length other than 30 ft. the allowance will be in proportion.

Results calculable by this rule will show that the spaces to be allowed for rail expansion when laying at the same temperature in different localities may vary considerably; and not only according to differences in the total variation of temperature of the different localities, but also because of wide variations which may exist between the lowest temperatures in the different localities. Thus, for illustration, suppose the total variation of temperature, between winter and summer, at each of two places is 150 deg. F. The expansion allowance for the lowest temperature will then be the same ($\frac{3}{8}$ in.) for both places. But suppose that the lowest temperature for one locality is —40 deg., while for the other it is zero. The difference in the expansion allowances for the two localities when laying rails at the same temperature in both, will then always be $^{40}/_{25} \times {}^1/_{16}$ in. $= {}^1/_{10}$ in., which is a matter worth considering. At some high altitudes, for instance, the thermometer may never register higher than 80 deg. in the sun, and rails laid in such places at that temperature should be butted end to end, because then the only movement to occur will be in the way of contraction. At some lower altitude, perhaps not a great distance away, rails laid at the same temperature may easily require a full $\frac{1}{8}$-in. space interval for expansion. It is thus seen that instances frequently arise when specific rules for rail expansion openings should not be followed.

The foregoing statements refer to the space necessary to permit rails to expand freely. Where the ballast is scarce or the rails of light section it is not considered safe to skimp the expansion openings, but late years, with heavy rails, on track well filled in, some roads have made it a practice to retain part of the expansion in the metal itself. The vindication of this practice is that heavy rails are stronger, considered as a column, and therefore better able to undergo compression without buckling than are rails of light section. It is the practice with a number of roads using rails as heavy as 85 lbs. per yd. (and possibly in some cases where the rails are lighter) to reduce the expansion allowance to one half the space required for free movement at the highest temperature. In long tunnels, where the temperature remains about constant, no allowance for expansion is needed and hence in laying rails therein they should be butted end to end. In laying rails across a sag which is later to be raised to grade it is necessary, in order to avoid cutting rails, to allow extra space at the joints to provide for the shortening of the track when it is lifted to the proper level.

A convenient form of expansion shim can be made out of narrow band iron by bending over one end at a right angle, so that it will hang in place over the end of the rail. As a matter of convenience there should be an assortment of three sizes or thicknesses—some $^1/_{16}$ in., some $\frac{1}{8}$ in. and some $\frac{1}{4}$ in. thick. If a single shim of one of these sizes does not suffice for the opening, two or more may be combined and used together. It is well to have the thickness plainly stamped on the shim. The expansion shims of the Southern Pacific road are of six different thicknesses, beginning at nothing (tight joint) for temperatures between 130 and 150 deg. Fahr. and increasing in multiples of $^3/_{64}$ in. for each 20 deg. decrease down to 50 to 70 deg., at which the thickness is $^3/_{16}$ in.; for 32 to 50 deg. the thickness is $^7/_{32}$ in., and for 0 to 32 deg. it is $\frac{1}{4}$ in. These shims are of iron, and the temperatures at which it is supposed they are to be laid are marked on the shims. For example, shims for use in temperatures anywhere between 70 and 90 deg. are marked "70-90." On its lines south of the Ohio river the Illinois Central R. R. uses but three thicknesses—$^1/_{16}$ in. for the very hottest weather, $\frac{1}{8}$ in. for spring or fall and $^3/_{16}$ in. for cold weather. On its northern and western lines a $\frac{1}{4}$-in. shim is used for the very coldest weather. An assortment of wire nails of different sizes make convenient shims, and such are sometimes used. Another form of expansion shim much used is a small star-shaped malleable casting with four legs radiating from the center at right angles. The legs vary in thickness to suit variations in temperature, usually from $^1/_{16}$ to $\frac{1}{4}$ in. This device is known as a "grasshopper" or "spider" shim.

The use of wooden expansion shims is not considered good practice, because they get squeezed when the rail is set back hard, and leave the opening smaller than it is intended to be; and besides, it then becomes difficult for the splice men to get them out. The rules of the Northern Pacific Ry. require iron shims for ordinary work, but to prevent the rails from being shoved back when laying track on steep grades sawed wooden shims are used and left in place until the track is fully spiked and bolted. Lath have been used a good deal for shims, the free end being easily broken off each time from the piece held between the rail ends. To mention still another method, expansion has been provided for in the following manner: A piece of wood about ½ in. thick is placed between the rails temporarily when they are set together, thus leaving the space too wide. The head strappers keep well up to the rail car, and each carries a steel shim of oval form about ⅜ in. thick in the middle, tapering off to about ⅛ in. in thickness at each end. By inserting this shim in the joint and putting the wrench handle through a bolt hole the rail is pulled back against the shim to make any desired opening, depending on how far the shim is shoved into the joint.

Shims, assorted as to the various sizes, should be carried in pails or boxes hanging at or attached to the head end of the rail car, on either side, where they can be reached by the heeler. They are collected after being used each time,and so answer their purpose over and over. In cases where shims of the thinner sizes are not at hand the proper joint spaces may be provided by an averaging process, using a shim of excessive thickness at part of the joints and laying the other joints tight. Thus, for example, a ⅛-in. shim laid at every other joint would serve the purpose of $^1/_{16}$ in. shims at every joint. Of course such is not the most desirable manner of distributing the expansion allowance, but, in the light of conditions widely existing, it is not after all so very objectionable. An ever-recurring trouble with expansion space is that it will not remain evenly distributed, howsoever carefully it is arranged at the start. The tendency of the rails under traffic is to bunch together at some points and pull apart at others, leaving abnormally wide openings. A familiar illustration of an extreme case of this action is the behavior of the rails on lines of frequently opposing gradients, where the rails run together, closing the joints in the sags, and pull widely open across the summits. This behavior would seem to be a good argument why the expansion allowance should not be permitted to exceed the least space consistent with safety.

Another difficulty frequently experienced in the way of maintaining the desired expansion allowance is the bodily movement of long stretches of track while it is being laid. Such a movement is most liable to take place when track-laying is carried on during the early spring or late fall. For an hour or two after work begins on a frosty morning the temperature of the rail may be at freezing or below, but by noon it may run up to 80 or 90 deg. in the sun. As the splices are tightly bolted and the ties less resistant than on ballasted track, a considerable stretch of newly-laid rails may expand without rendering in the splices and the same openings then exist that were provided for a temperature perhaps 50 deg. lower. Before the temperature falls a long piece of track may be laid which will hold the piece laid in the morning from pulling back, and thus the joints for some distance may permanently remain too open. Some trackmen when laying track under the temperature conditions noted attempt to make allowance for the movements described by decreasing the expansion allowance, but it is, after all, a difficult matter to regulate.

In allowing expansion space between rails with miter-cut ends the measurement should obviously be made in line with the rail, which is askew to the opening; and the thickness of the shim should be less than this measurement, and in the ratio of the cosine of the angle of the miter. For instance, if the rail ends are cut off to an angle of 45 deg. the thickness of the shim should be 0.7 of the expansion allowance. In using expansion shims in such joints the precaution should be taken to have the rail ends exactly in line as they are moved up to the shim, or when the space is measured, else when they are lined up by the splice bars the space allowed will either close up or open out, and thus be correspondingly narrower or wider than the intended allowance.

26. Splicing.—Following next behind the rail-laying car come the splicers or "strappers," as they are commonly called. These men are usually divided into two parties—the "head strappers," who should be quick and steady with the fingers, to put on the splices and one bolt in each splice to hold it in place, and the "back strappers," who put in the remaining bolts and finish tightening the splice. The act of putting on a splice quickly is worth some attention, because some men, apparently, never learn how to do it. It is not so much dependent upon rapidity of movement as upon having an eye to adjustment and a firm, steady manner of doing things. The first thing to be done is to get the ends of the two rails in line, at the same level, and take out the expansion shim. This the head strapper does by prying on the rail with his wrench in one hand, and grabbing up with the other hand a chip, pebble or some other object to put under one of the rails to hold it up even with the other; it then takes but an instant to put the ends in line. Then, standing inside the rail, if the bolt heads come on that side, he puts the splice bars in place, not by feeling for a bolt hole in the rail with his finger, but by sighting down with the eye—a more rapid method. He then puts a bolt through one of the middle holes, gives the nut a few turns with the fingers or wrench, far enough to hold the splice in place, and goes ahead to another joint. The head strapper should work some little distance in rear of the rail laying, as, if he gets too near, the removal of the expansion shims may permit the rails to be bunted back and close the joint openings.

The back strapper next comes along, puts in the full number of bolts and tightens them. He should stand so as to use his wrench across the rail; or, since it is hard work, he may rest himself occasionally by sitting down on the rail and tightening the nuts by pulling (not pushing) on the wrench. A man skillful at catching a nut with a wrench need not lose much time by sitting down at his work occasionally. He should carry a spike maul and, after the bolts are fairly well tightened, sledge the splice bars together by striking each a hard blow between every two bolt holes and at the ends; and each bolt head should be lightly tapped. This hammering will pulverize the oxide scale between the surface of the rail and the splice bars and drive the splice bars to a closer fit. The bolts will be found loose after this hammering and should then be tightened again about as tight as a man can conveniently pull on them with an 18-in. wrench, using both hands and standing on his feet. Such an adjustment will not be too tight, as it would if the splices were worn to a closer fit with the rail, as is the case after trains have run for awhile. Nuts should be put on flat side to the washer or nut lock, and before they are tightened the splice bars should be adjusted to bring the bolts squarely across the rail. A good fit for the bolt head cannot be obtained unless the bolt is at right angles to the splice. After the track is ballasted and lined the bolts should be thoroughly gone over again, for after surface kinks have been taken out and the rails put in line some of the splices will be found to have loosened. Some roads require that within a month after traffic begins running the bolts shall be tightened again.

In the days when rails were of light section it was necessary, in order to keep the nuts out of the way of the wheel flanges, to put the bolts through the splice from the inside. As rails increased in hight such interference became no longer possible and the practice of placing the nuts on the gage side of the rails is now quite extensively in vogue.

A supposed advantage sought by this arrangement is to place the nuts where they are most readily caught by the eye of the track-walker, for on large steel they are not easily seen over the edge of the rail by one walking inside the track. So far as concerns the track-walker's convenience, however, the advantage lies rather with the old way, or with the practice of placing the nut on the outside. A track-walker locates a loose bolt, not by looking at the nut, but by the appearance of the bolt head, there being always a ring or streak of rust on the splice bar around the head of every bolt the least bit loose; with a bolt kept tight such is not the case. Where the nuts come inside it is not so convenient for the track-walker to tighten loose bolts as it is where they come outside, for in the former case he will step outside the rail to tighten the nut and in the latter he will simply reach over the rail while standing in the track, give the nut a few turns and walk on. It is sometimes claimed that derailed wheels are not so liable to cut the nuts from the gage side as from the outside of the rail, but the only security to be had in this respect is by placing part of the bolts one way and part the other way, so as to have nuts on both sides of the rail. This arrangement will prevent a derailed wheel or car truck from shearing all of the nuts, thus insuring that there will be bolts to hold each splice in case of accident. The importance of this precaution is well understood, for it has happened many a time that a derailed freight car truck has been hauled several miles over the ties, stripping all the nuts from the joint splices on one side of the track, to the peril of following trains, or even to following cars in the same train. With such danger in prospect it is now quite largely the practice to reverse the position of alternate bolts in joint splices, thus bringing half the nuts on each side of the rail. In some cases the two middle bolts in each splice are placed to bring the nuts on the opposite side of the rail from the remainder. Some trackmen profess to believe that the scheme of putting bolts both ways through the splices affords a tighter adjustment of the splice bars to the rails, and it is pretty well agreed that it does not permit the joint to pull so widely open when the rails contract in cold weather, and that it disposes the bolts in a manner to oppose the contraction of the rails with less liability of being broken. When this arrangement is in contemplation for bolts to be held from turning by a shank of square or oval section, the punching of the splice bars must be arranged to correspond. In some cases both splice bars are punched with oval holes throughout. The practice with the Pittsburg & Lake Erie and the Michigan Central roads is to punch the holes in both bars alternately round and oval, but relatively reversed in the two bars of each pair. In doing this the spike slots can be located to dodge the nuts of the bolts. It should also be borne in mind that the presence of nuts on the gage side of the rails may have some bearing on the design of snow flangers.

Where rails of different hights come together in main track the splice bars should be stepped and made to fit accurately, and it is sometimes found necessary to offset them to suit a difference of thickness in the two webs or a jog in the alignment of the same. The joint in this case should be made supported and an iron shim should be put under the rail of lesser hight, or a stepped shim under both, to bring the top surfaces of the rail heads even. This shim should be spiked to the tie, like a tie plate, so that it will remain in place. A splice made to fit two rails of dissimilar section is generally known as a "compromise" or "offset" splice, and some of the affairs turned out at blacksmith shops by working over common angle bars are badly crippled, in one way or another, usually by heating and pounding until the section of the bars is much reduced, and also by forming a square shoulder at the jog (See §95 and §212).

27. Spiking.—Spiking is one of the most important details of track-laying, because it is very troublesome to remedy when wrongly done. Spikers should not be pushed, for if they are they will surely slight the work in some respect. Two men drive spikes together, delivering blows on opposite sides of the rail at alternate intervals. Right-handed men should be paired with right handed men, and left-handed men with left-handed. Frequently right and left-handed men are paired together, principally because it looks better, perhaps, to see both facing the front; but there is nothing gained in rapidity thereby and the work cannot be done so satisfactorily. While driving a spike the spiker invariably pulls or starts the tie toward himself at each blow. It is clear, therefore, that two men driving from the same side of the tie will both move it, unless it can be held up more tightly than can always be easily done, and both will tend to move it in the same direction; but when they stand facing each other the tendency to pull or start the tie one way is balanced by a like tendency from the opposite direction, and the tie is not moved in being spiked. Spikers usually stand beside the rail while driving spikes, but a good spiker can drive well while standing in almost any convenient position. A poor spiker, like almost any other poor workman, will make a good many movements on his feet which a good spiker would not; such, for instance, as stepping astride the rail or measuring his steps when about to begin driving. It is a poor spiker who will go about the work with as much deliberation as when aiming a gun. Some men train themselves to spike equally well either right or left-handed, and it is a good habit to get into, not only because it enables one to handle himself more adroitly at the work, but because the man who can change hands with a tool occasionally will become less fatigued at using it, and after years of work of this kind he is not so liable to get that "hump" on one shoulder, so commonly seen with trackmen.

The line side of the track is of course spiked first. To begin with, the spiker on the outside sees that the tie end is at proper distance from the rail, driving it through when too long, or having his partner drive it from his end when too short; he then sets his spike. When a gage mark is not placed on the tie face he measures by a notch cut on his hammer handle. This length should be such that a tie of standard length projects equally beyond both rails when they are spiked to proper gage. When the rail is too far out of gage with most of the tie ends the man holding up the ties, called the "nipper," should take his bar and throw the rail over to approximate gage. After the spike on the outside of the rail has been set, so as not to allow the tie to shove through while it is being raised to the rail, the nipper holds it firmly up against the rail base while the spikers do the rest. Before the spikes are driven, however, the men should see that the tie is properly spaced from the others and square across the track. If this is not attended to the spikes will be out of true when the tie is shifted to proper position.

The nipper is usually provided with a pinch bar (a crow bar is a poor tool for this purpose) and a block of wood about 2x4x12 ins. in size, for a fulcrum, with a spike driven into it for a handle, and ordinarily they answer the purpose well enough. In narrow cuts, however, and in other places where special conditions prevail—as, for instance, when laying street railway track in a trench excavated but little wider than the length of the tie—the lack of room on the shoulder at the end of the tie will not permit a bar to be used at that point. In such a case either two bars—one each side of the tie—or a special contrivance must be used to hold the tie up to the rail. Two or three devices for this purpose operate on the principle of holding the tie to the rail by prying over the latter. The Sterlingworth holding-up bar (Fig. 33) is a device of this kind. It is a long, heavy bar, forked at one end and provided with hooks which engage the tie in the middle of the under face. The fork of the bar is placed astride the rail, as seen in the figure, which also shows the inclination of the bar when holding the tie in position for driving the spike.

Spikes should not be leaned to suit the swing of the spiker's hammer, but should be driven perpendicular to the tie face. It requires some vigilance to get men to abide by this rule, since one must bend his back a little in order to do so, but it must be insisted upon. Where a spike has been driven slantwise it is a difficult matter to catch the head with a claw bar when the spike must be pulled, and if the spike is inclined under the rail the latter will ride the neck of the spike and cut it. One aid to good spiking is to have the hammer handles the full regulation length of 3 ft. Ordinarily men will not drive spikes properly unless they are watched and criticised occasionally; let foremen not forget this. The spike should be started plumb, with the side of the point against the rail flange, so that it will crowd the rail all its way down. The finishing blow should tap the head down to a firm hold upon the rail flange, but not too forcibly, lest the spike be broken off or cracked under the head or the neck of the spike be forced away from the rail flange. The effect of this last blow is to spring the rail base slightly into the fibers of the wood and start the spike farther into the tie, so that the spikes are made to hold the rail base to the tie with a force of several hundred pounds. This drawing force is caused by the action of the wood fibers, which are forced inward with the spike and act somewhat like a pawl to resist any tendency to pull the spike back.

The usual practice is to drive two spikes in each tie for each rail, and to drive them staggered; that is, on opposite sides of the same rail the two spikes stand near opposite edges of the tie face. In ties sawed or hewn on four faces spikes should not be driven nearer than 2½ ins. to

Fig. 33.—Sterlingworth Holding-Up Bar.

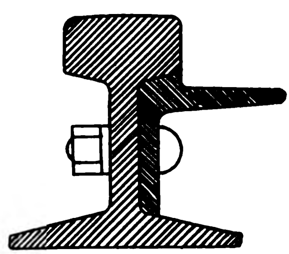

Fig. 40.

the edge of the tie face and in pole ties they should be driven at about ¼ the width of face from the edge of the face. Spikes should be so driven that they have no tendency to swing the tie askew to the rails before the track is ballasted. This requirement can be fulfilled by driving both outside spikes near the same edge of the tie face and both inside spikes near the other edge of the face. For the same reason spikes should not be driven in the middle of the tie face; besides, with pole ties, the heart of the timber being under the middle of the face, the spike does not hold so firmly when driven there and it is also more liable to split the tie or to come where the tie most usually checks open. Spikes should be driven to "cross bind," the purpose of which arrangement is to clutch the rail and resist creeping, as explained more fully and by diagram in § 103, Chap. VII. The advisability of driving spikes in the slots of splice bars is taken up in the same connection. On curves the outside spike on shoulder ties should be driven on the edge of the tie nearest the joint, as the nearer it stands to the joint the better is the assistance it can render in holding the joint to gage. The best plan, however, is to double spike the ties on the outside of the outer rail on all curves. The cost of the extra spikes is but a comparatively small item, and the rail is so much more firmly supported that the use of rail braces or tie plates may be unnecessary, where in many cases with single spiking they might be needed. This matter is referred to again under the subject "Rail Braces," § 49, Chap. V. When spiking ties in this manner the spiker standing inside the track should strike across the rail and help his partner down with the extra spike.

On the gage side of the track every third tie at the farthest, that is, at least one-third of the ties, should be spiked to the gage; but where the ties lie very unevenly, and on curves of short radius, the rail should be spiked to the gage on alternate ties. It is more important that men spiking with the gage should be experienced and skillful in driving spikes than it is with spikers on the line side. The nipper for the gage spikers should keep the rail thrown nearly to the gage ahead of them. If the line side is left badly out of line after being spiked it is well to throw it into fair line before spiking the gage side. Where the tie that is being spiked is held up firmly the rail can be moved slightly to gage by a stroke sidewise with the hammer; if not, or if it be moved slightly out of gage after the spikes have been started, but before they are down, it can be drawn powerfully by slightly bending over the spike on the side from which the rail is to be moved, and as the spike is driven further down it will crowd the rail over. There are those who object to such bending of the spike to crowd the rail while driving; but if it be done by one who knows how and who can handle a hammer properly it is the quickest and most practicable way, and no harm need be done. It saves time in getting the rail to good gage and an experienced trackman would think of no other way. In order that the spike may crowd or "draw" with most force when driven in this manner it should be started perpendicularly to the tie face, the same as when driving a spike under ordinary conditions, and not slantwise under the rail, as some wrongly suppose; then it should not be bent over until after half way down, since the body of the spike is then firmly held in the tie and, by bending the spike and driving straight down upon it, a powerful side pressure is exerted against the rail. In curves of short radius a sharply pointed pick is the best tool for crowding and holding the rail to gage. If the gage is tight the inside spiker starts his spike first, and if it is loose the outside spiker starts his spike first, and the first spike started should put the rail to gage before the other spike is started. Then if there be no tendency in the rail to spring itself out of gage both spikes should be put down together; otherwise the advantage should be given the spike first started. But if a slight bending inward of this spike will not bring the proper gage the rail should be moved by sticking a pick into the face of the tie ahead and prying it over. The gage should rest squarely across the rail just far enough in advance of the tie which is being spiked to be out of the way of the hammer of the inside spiker, and it should be kept there until the tie is spiked. The men who do the gaging cannot spike as rapidly as the other spikers and, where the ties are so soft that a spike can be put down with not more than three hammer blows, one spiker is enough to go with the gage; for where under such circumstances there are two, one will be standing still doing nothing a large part of the time; and so, to economize time, he might better form part of another spiking crew.

Rails should be gaged to within almost a hair's breadth, because it can just as well be done that way after men become a little expert. Of course there is no real necessity for such close work except in its moral effect, for if any looseness is allowed in this respect there is no telling where it will end. The gage should just come to place on being raised 3 or 4 ins. at one end and let drop; if there can be any movement of it across the track it is too loose; if it will not drop to place it is too tight. The gages should all be tested and closely inspected by the foreman every morning, without fail. There is more necessity for watching gages on track-laying than in track repair work, for irresponsible men will sometimes permit the rail to spring inward on the gage with such force that one of its lugs is loosened, and say nothing about it. It is the duty of the men spiking the gage side to see that all ties spiked are put square with the rails, and also to spike no tie having a warped or twisted face until it has been adzed to fit evenly with the rail base on that side. Of course it is taken for granted that when spiking the line side both edges of each tie face have been brought up evenly to the rail base on that side. Sometimes the necessity for adzing does not appear until after one end of the tie has been spiked.

In order to make haste, sometimes, when the crew is short-handed, only the joint, center and quarter ties are spiked before the outfit train is let over them; but it is better not to do this, because where there are so few spikes holding, on rails which have not as yet been brought to line and surface, there is, at best, liability of spreading slightly the gage, thus making it necessary to regage the rails before the remaining spikes are driven, if good work is to be done. It is cheaper in the end to go slower, spike all the ties as the work progresses, and do everything well. The expense of regaging new track disturbed in the manner noted will usually be found to exceed any saving that can be effected by skipping part of the work temporarily and leaving the rest to be done at some time later, especially if the first work done is liable to be injured in the meantime. Foremen should bear in mind that the tendency of things in track-laying is usually toward loose methods, and that they must constantly look out for careless work and correct it as occasion requires. Possibly it may seem to the casual observer that much has been said in the foregoing about a matter of little consequence, as spiking might at first appear to be, but experienced trackmen well know that there are men who, if not taught, would not learn to spike properly in 40 years.

In the present connection mention may be made of a machine for driving spikes in track-laying that has been used on the Detroit United

Ry. There is a low four-wheel truck, the frame of which is suspended below the axles, and this truck carries an upright boiler and two steam hammers, the latter being located to stand in position over the two rails. Opposite each hammer there is a pair of tongs used for picking up the tie and holding it firmly up to the rail as it is being spiked. These tongs are operated by a rock shaft extending across the tops of the cylinders of the steam hammers, and the leverage is such that the tie is held up against the rail with a pressure of four tons. Each hammer drives two spikes at one time, and the force applied is such that spikes in cedar ties are driven with two blows. The rail is held to gage by a cross bar in front of the machine, engaging the rails by means of rollers at the ends, and unless the gage is exact the hammers will not hit the spikes. The machine is operated by two men, and it will spike about a half mile of track per day. It was designed by Mr. J. Kerwin, superintendent of tracks for the road named, and is illustrated in the Railway and Engineering Review of May 17, 1902.

28. The Track-Laying Crew.—Since much depends upon the skill which men acquire while engaged in the different kinds of work in track-laying, it is well to endeavor to get men who will remain while the work lasts. Almost all of the work requires lively men, to expedite the work, of course, but more especially because there is much to be done where two or more men must work together, and each at intervals which begin only after some other has made ready; that is, in many cases one man must "wait on another man's motion." Take, for instance, two spikers at work, with a nipper. Each spiker must wait while the other starts his spike, and both spikers must wait for the nipper to hold up the tie. After the spike is driven all three must take a step or two to the next tie ahead. So it is that a large portion of the time is consumed in getting ready and only a comparatively small portion at putting down the spikes; and thus it necessarily goes throughout all the work. But men who are slow of motion, unsteady of movement, or lazy, always "get ready" with deliberation; and here is where much time can be killed and not be so easily seen, except as results will show. There is but little use for lazy men or men of slow motion around track-laying, even at any price. Men who are lively, steady and intelligent will do much more work than men not so qualified, and do it better, without hurry, worry, fatigue or grumbling.

Men working with the rails, commonly called "the iron men"—splicers, spikers and rail-car men—are usually paid about one-third more wages than the men who handle the ties. It is well to so grade the work, since it has a tendency to make each man feel some responsibility in his position. Men who work with the rail car, including the foreman, should all be able to speak the same language, and they should be strong, active men; no old or infirm men should be put at handling rails; and it is a place where awkward men of any age are liable to get hurt. Spikers should be reliable men, able to swing a hammer freely; muscle-bound men can never spike well. Strappers should be quick and steady, although it is not necessary that rapid movements should be constantly kept up. It is a great mistake to think that almost any kind of a man will do for "nipping" or holding up ties. If there is any tool a slovenly man will handle awkwardly it is a bar; while for a lazy man a job at sitting on a bar holding up ties is a "picnic." The nipper should be an active man. Instead of standing and watching the spiker start his spike he should be getting his block and bar in position to raise the tie promptly when the time comes. He should also know enough intuitively about the laws of the lever to fix a fulcrum properly for his bar, so as to get a good purchase. Reliable, industrious boys can do this work. Old or infirm men do well at distributing spikes and bolts, collecting expansion shims, carrying water, etc. Men not active at handling tools can work on the ties better than anywhere else, but lazy men should be discharged. The two or more men who line and space the ties should be paid the same wages as the iron men, because they are engaged in work which must be relied upon.

In regard to the length of track a given number of men can lay in a day it is difficult to give definite estimates, since so much depends upon local conditions and the circumstances. The opportunity for distributing the ties cuts the most variable figure in the cost of labor in track-laying. The weight of the ties and their quality, as to whether hard or soft; the weight of the rails, and manner of laying them (square or broken joints); the condition of the roadbed with respect to grades, curves, open culverts, etc.; the intelligence of the foremen and the control they have over the men, as well as the general intelligence and willingness of the men; the success of the system of forwarding materials from the base of supplies; and a score of other things—all determine very largely the number of men required to lay any certain length of track per day.

Where the ties are hauled ahead with teams, 56 laborers, three foremen and 11 teams ought to lay a mile of track in 10 hours, under average conditions, without hurrying. The men would be divided up about as follows:

4 men loading tie wagons.
10 teamsters and 10 teams haul. ties.
6 men placing, lining and spacing ties.
8 men unloading and placing rails*.
2 head strappers.
4 back strappers.
12 spikers.
6 nippers.
1 man distributing spikes.
1 distrib. bolts and collect. expan. shims.
1 water boy.
1 teamster, 1 team haul. rail car.

56 men, total laborers.

*These men unload the rails from the supply train, load the rail car and lay the rails to place on the ties.

Where the ties are run out on rail cars and carried ahead—one man carrying a tie—64 laborers, three foremen and two teams ought to lay a mile of track in 10 hours, under average conditions, without hurrying. This arrangement allows 21 men to unload ties from cars, load them upon the rail car, and carry ahead and drop them upon the grade. Circumstances might so require that to keep things moving smoothly a slight change would be made from the arrangement given and the men changed around to some extent; as, for instance, should the tie men get behind in their work the rail car men could give them a hand; or if the force at splicing and spiking be not able to keep up, the rail men could be shifted for awhile to assist them. It is practicable to get enough men together to lay four or more miles of track per day of 10 hours; but, all things considered, where time is not the most important element, it probably costs least per mile to lay about 1½ miles per day, providing all conditions are most favorable.

Two men working together can lay to place, line and space about ⅓ mile of ties per day of 10 hours. One man can put on and bolt up about 60 four-bolt splices in a day. Two men and a nipper ought to spike about 1100 ft. of track in soft ties, or 750 ft. of track in hard ties, in a day. Eight men can unload from supply train, load on rail car, unload and lay to place enough 30-ft. average-weight rails for a mile of track per day; where they do not go back to load they can unload from a rail car and lay to place 2 miles per day. This latter arrangement would require a crew part of the time to load; the rest of the time they could be put at handling ties. Two rail cars would be needed. The rail car should always be hauled with the team, whether loaded or empty, unless when going one way it should be down grade sufficiently for the car to run itself. To lay to place the rails for 3 miles of track per day requires two sets, or about 15 men, unloading from both sides of the rail car at the same time. One crew, large enough to pick up and carry the rails easily, could attend to the loading of the rail cars. The outfit train would have to be kept close up to the work. To expedite the work it is sometimes the practice to lay only half of the ties ahead of the supply train. As the train moves along the remaining ties are thrown off about where they are needed and a gang working in rear of the train places them in the track and completes the spiking.

Track-Laying Records.—In order to show what has been done in the way of rapid track-laying some official records of work on the Great Northern Ry. will be given. The materials were distributed with teams and rail cars just ahead of the train, and the work throughout was done in the ordinary way. Between Minot, N. D., and Great Falls, Mont., during the month of August, 1887, an average of 4.27 miles of track was laid per day of 10 hours. The force was distributed as follows:

Unload rails and load iron cars....	24	Marking and adjusting joint ties...	4
Rail car gang	13	Lining ties	2
Spikers	32	Hauling ties ......65 teams, men	65
Nippers	16	Distributing spikes	2
Strappers	10	Lining track behind	8
Loading ties	26	Hauling rails ......6 horses, men	3
Distributing ties	8		
Spacing ties	4	Total men.....................	217

Six rail cars were used, and as soon as each car was unloaded at the front it was run back behind the spikers and taken off the track. When the last of the six cars had been unloaded the other five were again placed upon the track and the supply train moved ahead. The best record made was 8.01 miles of track laid in 11½ hours, the force being distributed as follows:

Hauling ties ......75 teams, men	75	Spikers	38
Loading ties	28	Nippers	19
Distributing ties	10	Strappers	12
Spacing ties	4	Distributing spikes	2
Lining ties	2	Lining track	8
Marking and placing joint ties....	4	Hauling rails ....6 horses, men	3
Unload. flats and loading iron cars	24		
Unload. iron cars and placing rails	13	Total men	242

This day's work at track-laying, "from one end," is supposed to be the best on record. I was told by a reliable trackman, who worked with the rail-laying crew on that occasion, that the same party of 13 men unloaded from the rail cars and laid down every rail in the whole distance of 8 miles. Such must have been a remarkable test of human endurance. On another day (July 16), working from daylight to dark, 7 miles and 1040 ft, of track were laid. It is said that between Apl. 2 and Nov. 17 of that year the same outfit laid 643 miles of track, or an average of 3¼ miles for each day excepting Sundays. The man credited with the entire charge of this work, including the organization of the working forces and the arrangements for forwarding materials and supplies, was Mr. David C. Shepard, of St. Paul, Minn. An average progress of three miles of track laid per day and occasional records of four miles per day, with 160 to 185 men, has been made on other roads. On Apl. 28, 1869, the Central Pacific R. R. made a record of 10 miles and 58 ft. of track laid from one end in 11 hours. There were 96 two-horse tie teams and a very large force of men. The ties for 2 miles and a fraction had been hauled out the day before, but all the rest of the material was hauled to place on the day it was laid, some of the ties being teamed 12 miles. Some time before this the Union Pacific R. R. laid 6.8 miles of track in one day, working from 4 a. m. to midnight.

Some data on laying tie-plated track will also be of interest. In building the Kersey R. R., in 1900, the method followed was to run out the rails and ties together, on the same rail car, and lay only half of the ties in advance of the supply train. The working forces were distributed as follows: Track-laying gang, 1 foreman, 7 men with the iron car trucking rails and ties, 4 strappers, 4 spikers, 2 nippers, 1 lining ties (total 19); supply gang, 1 foreman, 12 unloading ties and rails and loading upon iron cars, 5 at supplying joint fastenings, spikes, etc., and picking up scattered material (total 18); back-tieing gang, 1 foreman, 4 spikers, 2 nippers, 1 lining ties, 4 unloading ties, spikes, etc. (total 12). In the three gangs there was a grand total of 3 foremen and 46 men. The track was laid with 85-lb. rails, Weber 6-bolt splices, and Q & W 3-hole tie plates were used on all curves. The maximum curvature was 12½ deg., the average curvature 5½ deg. and the curves constituted 43½ per cent of the length of the road. The tie plates were applied to the ties by a swedging gang in advance of the laying of the rails. The track was laid on a descending grade of 2 per cent, so that teams were not required to haul the two rail cars that were used. The cars containing material for back-tieing were cut loose some distance in the rear and let down by means of the brakes toward the material train ahead. The average length of track laid per day was 2870 ft. and the maximum 3290 ft.

In building the Point Richmond extension of the San Francisco & San Joaquin Valley Ry. material for 1 mile of track, including 4 car-loads of rails and 6 car-loads of ties, was carried out from the nearest side-track each morning. The train was made up in the following order: Pioneer car, 3 cars ties, 2 cars rails, 3 cars ties, 2 cars rails and the tool car. All the ties had tie plates embedded in them, in the yard, before shipment. The tie plates used at the joints, however, had a different spacing of the spike holes from those used on intermediate ties, and after the ties were laid one man, called the "tie-plater," took out the ordinary plates and put in the joint plates. During October, 1899, an average force of 44½ men laid an average of 2850 ft. of track per day, the maximum day's work, with 57 men, being 5400 ft. of track. The rails weighed 62½ lbs. per yard and were laid with broken joints. During February and March, 1900, an average force of 48 men averaged 3500 ft. of track laid per day, the maximum day's work being 4500 ft. of track laid with 52½ men. The rails were of 75-lb. section and were laid broken jointed. The rail-car men unloaded the rails from the material train and loaded them upon the rail car. The fastenings—splice bars, bolts and spikes—were also loaded upon the rail car, with the rails, and dropped off at proper intervals by the heelers. The ties were hauled out on a rail car and carried around to the front by hand. The general distribution of the men was about as follows:

General foreman	1
Sub-foremen	3
Strappers	4
Rail-car men	10
Spikers	8
Nippers	4
Tie line man	1
Lining ties	2
Tie-plater	1
Spike peddler	1
Spacing ties	2
Spacing rails and head bolting	2
Back bolting	2
Carrying ties	10
Picking up scattered material	1
Total men	52

It is doubtful whether an experienced man would estimate closely the cost of laying any certain piece of track of considerable length, no matter how good his facilities for getting statistics. There are so many outside circumstances to affect the work, and so many delays that cannot be foreseen, that frequently old contractors have lost heavily after having based their estimates upon conditions which their experience led them to think were like or similar to those to be met in the work at hand. The cost has ranged from $175 to $500 per mile. An average rate for long-distance track-laying would perhaps be somewhere between $200 and $250, for common labor at $2 per day without board.

On lines where there are numerous bridges to be built it is frequently the case that track-laying is seriously delayed. Especially is such liable to occur in a country where suitable timber for trestles or other bridges cannot be found and the country is badly cut up and without roads over which material may be hauled for the construction of the bridges in advance of the track-laying. It is quite commonly the practice to cut out the timber for the framed wooden bridges in advance and have it ready to be put together as soon as it arrives on the ground. Then as the track-laying forces approach the site of the bridge the timber is shipped to the end of the track, hauled ahead by teams and erected as rapidly as possible. Another scheme where streams are met and bridges are not ready, if not too high, is to "shoofly" and go around on the ground, or on cribbing, rather than to stop and wait for the bridge builders. When track is in this way laid around some point where a bridge or fill is to be built across, or is laid temporarily on the line, but at a lower level than the bridge or fill, measurements should be taken across with a steel tape to get the distance on the permanent line at grade; this is to determine where the joints should begin in laying rails on the other side, so that after the bridge or fill is completed rails can be put in without requiring short pieces. Allowance should be made for expansion, and if the measurements cannot be taken on the grade of the permanent line, plumb lines should be used. Where piles are to be driven, as in crossing swamps, small streams, gullies, etc., the track is sometimes laid on temporary cribbing on the permanent line, at or near grade. A temporary cribbing can be made quickly and cheaply with cross ties, sawed ones being preferred. The ties are easily handled and are not injured when so used. If the ravine or other depression crossed is deep the crib should consist of several tiers and sometimes it will be found necessary to lay the ties double, that is, two ties side by side in each tier, in order to make a high crib stable enough to bear the locomotive. In cases where the track-laying must be delayed on account of bridge building or for other cause, it is well to send the men back to surface and ballast what has been laid, and so keep them at work. It is a good plan to begin surfacing as soon as the track-laying gets well started, as then the crew so employed will be a reserve force from which men may be drawn to recruit the track-laying gang as the laborers become sick, sore or dissatisfied and fall out.

29. Tools for Laying Track.—Allowing for breakage and for changing men from some kinds of work to other kinds at times, the following tools will be needed for a track-laying crew of 64 men:

26 spike hammers
18 pinch bars.
12 track wrenches.
16 picks.
4 pinch bars 3½ ft. long.
2 water buckets, 4 dippers.
72 track shovels.
3 adzes.
4 chopping axes.
2 hand axes.
4 rail forks.
6 rail tongs.
2 ratchet drills and bits.
50 expansion shims, ¼ in.
100 expansion shims, ⅛ in.
200 expansion shims, 1-16 in.
1 grindstone.
3 sixteen-pound sledges.
3 adz handles (extra).
48 spike ham'r h'ndl's (extra).
12 pick handles (extra).
4 ax handles (extra).
2 track jacks.
2 tie-spacing poles.
1 drawshave.
4 claw bars.
1 push car.
3 rail cars.
1 hand car.
1 keg 10 d. wire nails.
1 keg 20 d. wire nails.
1 keg 40 d. wire nails.
1 keg 60 d. wire nails.
3 oilers.
4 gallons black oil.
4 white lanterns
2 Red lanterns, 2 red flags.
Extra white and red lantern globes.
3 monkey wrenches, 6, 8 and 12-in.
2 nail claw hammers.
1 steel tape 100 ft. long.
1 linen tape 50 ft. long.
6 track gages.
2 crosscut saws.
2 hand saws.
4 water barrels.
2 tie squares.
1 rail curver.
1 rail bender (jim-crow).
2 curving hooks.
2 track levers.
1 tie line, 1,000 ft. long.
Flat, round, quarter-round, eighth-round, and three-cornered files, three or four sizes of each.
4 horses or mules, with harness for hitching double, single or in tandem.
2 lumber wagons.
2 large tool boxes.
2 thermometers.
1 rail car clamp gage.
24 track chisels.
3 one-inch ropes for rail cars, ring and hook on each.
1 chalk line.
1 track level.
6 cold chisels.
6 switch locks.
4 doz. torpedoes.
1 tool car.
1 brace and 6 bits.
1 two-inch auger.

In case it is intended to turn the crew to surfacing and ballasting at times there would be needed, in addition to the above, 1 level board, 2 track jacks and 32 tamping picks, where broken or crushed stone ballast is used. A small car about 3 ft. long, consisting essentially of a box about 2 ft. long, 12 ins. wide and 6 ins. deep, mounted on two double-flanged wheels in tandem, so as to be pushed along on one rail, is sometimes furnished the man who distributes or "peddles" the spikes. It will carry about 100 lbs. of spikes and is quite convenient. Another receptacle sometimes furnished the spike peddler is a strong apron of thick leather or coarse bagging, which he may fill with spikes and carry in convenient position for distribution. The rail fork (*E*, Fig. 295), included in the list of tools, bears some resemblance to a track wrench. It is generally 30 to 36 ins. long and the head is slotted ¾x4 ins. In use the forked end is thrust straddle the web, at the end of the rail. It is most serviceable in handling or turning over rails in piles, or in lifting them clear of the pile so as to get hold with the hands or get a chance to pry with a bar. It comes handy in unloading rails from cars, in track-laying and on work trains when distributing rails for renewals.

30. Track-Laying Machines.—A track-laying machine is an arrangement of devices for running ties and rails to the head end of a material train. The Holman machine consists of a series of tramways or rollers about 20 ins. wide, arranged in frames or sections about 30 ft. long, which are supported upon brackets attached to the stake pockets at the sides of ordinary flat cars on which the materials for laying the track have been forwarded, no change in the cars being required. The brackets are in adjustable lengths, so that each tramway may be inclined slightly from the rear forward. The brackets which support the tie trams at the rear stand above the level of the car floor, about knee high, while those at the front end are suspended below the level of the car floor. The sections are connected up continuously, forming an inclined rollway the whole length of the train, over which the ties and rails are pushed to the front, to be lifted and placed on the roadbed by the track-layers. The rollway for forwarding the rails is arranged on one side of the train (left hand facing the front) and that for the ties on the other side. The head car of the train carries a derrick or braced tower supporting stays for the chute or end section of the tie rollway, which is extended beyond the car 35 or 40 ft. The rail tramway extends ahead of the car 8 ft. On this car, called the "pioneer car" or "pilot car," are carried the tool boxes and the spikes, bolts and splices for each train-load of material. The spikes and bolts are usually carried in a large box (called the "pig trough") 7 ft. long suspended at the head end of the car crosswise the track, about hip high. As the ties and rails are placed in position two strappers and four spikers quickly fasten each pair of rails, placing only two bolts in each splice and spiking only the center and quarter ties. The train advances one rail length at a time, the locomotive engineer at the rear taking signals from a man posted on top of the frame on the pilot car. The work of completing the splicing and spiking is attended to in rear of the train, only such work being done in front as is necessary to make safe for the train to pass. The splice bolts are not fully tightened, and it is also quite commonly the practice to place only half the ties in advance of the train.

The ordinary and most convenient rate of laying track with this machine, when full tieing ahead, is 1½ miles per day. The force required at this speed includes 40 to 45 men with the machine and 22 to 28 men behind the train, the ordinary distribution being about as follows: In front of the machine, 6 or 8 tie carriers, 1 tie liner, 1 chute man, 6 or 8 rail carriers, 2 bolters, 2 nippers, 4 spikers, 1 foreman; on the train, 2 men unloading rails, two men pushing rails, 14 to 16 men handling ties; behind the train, 2 tie spacers, 8 to 12 spikers, 4 to 6 nippers, 3 bolters, 1 spike peddler, 4 men lining track, 1 foreman. With larger crews 1¾ to 2 miles of track can be laid each day. In the construction of the Washington County R. R., in Maine, in 1899, a crew of 110 men working with a Holman machine laid 10,300 ft. of track, fully tied and spiked, in 9 hours. On the Pacific extension of the Great Northern Ry., in 1891, the average speed with a Holman machine for 82 short days during the winter was more than 1½ miles per day, and in 25 days the average speed was 2 miles per day; the best record was 140 stations, or 2.65 miles in one day.

The method of operation just described applies to what is now known as the old Holman machine, and was in vogue for many years. Important changes have taken place, however, the first of the improved machines being used in 1901. With the old machine the cars loaded with rails were placed ahead of those loaded with ties, or in rear of the pioneer car. With the new machine the former plan of making up the construction train is entirely reversed, the cars loaded with ties now being ahead, coupled in directly behind the pioneer or tool car. The cars loaded with rails are placed in rear of the ties. By this arrangement fewer tie shovers are needed, thus economizing in the number of men required to operate the machine and also to some extent expediting the delivery of the ties. The rails, instead of being pushed ahead singly, as on the old machine, are now coupled together with trace chains or with regular splices and bolts, and pulled forward in a continuous string by means of a drum and cable on the pioneer car. This drum is on the end of a shaft extending beyond the side of the car, and is located over the

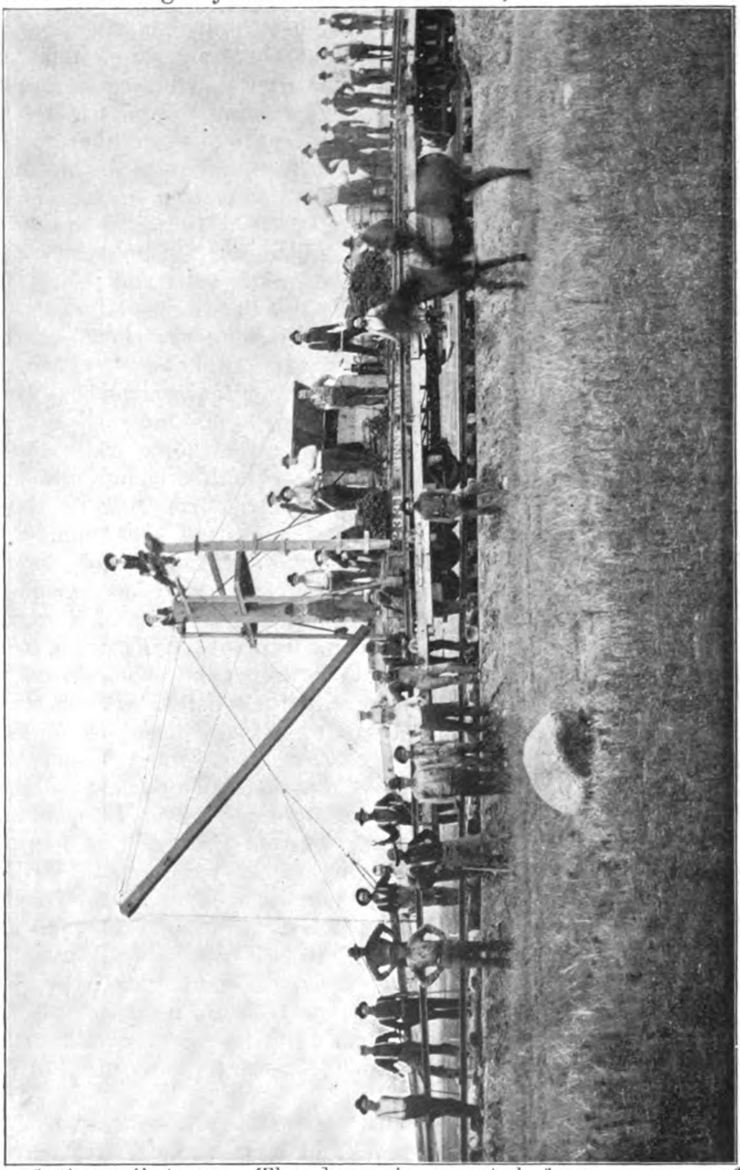

Fig. 34.—Holman-Burke Track-Laying Machine, M., St. P. & S. S. M. Ry.

center of the rail tram. The drum is operated from an axle of the car, by means of a sprocket wheel and chain. The rails are run forward over the tram in two lines, side by side, until they reach the pioneer car, where they take separate rollers, to facilitate uncoupling the splices as they are lifted down to the ties. The cable is provided with a clamp, which is carried back and attached to the rail. The mechanism is so adjusted that the rails are pulled forward at the same speed as that of the train; and as the train moves forward the length of a rail a new pair of rails is coupled on at the rear. As each successive forward movement is completed a clutch connecting the winding drum to the shaft is thrown out of gear and the clamp is carried back a rail length and attached to the rails for another pull ahead. The operation is repeated each time a length of rails is taken down by the rail gang. The new arrangement dispenses with four or five tie tramways and attachments, which are heavier than the rail tramways, thereby saving labor and time in putting up the machine. A foreman and 30 to 33 men distributed in front of the machine and on the train can lay 1½ miles of track per day.

An interesting improvement of the Holman machine, devised by Mr. James Burke, formerly general roadmaster of the Minneapolis, St. Paul & Sault Ste. Marie Ry., has been in service on that road, having been first put to use in laying the Bismarck extension from Kulm to Braddock, N. D., 80 miles, during October, 1898; since which time other machines have been built and used by railway contractors. The improvement consists in a derrick erected at the front end of the pilot car, to lift the rail from the end of the tram and lower it to position on the ties, the purpose of the device being to do the work which is usually performed by a rail-lifting gang. The arrangement is illustrated in Fig. 34, which shows a Holman track-laying machine, the rail tram of which appears to view at the front side of the pilot car and the tie tram or chute at the rear side. The derrick mast, which is stayed to the pilot car, carries a platform near its top for the pilot, who signals the engineer for the movements of the train. The rail is lifted by a chain that winds upon a windlass which is attached to the mast of the derrick and is operated by one man. In the operation of the machine one man stands at the windlass of the derrick, another attends to the grapple and one man at each end of the rail guides it to place. Before the middle point of the rail travels beyond the end of the tram the rail is caught by the grapple, at about the middle, and almost simultaneously by the man at each end of the rail. At the same time the man at the windlass manipulates the same to lift the rail and sustain it entirely from the derrick, when the two men at the ends of the rail swing it into its position on the ties. The man at the rear end of the rail heels the same to the forward end of the rail previously laid, while the man at the forward end of the rail moves it to proper alignment. In this way the rails are laid without any lifting by hand, and the arrangement does away with the laborious and slower way of carrying them by hand from a tram which projects only a few feet beyond the front end of the car.

On one occasion this machine, in 10 hours, handled the material for laying 12,000 ft. or 2.28 miles of track. This track was laid by 93 men stationed as follows: 12 men carrying ties from the end of the tram, 1 man running the tie line, 1 running the tie spacing poles, 1 holding ties at the end of the tram, 1 tapping rails back with the spike maul to insure proper expansion, 3 handling rails with the derrick, 1 on windlass of the derrick, 3 spikers and 3 nippers ahead of the pilot car, 1 gage bearer, 2 bolters ahead of the pilot car, 1 bolter on the platform putting on angle bars as the rails were shoved by him in the tram, 1 man on the pilot car keeping bolts, spikes and angle bars in place, 6 men putting ties into the tram, 12 pulling ties to the front, 2 moving rails into the tram, 3 pulling rails. In rear of the train there were 10 spikers, 5 nippers, 2 spacing ties under joints, 2 spike and bolt peddlers, 6 bolters, 6 men lining track and one man carrying water.

There was 1 foreman in charge ahead of the pilot car, 1 in charge of the men on the train, 1 in charge of the men in rear of the train, 1 lining track and 1 general foreman. One conductor and two brakemen handled the train. The track was laid with 60-lb rails, 16 ties to the rail and four-bolt angle bars. This was the largest day's work. In laying 77 miles of track the average fair day's work was two miles, with a few less men. According to official statements this derrick put the question of rails out of the way, so far as the speed of track-laying was concerned, as then the amount of track that could be laid was determined only by the number of ties that could be got to the front through the tie trams, carried away from the end and placed for the rails to be laid upon. Previously to that time the part of the work most responsible for delays was the slow and laborious way of handling the rails by hand. When it was desired to lay two miles of track per day, it required 14 men to handle 70-lb rails and 12 men for 60-lb. rails. The spikers were obliged to wait until the second rail was laid before they could drive any of the spikes, there being so many men in the way, and the large body of rail men were then obliged to wait for the spiking to be done. With the

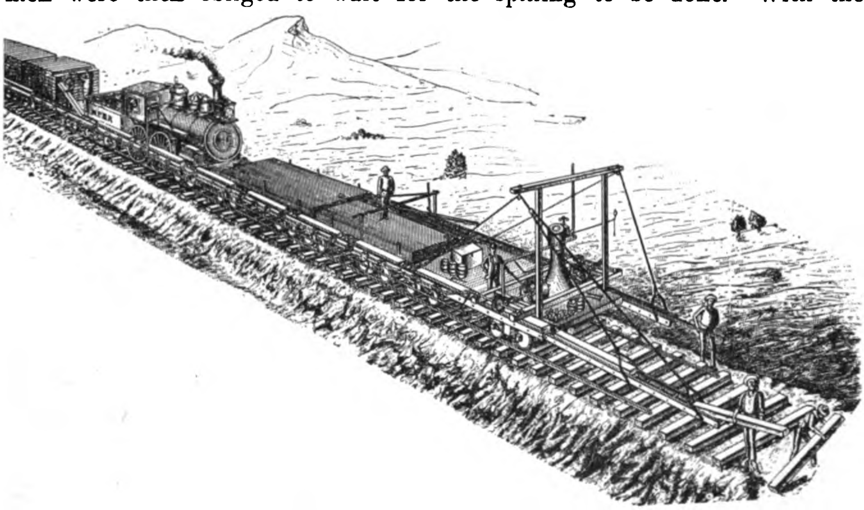

Fig. 35.—Roberts Track-Laying Machine.

derrick and the rail tram extended out to 16 feet ahead of the car the rail first to be laid when the stop is made is out and suspended, held by the derrick ready to be dropped the instant the car stops. By this time the second rail has traveled forward as far as the point where it is to be laid, and is quickly dropped to its position on the ties. It is figured that the derrick saves from $12 to $14 per day, over the old method of lifting the rails by hand; and not only this, but it increases the efficiency of the whole machine.

The Roberts Machine.—The general arrangement of the Roberts track-laying machine is similar to that of the Holman, except that in the former the tram rollers are driven by steam. The conveyor part of the Roberts machine (Fig. 35) consists of rollers arranged in framed sections about 32 ft. long, supported at a plane just below the bed of the cars on brackets hung from the stake pockets. These tramways may be attached to any kind of car—a gondola, box or stock car, as well as a flat car. The supporting brackets are inserted from the bottom of the stake pockets, so that ties which project over the edge of flat cars do not interfere with the work of attaching the machine to the cars. Alternate rollers are bevel geared to a shaft extending the length of the cars, driven by an upright steam engine on the pilot car, taking steam from the locomotive. The shaft is in sections and provided with universal couplings, so as to allow for angularity occasioned by curves in the track. As half of the rollers (alternate ones) are idle, the live ones on the tie side are corrugated or fluted, so as to bite into the tie and force it along. The upper surface of the live rollers is about 1 in. higher than the idle ones, which throws most of the weight on the live rollers. The tie trams can be operated when filled with ties their entire length, the maximum rate of delivery being 50 ties per minute. The connection between the driving shafts and the engine is by friction clutch, so as to prevent breaking in case of clogging or sudden stopping of the shaft in any manner. The rails are carried along one side of the train and the ties along the other, as in the Holman machines, but the two sets of shafting may be driven independently, if desired. The flats loaded with rails are usually placed ahead of the locomotive, immediately in rear of the machine car, and the ties behind the locomotive; it is necessary therefore to arrange the rollway so as to carry the ties past the locomotive. In this machine the tie chute is extended 60 ft. ahead of the pilot or machine car, such arrangement enabling the tie men to keep out of the way of the men laying the rails, which are delivered but a little in advance of the end of the car. In order to allow room for bolting, the end rail chute extends 6 ft. ahead of the end of the car. The front end of the machine car is used to carry splice bars, bolts and spikes, where they will be within easy reach of the track-layers. The rear part of the car carries tool boxes and such short pieces of rail as may be necessary.

In the operation of the machine eight men are required on the train, in the following positions: Four men throwing ties into the tramways, 2 men loading rails into the rail trams, 1 man to operate the engine on the pilot car, and one oiler and pilot-car assistant. To facilitate close movement and prevent running off the end of the track a brake is set on each end of the train, to take out the slack between the cars. The locomotive engineer is signaled by means of a small whistle attached to the steam piping on the pilot car. A feature of great convenience in the operation of the machine is the flexibility of which it is capable in the delivery of material, it being equally convenient to forward pieces from any car of the train at any time, and in any desired order. Thus if hardwood ties are to be used on the curves and softwood ties on the tangents the cars may be coupled into the train in any convenient order and the ties of particular quality sent forward on the trams as required, without reference to the location of the car or cars on which they are carried. The same convenience of delivery applies also to the forwarding of curved or short rails from whatever car of the train they are on, and just at the particular time or place they may be in demand. For the building of temporary structures where small bridge or culvert openings occur the timber or other material may be carried on extra cars at the rear of the train and sent forward over the tramways as needed. It is also to be noted that the labor required in connection with the operation of the machine and the speed of delivery are independent of the length of the train, since the material requires no attention from the time it is put into the trams until it arrives at the front. From the fact that no labor is required to push the material forward the practice in vogue when using this machine is to full tie the track ahead. As the speed of delivery is regulated by steam power and the work of throwing ties into the trams nothing is to be gained in speed by half tieing ahead of the train.

The usual method of procedure with the Roberts machine is to full tie, half bolt and quarter spike the track ahead of the train, completing the work with a gang of bolters and spikers in the rear. The convenient average speed of track-laying seems to be about 2 miles per day, with a capacity for better records by rushing the work. The force required at a 2-mile gait is three foremen and 65 to 80 men, all told, distributed about as follows: Ahead of train, 8 placing rails, 8 to 10 carrying ties, 4 head spikers, 2 head nippers, 3 head strappers, 1 tie liner (total 26 to 28 men); on machine and train, 8 men, as already noted; in rear gang, 4 to 6 back bolters, 2 spike and bolt peddlers, 12 to 20 back spikers, 6 to 10 back nippers, 2 spacing ties, 5 lining track (total 31 to 45 men). In laying the Columbia & Western branch of the Canadian Pacific Ry., in 1899, the average speed with this machine was 1000 ft. of track laid, complete, per hour. In this work no spiking was done in advance of the machine or train. The rails were held to gage by "bridle bars," two in each rail length on tangents and three on curves. These bars consisted of ⅝-in. rods flattened at the ends and turned up to hook over the rail flange, on the outside, with a slot at the inside edge of the rail flange, into which a spike was dropped to secure the rail. The crew ahead of the machine contained 22 to 24 men, including 1 tie line stretcher, 8 to 10 tie carriers, 1 tie marker, 2 tie liners, 8 men placing rails, and 2 strappers. At the most rapid rate a pair of rails was laid every minute, and sometimes a little quicker. In rear of the train

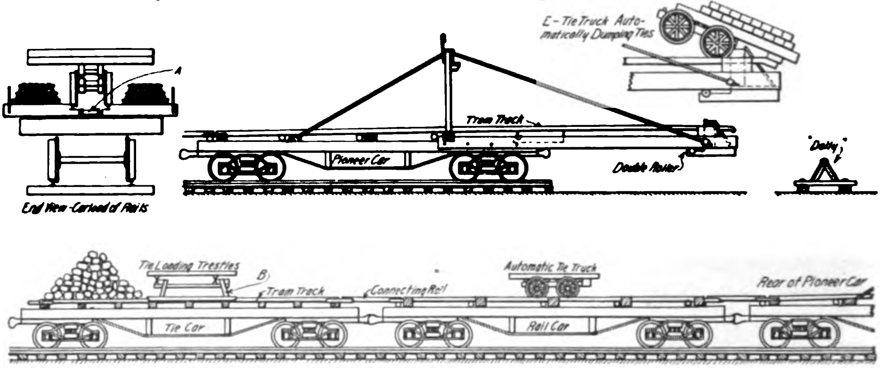

Fig. 36.—Details of Harris Track-Laying Machine.

the bridle or gage bars were taken off and sent forward over the tie trams in a long, narrow box. The tie plates, which were used, were dropped off the train and placed under the rails at the rear. The grades being heavy, two medium-weight consolidation locomotives were required to push 14 car-loads of material. The track-laying machine would work on 14-deg. curves, but not on a 22-deg. curve on which it was tried. A night train crew brought up during each night the loaded cars for the next day and at noon did the switching and made up the material train for the afternoon. In extending the St. Louis & San Francisco R. R. from Sapulpa, Ind. Ter., to Sherman, Tex., in 1900, 2.27 miles of track was laid each day of 10 hours with a Roberts track-laying machine, "without difficulty;" and during the same year, in laying extensions to the Chicago & Northwestern Ry., in Iowa, a machine of the same type made a record of 2½ miles per average day of 9 hours.

In the extension of the Chicago, Rock Island & Mexico Ry. southwest from Liberal, Kan., a Roberts track-laying machine was used, and when this work was started, in 1901, it was decided to call 2½ miles of track a day's work, regardless of the time taken in laying the same. This work was invariably performed in seven hours. The material was taken out in two trains: one in the early morning, the men returning to camp as soon as this was laid, when the second train would be taken out. The best time made in laying 1¼ miles of track (half a day's work) was three hours flat. This was done several times when the grade was favorable. The track-laying force consisted, on an average, of 190 men. The steel was of 80-lb. section, with Continuous joint splices. The ties were oak and hard pine. The surfacing gang, of about 250 men, followed the front as closely as practicable, generally one side-track in rear of the front camp. The telegraph line was built as rapidly as the track was laid, the telegraphic supplies forming a part of the track-laying material train. The fence gang was kept immediately in rear of the surfacers. The work of completing the line was practically finished simultaneously, in so far as track, telegraph line and fencing were concerned. The only delays sustained were those incident to overtaking the graders occasionally.

The Harris Machine.—The Harris track-laying machine consists of ordinary flat cars fitted up with a rollway for forwarding the rails and a tramway for a push car or truck on which the ties are run out to the front. Five 6x8-in.x11-ft. timbers or switch ties are laid across each car and spiked fast, and on these is laid a tram track of ordinary rails. On the old machines (which went out of use in 1900) the gage of this tram track was 8½ ft., but on the machines of later design the gage is only 2 ft., and the track is laid along the middle of the cars. Between the rails of this track, and on a level with base of rail, there are cast iron rollers 15 ins. long, on which the rails for track-laying are pushed to the front (*A*, Fig. 36). On the cars which carry the rails the cross timbers are framed out at the middle and the rails of the tram track are depressed to bring the top of rail flush with the tops of the timbers. This arrangement permits the supply rails, which are carried in piles on either side of the tramway, to be easily slid or rolled onto the rollers. Only the cars loaded with rails have the rollway, and these cars are, of course, placed ahead of the cars loaded with the ties. On the cars loaded with the ties the tram rails are laid on top of the cross timbers, and alternately between these long ties or timbers there are 8 ft. ties to afford close supports for the truck-loading horses or "trestles," to be described presently. The gaps in the tram track between the cars are closed by short pieces of rail having the bottom flange cut off at each end so that the web may be dropped between splice bars bolted to the ends of the fixed tram rails on the cars. Allowance is made in the length of the short connecting rails for slack between the cars. On the front car the tram track is extended 20 ft. ahead of the car and is held up by truss rods carried over a framed bent 10 or 12 ft. high and anchored at the back of the car. The ties are piled across the tramway, and the spikes, bolts and splice bars are chinked into spare space on the rail cars. The cross timbers, which project over the sides of the cars, carry a running plank on either side for the men to stand upon while loading the ties. It also affords a footway for the men pushing the tie truck and a place for the rail men to step aside while the loaded tie truck is passing.

The ties are not loaded upon the tie truck direct, but are first placed crosswise a pair of portable wooden horses or "tie-loading trestles" (*B*, Fig. 36) stood parallel with the tram track, on either side. These tie horses each have a top piece or upper frame carried on links, which is raised 4 ins. before the ties are placed upon it. After a truck-load of ties has been placed across the horses the empty truck, which is 2 ins. lower than the tops of the horses in their raised position, is run between the horses and under the pile of ties, at the same time automatically disengaging a latch which holds the load of ties in the raised position. In this manner the load is caused to drop 2 ins., onto the truck, the top pieces of the horses dropping 2 ins. further, clear of the load and out of the way of the movement of the same. The truck, as thus automatically loaded, is pushed to the front and the work of loading the horses is repeated. The horses stand on runners, and as each truck-load of ties is delivered they are pulled ahead to a new position within reach of the receding tie pile on the flat car.

In starting out to lay track the rails are thrown onto the rollway with a rail fork and pulled ahead to the pilot car by men with tongs or hooks. Here they are spliced and bolted together four rails at a time—that is, two rails in a stretch for each side of the track—using two bolts to each splice, allowing for expansion and putting in the expansion shims. In the meantime the tie truck or tram car has been loaded and pushed forward, and at the end of the tramway is run against chocks or stop blocks. (*E*, Fig. 36). The tram car body is made in two parts, the upper of which slides between guides, over the lower part, on rollers, so that when the car is brought to a stop at the end the load is shifted forward 30 ins., causing the car to overbalance, tilt forward and dump itself, throwing the ties crosswise on the roadbed. The car is then righted and run back for another load, while the rails which had been spliced and lying on the pilot car are run ahead off the car onto a portable dolly about 30 ins. high standing on runners, on the ties, about 25 ft. ahead of the extended tram track. Suspended from the cross timber at the end of the tram track there is a roller about a foot lower than the rollers on the flat car, which serves as an intermediate support for the rail between the end of the car and the dolly. The rails are run to a position opposite their place in the track and are then lifted down and heeled into splice bars fastened loosely to the last rails laid. In laying broken-jointed track the rails on the "long side" are simply run a half rail length further ahead on the rollers. As soon as the rails are in place the track is quarter spiked and the train is moved ahead 60 ft.

The foregoing is known as the method of "standard 60-ft. set-outs" and is the usual way of proceeding to lay 2 miles of track per day. In this case 34 to 42 men are required with the machine, according to the weight of rail, quality of the ties (soft or hard wood), efficiency of the men, organization, &c. Of this crew 14 men, called the "top force," are engaged on the cars as follows: four men loading ties, 3 men running tie car, 1 man breaking out rails onto the rollers, 4 men pulling rails with hooks and delivering them ahead, and 2 top bolters. The "ground force," or the men ahead of the machine, are distributed as follows: One man with tie line, 1 man with spacing pole and marking ties for line rail, 1 spike peddler, 1 man serving splice bars, 8 spikers, 4 nippers, 2 men carrying dolly, 1 "expansion man" (with sledge to drive rails back when necessary), 1 heeler (who, as a rule is the foreman of the ground force), 2 bolters and 4 to 6 extra men; or a total of 26 to 28 men. With soft wood ties the 4 to 6 "extra men" are usually dispensed with, and sometimes the force is cut down one or two more. The usual practice in laying 60-ft. "set-outs" is to half tie ahead. If it is desired to work a smaller crew, laying 1 to 1¼ miles per day, the rails are run down singly, or in 30-ft. "set-outs," the train moving ahead 30 ft. at a time; or by using the same force, half tieing the track and handling single rails in 60-ft. "set-outs," 1¼ to 1½ miles of track can be laid per day. For fast work, as when it is desired to lay 3 miles per day, a larger force is put on and the rails are handled in spliced sections of three each, or in 90-ft. "set-outs," the train then moving ahead 90 ft. at a time. In this case three dollies are used ahead of the pilot or pioneer car in running the rails to place.

With the Harris machine the track-layers in advance of the train are not divided into separate squads designated as tie carriers, rail carriers, spikers, etc., as in usual practice with other machines. Each truck-load of ties contains the proper number to lay the "set-out" of rails (30, 60 or 90 ft. of track, as the case may be) and as they are dumped the momentum of the truck throws them sprawling ahead over about 30 ft. of roadbed. As the rails cannot be laid until the ties are placed the whole track-laying gang ahead of the car, except the tie-line man, the two bolters, the splice carrier and the "fiddler" or tie marker, is first engaged in placing the ties, which is quickly done. The same men then run out the rails and lift them down and then divide up into spiking gangs and make ready for the train to advance. In rapid work the track in advance of the Harris machine is only half tied, the remainder of the ties being dropped off the box or other cars in which they happen to be loaded and which are coupled in behind the tramway cars. This arrangement saves transferring half the ties to the machine cars.

Before referring to records of work performed in connection with the use of this machine the difference in the methods of handling the ties on the old and new machines should be explained. On the old machine the tie truck had to be built wide, for the wide-gage track, and it was high enough to straddle the piles of rails on the rail cars. The tie truck for the machine of later design is narrow, running between the rail piles, as shown at the left in Fig. 36, and it is much lighter and easier to handle than the old device. On the old machine the ties were loaded directly upon the truck, by hand. For rapid work two tie trucks were used after the train became half unloaded, as then some time was lost in pushing the truck over the increased distance. In that case the hindermost truck was being loaded while the forward one was being pushed to the front and dumped. The rear truck was made somewhat higher than the other and when they met the load was transferred by sliding the ties onto the lower truck. The automatic tie-loading device of the present machine enables faster work to be done than was possible with the old machine. On the present machine the tie truck can be shoved forth and back on the run, if need be, stopping only an instant at either end for the truck to receive or dump its load. It is thus possible to keep a loaded tie truck on the move half the time. At the same time the present machine is more adaptable to the convenience of working a small crew and laying track at moderate speed, when desired. Four to 6 men can load and deliver ties for laying a mile of track per day; in laying 2 miles per day 7 or 8 men are required. Four men can work at loading the horses—two men placing the ties upon the front end of the horses and two more shoving them back and piling them up.

A seeming drawback with the Harris machine is the necessity for transferring the rails and at least half of the ties to the specially equipped flat cars. In fairness, however, it should be considered that both rails and ties are frequently shipped in box, stock or gondola cars, in which case the rails must be transferred, in any event. In the yards, where the cars between which the transfer of materials is to be made can be switched to stand side by side or end to end, the cost of loading the "machine cars" is but very little more than the cost of taking the material out of the cars in which it was shipped. There is also an advantage in having the material on the machine cars, for as soon as they reach the front there is no delay in starting the work, whereas with other machines some time is lost in putting on and taking off apparatus. When working with the Harris machine it is customary to rig up as many cars as may be necessary to have in order to keep the transfer gang in the material yard steadily at work while track is being laid at the front. This arrangement should always provide loaded "machine cars" as they are needed. The equipment of the cars is comparatively inexpensive, as the material required is standard track material and its usefulness for further service in the track is not impaired, except in the case of the framing out of the cross timbers on the rail cars. The labor of laying the tram track on the flat cars and of dismantling the cars after track-laying has been completed is small. The narrow-gage tramway, located as it is along the center of the train, is less distorted in rounding a curve than is the case with a track or devices at the sides of the cars. As a practical test of this matter, one of these machines was successfully used in laying track on the 24-deg. curves of the Montana R. R., a standard-gage road running out of Lombard, Mont.

As a matter of record 3.2 miles of track have been laid with this machine (old pattern) in 9 hours. On the Chicago, Kansas & Nebraska Ry. (now Chicago, Rock Island & Pacific Ry.) in 1887 the average record for 132 days with the Harris machine was 2.18 miles of track laid per day, with a total force of 3 foremen and 100 to 115 laborers, including the gang which transferred ties and rails to the material cars. In building the Guernsey extension of the Burlington & Missouri River R. R., in Wyoming, in 1900, a record made with one of the improved machines (Fig. 37) was 3750 ft. of track laid in 2 hours and 35 minutes. The track was laid with 75-lb. rails and oak ties, and was full tied ahead of the machine. The crew on the cars and ahead of the machine consisted of 28 men, distributed as follows: ground force, 1 tie-line man, 1 spacing-pole man and tie marker, 1 spike peddler, 1 splice carrier, 1 heeler, 6 spikers and nippers, 2 bolters and 4 or 5 extra men; top force, 4 men loading ties, 3 men on tie car, 1 man breaking out rails, 2 men pulling rails. The average day's work with this crew, laying by 30-ft. "set-outs" and full tieing ahead, was 6000 ft. of track per day.

The Hurley Machine.—The Hurley track-laying machine, which was used for the first time in the construction of a new piece of track for the Bessemer & Lake Erie R. R. in 1902, consists principally of a machine car 55 ft. long carrying at the front end a pair of cantilever steel trusses extending 60 ft. ahead of the car, and at the rear end a raised platform supporting a boiler and two reversible stationary engines of 100 h. p. Following this there is a tender car carrying a water tank and fuel on a raised platform. Coupled in behind the tender are the cars loaded with ties, the cars loaded with rails bringing up the rear. At the middle of each material car, on each side and about a foot inside the edge, there is a roller, used for moving the rails ahead. The rails are coupled up with two bolts in each splice and are pulled forward over the rollers in two lines, one on either side of the train. On the tie cars the lower tiers of ties are laid lengthwise the car and clear of the rollers, so that there are open spaces for the rails to pass underneath the ties that are piled crosswise. On the machine car each line of rails passes between two sets of steam-driven friction rolls which drive them forward and also pull the whole string of rails behind. As each string of rails is fed forward to the machine car, rails are coupled on behind at the rail cars at the rear of the train. This can be done one rail at a time, but in practice about six rails (or one from each of the rail cars) are coupled on at a time. One rail on each of the cars is shoved out and run ahead on dollies and coupled to a rail on the next car ahead, this being done while the rear end of the long string of rails is moving by. As soon as the rear end of the line of rails arrives at the front end of the newly spliced section the latter is quickly coupled on by means of two pairs of clamps connected by a short chain. This chain has an adjustable attachment whereby the rear section is pulled up to a close joint and held there while the splice bars and bolts are being applied, the line of rails, meanwhile, being pulled toward the front.

The ties are carried forward on the two lines of rails. At the front end of the first tie pile back from the machine car, the ties are rolled down and laid across the rails roughly spaced at the same intervals as they are laid in the track. As the rails move forward they therefore convey all the ties necessary to lay them. Figure 5A shows the machine car, and three material cars, with the rails and ties as they appear when moving forward over the train. As the ties arrive at the machine car they are caught on an endless chain and conveyed up an incline over the top

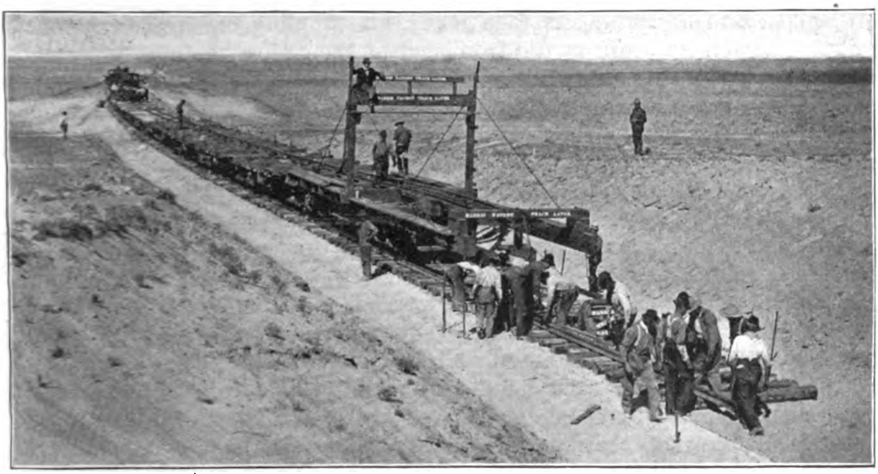

Fig. 37.—Improved Harris Track-Laying Machine.

chords of the cantilever extension, and as they arrive at the front end of this they slide down an incline and fall upon the roadbed crosswise the alignment of the track. In this manner they drop approximately to place, and it is only necessary for two men to square them around and properly space them. In this way the roadbed is constantly supplied with ties in advance of the laying of the rails. Figure 16 illustrates the delivery of the ties in this manner.

The trusses of the cantilever extension of the machine car are 8 ft. apart, laterally braced together, and stand 8 ft. clear of the roadbed, or high enough to allow free action of the spikers underneath. Attached to the bottom chord of each truss there is a channel, in which are power rollers for moving the rails forward. As the rails arrive at the front of the machine car they are uncoupled, one at a time, by taking out the rear bolt at each joint, leaving a pair of splices loosely coupled to the rear end of each rail. A rail on each side is then sent forward under the overhang to a point about 20 ft. ahead of the machine car, where it is grasped by a pair of hoisting tongs and lowered by one man onto the ties below. To explain this movement a little in detail, the rail is gripped by the tongs somewhere near the middle. These tongs are suspended from a bar, at each end of which there is a stay which maintains the bar parallel with the rail. This bar is supported from above at two points, so that the rail is held in a horizontal position whether gripped exactly at the balancing point or not. In dropping the rail to couple on at the end of the last one laid, it is lowered to within about 2 ins. of the rail already laid, and when the car has moved it nearly to place the heeler swings it ahead 1½ or 2 ft., so that the rail is dropped to place an instant before the car has been moved far enough to place it there if it was dropped vertically. There is therefore no chance for the machine to drag the rail ahead should the man be a little tardy in releasing the tongs. The operations are so gaged that the rail is set down just about a foot in advance of the last rail laid and spiked. The rail is then pulled back by the track-layers, and as the splices with one bolt are already in place, the joint can be very quickly coupled. To facilitate the work of getting the splice bars home, use is made of a U-shaped clamp worked by a lever and eccentric. This tool quickly forces the bars to a fit and brings the ends of the rails into line before the bolt is tightened. While one man on each side is doing this the quarters and centers of the rails are spiked and everything is then ready for coupling on another pair of rails. The spikers begin at the front end of the rail, each time, and work back toward the advancing car, so as to be out of the way when the next pair of rails is lowered. The length of the overhang is such that the rails for the two sides of the track can be set down in pairs when laying with either square or broken joints.

The train moves gradually forward at the rate of 20 to 30 ft. a minute, and with experienced track-layers it is not necessary to stop. With inexperienced men a brief pause is made each time a pair of rails is disconnected on the machine car. The machinery is so geared that the material is moved forward over the cars at exactly the same speed that the train moves over the track. Chief attention is therefore paid to lowering the rails, splicing them on ahead and partially spiking them, for as fast as the train moves ahead the material is in place for laying the track. The rollers on the overhang are driven about five times as fast as the main feed rollers, so that there is no trouble in keeping the front end of the machine car cleared for action. While one pair of rails is being lowered to the ties another pair can, if desired, be run forward ready for the tongs as soon as the car has advanced sufficiently far ahead. When laying on curves the incline at the front of the cantilever extension is swung into position to land the ties on line. The motive power for the train is supplied by the machine car, so that no locomotive is required. Power is applied to all three of the trucks supporting the car, and the machine has shown itself able to handle 19 car-loads of ties and rails on a six-tenths per cent grade over a very rough roadbed. When the machine is transported from one road to another the cantilever extension is unjointed and let down upon a separate car. The tender car is generally used for this purpose. Besides the water tank on the tender car, three of the tie cars are equipped with tanks underneath, from which water is pumped into the tender tank from time to time while track-laying is in progress. The purpose of these storage tanks on the tie cars is to keep the tender tank supplied with water so that it may remain with the machine car at all times. The weight of the machine car is 50 tons. Owing to the excess of weight at the head end, this part of the car is carried on two trucks, which is supposed to be a better arrangement for running over partially spiked rails than that of carrying all the weight of the front end on one truck.

It is said that 30 to 35 experienced men working with this machine can lay 2 miles of track per day. The features of advantage are several. The rails and ties are moved by power, and the ties are dropped to place on the roadbed without lifting or carrying by hand. Six men do all the labor necessary to transfer the ties from the cars to the roadbed. The ties are dropped well in advance of the rails without interfering with any part of the work. The rails are lowered to the ties without hand labor. The men are so distributed about the work that no one is in another's way. The most important consideration from an economical standpoint is the fact that the use of a locomotive with the track-laying outfit is dispensed with.

General Considerations.—It has already been seen that the methods of laying track with these different machines are practically the same, so far as the work on the roadbed is concerned, the only differences in any way being in the manner of getting the materials to the front. In comparing what is commonly, but erroneously, called "machine" track-laying with "hand" laying, the machine and the men employed on it stand against as many tie teams, rail cars and men loading and driving the same as may be required to forward the same amount of material in the same time. In case the ties are hauled out on rail cars and carried ahead by hand the comparison would include as many of the tie carriers so employed as are in excess of those carrying ties from the chute of the track-laying machine to lay the same number in the same time. This is because the tie carriers with a track-laying machine carry the ties only such a short distance that they may be considered to offset or stand against the tie placers who work in connection with tie teams. The men who carry ties ahead from a rail car must walk some little distance, usually 80 to 100 ft. or farther. In other words, to get at the economy of a track-laying machine we have to take account of the labor required by either method in forwarding the rails from their position on a flat car of the material train to the end of the track, and that of forwarding the ties from the *cars in which they are shipped,* to their approximate position in the track. The work of half tieing operates the same in either case. The same number of tie placers, liners and spacers, rail carriers (except with the Hurley machine), strappers, spikers, nippers, spike peddlers, etc., are required for the same speed of track-laying by either method, whether the track is full tied or half tied ahead of the material train.

The work required to put the track materials together is always about the same, once they are on the ground, whether it is all completed ahead of the material train, or partly done and then completed by a rear gang. The advantage in deferring part of the work until after the passage of the material train is that there is less interruption in the delivery of the material from the train. This advantage is greater where track-laying machines are being used than it is where the case is otherwise, for the number of men who can work in front of the machine without interference is necessarily small relatively to the number required to complete the track as fast as the materials can be forwarded over the train. For fast work at machine track-laying it is desirable, therefore, to do just as little work in advance of the machine as will make safe for the train to pass over the track. One measure already referred to in connection with the work on the Columbia & Western road, that of using bridle or gage bars in order to omit the spiking in advance of the machine, is now quite commonly in practice. Another expedient in vogue is to have the strappers begin the work of splicing by putting the splice bars loosely on the ends of the last rails laid, with one bolt in place. When the next rail is heeled the strapper pries open the splice bars with his wrench, to receive the rail end, inserts the expansion shim, puts in one more bolt and goes ahead to the end of the last rail laid. To avoid delay occasioned by hard-turning nuts two slotted bolts with cotters have been used to hold each splice temporarily. As it is not usual to tighten the splices ahead of the machine the spiking of the joints cannot then be properly done and such work is also omitted, the rails being held to gage by spiking the centers and quarters.

The claim for track-laying machines is economy in the cost of handling the material rather than a maximum speed of laying track. According to estimates and comparisons based on actual work under similar conditions a saving of $50 to $100 per mile in total cost of laying track has been shown in favor of track-laying machines. While, for the purposes of track-laying, their capacity for forwarding material ahead is practically unlimited, the movements of the head track-layers are necessarily hampered, since only 30 to 60 ft. of track is laid at a move of the train, and of course the number of men who can be worked in this distance is necessarily a comparatively small party. It is possible to put enough teams, rail cars and men to work to lay more track per day than can be done with any number of men working with a track-laying machine, as already indicated by the records, but the cost of rushing the work in this manner is excessive. Under certain conditions, however, such as are found in mountain regions where the grades are heavy and room at the side of the track is scarce, or in swampy country where teams would get mired outside the roadbed, the track-laying machine may, besides contributing greatly to convenience, enable a more rapid speed in construction than could be accomplished without it. It does not work as well on sharp curves as on tangents, and formerly it was not thought advisable to employ it except on construction of considerable extent. Still, the use of track-laying machines has been growing during recent years, notwithstanding that railway building for the most part is now confined to short stretches of branch lines, side-tracks and second tracks. Generally speaking, conditions in track-laying now are different from what they were in the days when so many long lines were being built, and the class of work is different. The cost of the work is now more carefully considered and there is less of the old-time reckless haste. It is the tendency of the age to substitute machinery for flesh and blood.

It is frequently desirable to start the track-laying at a slow pace, working a small crew and laying a mile or perhaps less of track per day, and then, when all of the grading has been completed, push the work along at double this speed. Where such is the purpose a track-laying machine is well suited to the work, because the change in speed can be made without change in the organization of the forces and by hiring fewer extra men than would be the case if the material was handled with teams and rail cars.

31. Highway Crossings.—In laying track the grade crossings at the public highways must be attended to promptly. Planks may be laid temporarily as soon as the ties are spiked, and a heap of dirt at the ends of the ties may serve for an approach. After the track has been surfaced and ballasted, however, or when putting in a crossing in old track, it is important to first see that the track at that point, and for some distance each way, is in good line and surface before laying the plank. They should then be put down with 8-in. wrought timber or boat spikes so firmly that a dragging brake rod or piece of car truck will split out a chunk before it will tear the plank out or loosen it. The standard crossing spike of the Pennsylvania R. R. is 8 ins. long under the head and $\frac{1}{2}$ in. square in section. The head is $\frac{3}{4}$ in. square and $\frac{1}{4}$ in. deep, and the wedge-shaped point is $1\frac{1}{8}$ ins. long.

There is a saving of lumber in using only four planks at a crossing—one each side each rail—but if the highway travel amounts to anything there is no economy in sparing the plank. The practice of using only two planks inside the rails and filling the space between them with gravel, broken stone, cinders or earth is sure to result in an ugly hollow, in time, wherever the travel is considerable. Such is unpleasant to road travelers, the inside planks wear out rapidly and the material used to fill the space is constantly being carried or pushed by wagon wheels into the flangeways, to be packed down by the car wheel flanges and require picking out by the section men every few days. It is better to use planking all the way across; it makes a better crossing every way, lasts longer, and is much cheaper to maintain than one at which a space is left unplanked, to be refilled every little while. The space between tracks is another place where troublesome depressions are liable to result from highway travel, and at crossings with busy roads or streets it might pay to pave such places or plank them entirely over.

White oak and hard pine are the kinds of lumber most commonly used in road crossings. Crossing plank should be at least 4 ins. thick, and 12 ins. is a convenient width. The length of the crossing should conform to the required width of the traveled highway, which is seldom less than 16 ft. For a single driveway or private crossing planks 12 ft. long are long enough, but where the whole width of the road or street is planked in they may be of any convenient length and be laid to break joints. On the outside the planks should be laid against the rail head, notching out the under corner to fit over the spike heads in case the plank would stand too high by resting on top of them. The position of each spike head may be found by placing the plank against the rail, in its proper position, and striking it a blow on the top approximately over each spike. The position of the spike heads will then be indicated by the indentations. It is better to notch out for the spike heads than to chamfer off the whole under edge, as such weakens the plank. The top of the crossing plank should come flush with the top of the rail, or not to exceed $\frac{1}{4}$ in. below it, and if the thickness of the plank does not correspond to the hight of the rail (it is usually less) strips of board or filler pieces may be nailed to the tops of the ties to shim the planks to the proper hight. A space $2\frac{1}{2}$ ins. wide should be left for a flangeway inside each rail but not more, because if made too wide it forms a trap to catch the hoofs of horses or cattle. It is well to lightly bevel off the corner of the plank next the flangeway, to prevent the wheel flanges from peeling off slivers.

The top edge of the plank next the flangeway in the standard highway crossing of the Pennsylvania R. R. (Fig. 38) is chamfered 3 ins., which is considerably more than is required to clear the wheel flanges. In this style of crossing the two inside planks are connected at the ends by short pieces of plank of the same thickness, enclosing a rectangular space which is filled with broken stone. Outside the rail the planks are laid in the usual way. On crossings planked solid between the flangeways in the usual manner four 12-in. planks will not quite fill the whole space, but cracks an inch or so wide left between the planks do no harm and soon get filled. The ends of all the planks, both outside and inside the rails, should be adzed to a slope after they are in place; but the planks should first be cut to such length that each end rests on a tie, to which it should be spiked; and the planks inside the rails should be cut to even lengths. Such work gives best security against dragging parts of cars. On some of the crossings of the Pennsylvania R. R. there is a sloping steel plate at each end of the crossing plank. The ballast between the ties, under crossing planks, should be dressed off about an inch lower than the tops of the ties. If it is permitted to touch the planks it is liable to lift them in case it should heave in winter. In laying crossing plank they should be placed to bring the convex side of the grain upward, as in Fig. 39, in order to shed water. If the concave side is upward the dish of the grain will hold water to rot the plank.

Private farm crossings or other crossings but little used may be, and usually are, more cheaply built than the crossings for well-traveled roads. A plank each side each rail with a filling of ballast between the two inner planks serves the purpose well enough, and hemlock or other cheap lum-

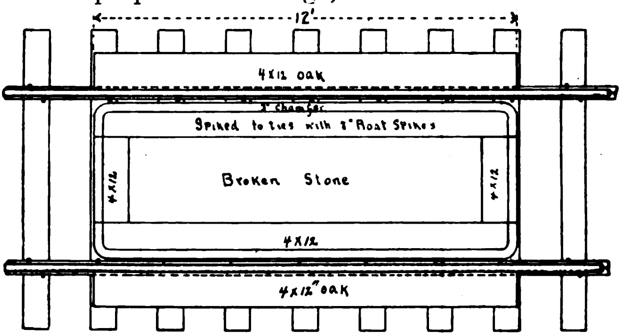

Fig. 38.—Highway Crossing, Pennsylvania R. R.

ber is sufficiently durable. In parts of the country where extra wide harvesting machinery is not used a private crossing 8 ft. long, made by cutting 16-ft. planks in two, is sufficiently serviceable. In fact it is not necessary to use plank at all. If the use of the crossing is to be only occasional the construction may consist simply in filling the track with ballast, level with top of rail, outside and inside, leaving proper flangeways inside the rails.

Deep flangeways at crossings give considerable trouble in winter time. Mud or snow which gets packed into these spaces and frozen is difficult to pick out, and if it is not removed it is liable to be crowded under the planks or against them so tightly as to start the planks loose. To obviate this difficulty the bottom part of deep flangeways is sometimes blocked with filler strips of wood, and in other cases the inside planks are laid against the web of the rail and cut out to desirable depth for the flangeways. A wood bottom for the flangeway helps the matter but very little, however, as mud and ice will freeze to it tightly and must be chipped off in small pieces when clearing out the space. On a number of roads, including, among others, the Chicago, Rock Island & Pacific and the Toledo, Peoria & Western, the flangeway at highway crossings is formed by laying an old rail on its side inside each traffic rail, with its head against the web of the traffic rail, as shown in Fig. 39. The upturned flange of the rail so laid forms the inside of the flangeway and a backing for the plank. If the space between the flangeways is to be paved this upturned flange should be placed as nearly vertical as is practicable, so as to permit the paving blocks to be fitted snugly against it. At each end of the crossing this flange is bent inward, toward the center of the track, to form a flare for the flangeway. On most roads where the flangeway is formed in this manner the rail laid on side is not made fast in any way except as shown in the figure. Its head lies under the head of the traffic rail and the planking is fitted tightly against its base, holding it securely. On some roads, however, about 6 ins. of the flange and web at each end of the rail are cut away and the projecting piece of the head is drilled and bolted to the web of the traffic or running rail. On the White Mountains division of the Boston & Maine R. R. it is the practice, where a joint comes in the running rail at the crossing, to drill holes directly through the head, web and flange of the flangeway rail that is laid on its side and use long bolts, the flangeway rail serving as the inside splice bar.

If the railway company has old iron or steel rails to spare the flangeway guarded by a rail laid on side is undoubtedly the cheapest plan in the end. The arrangement certainly answers the purpose well. There being no deep rut to hold mud, dirt or snow, such material is cut up by the wheel flanges and loosened. To clean out such a flangeway it is only necessary to draw the point of a pick, or shove the point of a bar along the bottom, and then to scrape away the loosened material with a shovel or brush it aside with a broom. By the use of salt such a flangeway can easily be kept clear of snow and ice.

The practice of forming the flangeway by laying an inside guard rail on its base, or workwise, is objectionable for two or three reasons. In the first place, the under corners of the rail heads, in the flangeway, form a dangerous trap for horses' feet. If the toe calk of a horse's shoe catches under the rail head in a flangeway of this kind the horse is liable to be thrown or have his hoof torn loose; or if a horse becomes frightened and attempts to turn around on the crossing there is danger of catching a wagon wheel. At crossings of this kind it is usual to keep the flangeway filled with dirt up to the level of the under sides of the rail heads, but unless the material is compacted very hard the danger referred to is not entirely removed. And then, again, as such a flangeway widens out below the rail heads and has no well defined bottom it is difficult to

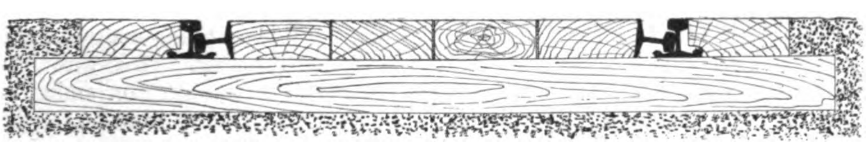

Fig. 39.—Highway Crossing Flangeways of Old Rails.

pick out and keep clear. A common form of crossing of this class, known as the "skeleton" crossing, has two guard rails laid inside the running rails to 3-in. flangeways for such distance as is desired for the length of the crossing, and then each guard rail is bent inward at an angle of 45 or 90 deg. to meet the end of the similarly bent opposite guard rail, in the middle of the track. The enclosed space is usually filled with broken stone or slag, covered with a top dressing of screenings or cinders.

Owing to the necessity for tearing up plank in order to raise the rail, low joints in highway crossings usually get less attention than they do elsewhere, and so when it can be avoided crossings should not be located to bring a joint within the planking. Of course this rule is more easily followed on square-jointed than on broken-jointed track, but by laying 60-ft. rails at all ordinary crossings there will usually be no difficulties in this respect. Even if a shorter rail is standard on the road it would pay to use rails of this length at the crossings. When building track it is an easy matter to carry enough extra long rails to lay the crossings, and on old track they may be laid gradually in the course of rail renewals. In the latter case the best plan is to order enough long rails to lay all the crossings on the division or stretch of track whereon rail renewals are to be made during the year, and then distribute all these rails at one time, before the rails to be laid in the ordinary course of renewals are delivered on the track. Where a joint does come in the crossing, the plank which is placed next the rail on the outside should be boxed out for the splice and bolts, rather than beveled off underneath, so that the nuts can be got at when loose, without taking up the plank. But if the rail be high enough to permit the wheel flanges to clear the nuts, it is better at crossings to put the bolts through the splice from the outside, so that the nuts come on the gage side of the rail and in the flangeway.

Railway companies are concerned in the lay of the land in the vicinity of road crossings at grade. Crossings in a cut or on or near a curve should be avoided in every case possible. The grade of the highway on the approaches to the crossing is one of the important considerations, for if heavily loaded teams get stalled on or near the crossing they are in danger of being struck by trains. In light cuts where the road must be depressed to meet the track at grade it should be graded back to a rise which does not exceed 1 in 10. On some roads the rules limit the rise to 1 in 6, but the safest plan to follow in any case would be to grade the road to the level of the crossing for the length of a wagon and

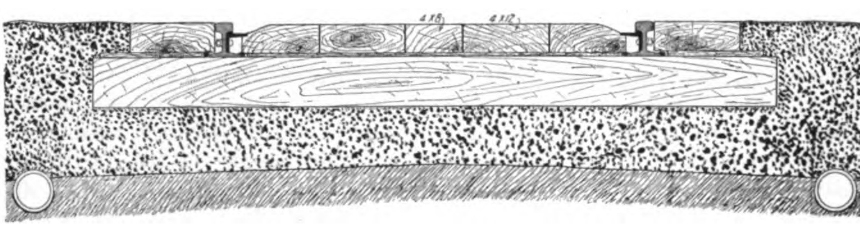

Fig. 41.—Highway Crossing with Detachable Tram Bars and Tile Drains.

team, and a few feet further, each way from the track; this arrangement gives a team a chance to pull quickly over the crossing. It is also important to limit the grade of highway approaches to crossings on embankments. The standard rules of the New York Central & Hudson River R. R. require that the grade of highway approaches shall not exceed 6 per cent and of farm crossing approaches 8 per cent. Where a highway runs up hill approaching a crossing the dirt will sometimes work down from the outside edge of the outer plank and cause a jolt to wagons. This difficulty may be overcome by filling in the road to a level with the top of the crossing plank, or slightly sloping from the track, for some distance out. Where there is a steep slope right up to the crossing plank the wagon wheels and horses' hoofs will usually wear away the dirt, so that a vertical lift of several inches is necessary to get the wheel onto the crossing. Where such conditions are found a heavily loaded team is liable to be stalled on the crossing. In some states railway companies are obliged to construct and maintain all that portion of the public highway which lies between the lines of the right of way at crossings.

The high speed of modern passenger trains makes it desirable to eliminate grade highway crossings at every opportunity. On many of the larger railway systems overhead bridges or subways are being substituted for crossings at grade, on a large scale. Generally speaking, accidents at grade highway crossings are too numerous on all railways, but in building independent lines where only light traffic is in prospect it is practically out of the question to propose the abolishment of the grade crossings: only the most prosperous railways can meet the expense. There are many situations, however, where, by diverting and consolidating highways, the number of crossings in a locality may be decreased, one crossing being made to carry the travel formerly passing over two or more that were near together. Moderate expenditures for such improvements are sometimes paying investments.

Crossing Drainage.—Ditches should not be discontinued at, or obstructed by, road crossings, but should be carried under the road by box culverts or vitrified or iron pipe. It is a good plan in any case, whether there is a ditch at either side of the crossing or not, to lay some kind of a drain near the ends of the ties to carry off the water. Farm tile, laid as in Fig. 41, answers well for this purpose; and small box drains or trenches filled with cobble stones are largely used. At crossings which come in a cut, or wherever water is liable to settle around the crossing, some kind of drain should always be provided. In the case of double track a tile or other drain should be laid along the midway, under the crossing, and then turned under one of the tracks into the ditch. No little difficulty in maintaining track at road crossings arises from the practice of grading highways up to a point higher than the roadbed close up to the ends of the ties, thus forming an obstruction which prevents the water from draining freely away from the track. Sketch "A," Fig. 41A, shows a mistake frequently found, where the track and ballast are made to lie in a trench which is formed by grading the road up to the level of the top of the rail, close up to the track. From this trench there is no side drainage. Sketch "B" shows a method of drainage recommended by a society of section foremen of the Chicago, Milwaukee & St. Paul Ry. for such places. The space for a distance of 5 ft. outside the ends of the ties is excavated to a slope starting 12 ins. below the ties at their ends and running to a depth of 18 ins. in the distance of 5 ft. This ditch is filled in with cobble stones, permitting not only the drainage of surface

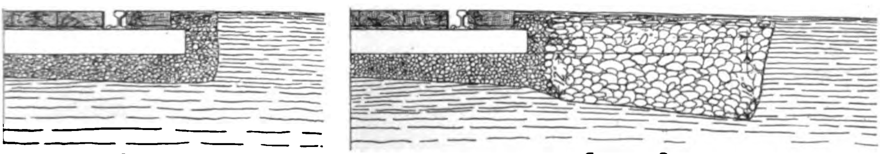

Fig. 41 A.—Drainage for Track at Highway Crossings.

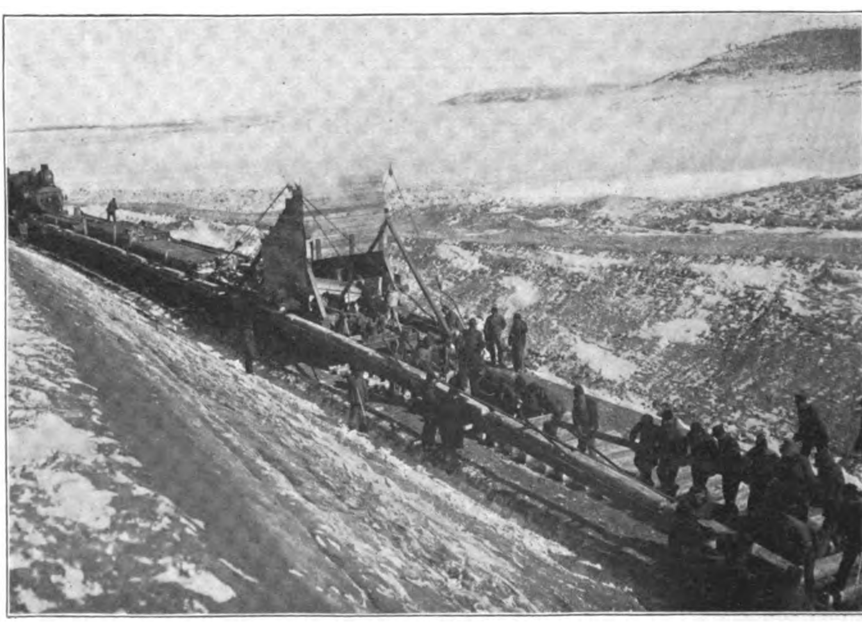
water sinking into the track, but also catching and diverting water which otherwise might run upon the track. The highway should, of course, slope away from the crossing at a slight grade. To facilitate the drainage at crossings they should be filled in with a good quality of ballast. To overcome the objectionable effect of "churning," the crossings of the Chattanooga, Rome & Southern R. R. (Central of Georgia system) are filled in with washed gravel.

Construction in Paved Streets.—In some of the eastern cities a built rail of girder shape has been gotten up to conform to local ordinances requiring that steam roads shall use girder rails in tracks which follow the streets for some distance. The design is formed by bolting a tram bar to the ordinary T-rail. This bar somewhat resembles an angle bar bolted to the rail in an inverted position, and is illustrated in Fig. 40 (shown with Fig. 33). It is attached to the rail by drilling holes through the web about 3 ft. apart and bolting. The expense of putting it on is small, and it is good construction for crossings. No trouble arises from joints, since the tram bar takes the place of a splice bar on its side of the rail, it being necessary to simply drill it for the bolts, either before or after it is in place. At a crossing provided with flangeways of this kind (Fig. 41) the planking or paving is beveled off on the top edge and laid up under the tram. As there is nothing to confine dirt and other material falling into the flangeways the wheel flanges cut it up and shove it aside, and but very little cleaning is required. The standard track of the New York Central & Hudson River R. R. for stone-paved streets is laid with these detachable tram bars.

At crossings in streets paved with deep blocks of stone or other material it is necessary to lay the ties low, in order to make room for the pavement. This may be done by supporting the rails directly on chairs spiked or lag-screwed to the ties, but for long stretches of track laid in streets paved with deep blocks it is better practice to use rails of special girder section, which are usually about 9 ins. deep. The paving blocks outside the track are sometimes laid directly against the head of the rail and ¼ in. below the top of the same, but if the track settles or some of the paving blocks work up the car wheels will bear upon the paving and loosen it. The paving is also liable to be loosened by the undulation of the rail. To provide against trouble of this kind a strip of timber may be interposed between the rail and the paving. For this purpose a 4x6-in. treated timber, laid on edge, is recommended. By cutting out at the top corner for the rail head it may be fitted against the web, and it should be laid to bring the top surface ¼ in. below top of rail. Track that is laid in paved streets or in long highway or street crossings should be constructed of materials of more than ordinary durability substantially put together. Improvements in these respects involving only moderate expenditure would be found in the use of creosoted ties and tie plates, with tile drains parallel with the track. A type of concrete foundation used by the Pere Marquette R. R. for track in the streets of Bay City, Mich., is described in § 169, Chap. XI.



Roberts Track-Laying Machine in Action.

CHAPTER IV.

BALLASTING.

32.—Construction trains usually begin running over the track as soon as it is laid, but such usage does not improve its condition, and the sooner it is ballasted, therefore, the better. As a general proposition track is better for having a depth of at least 12 ins. of ballast underneath the ties. Where the roadbed is a fill or wherever it is dry and compact, more than this depth is not needed, for even 5 ins. will maintain the track in fair condition in such places; but it ought not to be less than 5 ins. in depth in any case, except where the roadbed is gravel or some other material which answers well for ballast of itself; in fact, 8 ins. is considered the minimum allowable depth for good practice. The least depth of ballast which will distribute the pressure from the ties uniformly over the roadbed is about 12 ins. for broken stone and presumably more for gravel. In experiments made in Germany by Herr Schubert, with broken stone ballast 11¾ ins. deep under the ties, on a roadbed of plastic clay covered with a 2-in. layer of sand, the clay surface remained even when the load was applied; but when the layer of ballast was shallower than the stated depth the clay directly under the ties was depressed more than elsewhere. The load applied was 57 lbs. per sq. in. of tie bearing surface.

When it is necessary to economize in the use of ballast it is better practice to arrange the quantities to suit the conditions than to cut down the allowable depth and make it uniform at all places. As a rule more ballast is required in cuts than on fills, especially in wet cuts. In clay cuts the ballast should be at least 18 ins. deep under the ties, so that the pressure from the traffic will be uniformly distributed over the roadbed. While broken stone is good material to distribute pressure, it does not work well on a clay bottom or on a wet roadbed, because clay becomes plastic when it gets wet and the softened material will work up through the voids between the stones. The most satisfactory material to use in such places is a bottom layer of engine cinders 12 ins. deep, covered with 6 to 12 ins. of broken stone or gravel. As already stated, flat stones are sometimes used to cover a soft bottom, but cinders are just as good, or even better, and in any case it would be a good plan to use a layer of cinders over the flat stones, to prevent plastic material from working up. In cuts through hard rock the roadbed is not usually graded to a uniform surface, and full depth of ballast is necessary in order to properly bed the ties over the high points. It is good practice to excavate rock cuts a foot below the profile grade and then build up to sub-grade with broken stone, leaving proper side ditches. Above this the depth of ballast may be regulated to suit the conditions of the locality.

There are but few railroads in this country whereon the standard depth of ballast under the ties, for ordinary conditions, exceeds 12 ins. The most usual depths in the standard specifications for ballast are 12 ins., 10 ins. and 8 ins., in the order named. In the standards of 50 of the representative railways of the country a depth of 12 ins. is found 20 times, 10 ins. 14 times and 8 ins. 12 times. The least standard depth is 4 ins. and the maximum 24 ins., in a few instances. In this connection, however, it is well to again bear in mind that the fashion of "standards" is contagious, and the amount of ballast which the section foremen actually get under their ties may not always measure fully up to the chief engineer's "standards." It is true, nevertheless, that better ballast and more of it is being used than formerly.

The use of ballast in raising track to the original grade on settled embankments and to a uniform grade across sags may, of course, increase its depth considerably beyond the standard specification. For this reason many think that it is extravagant of material to put track up on first-class ballast before the banks have become well settled. The idea is worth careful consideration. The plan would be to surface the new track with dirt on or but little above the sub-grade. As dirt ballast is very cheaply obtained and handled, and can be dressed to keep water out of the roadbed to a large extent, the use of the same for two or three years should enable the embankments to settle compactly without becoming plastic in the center and "pushing out." After that the dirt can be removed from between the ties, the top of the roadbed dressed to the desired slope in its compacted condition, and then the track can be raised and ballasted with gravel, broken stone or other good material in just such quantities as are desired to suit the various requirements of the roadbed in cuts, on embankments, etc.

Surfacing consists in placing the top of rail to an even line. Ballasting consists in filling the space underneath the ties with ballast, making it as compact as is practicable, and filling the space between the ties. Where suitable ballast material can be obtained along the line, close at hand, it should be hauled out with teams and a layer of it, within about 2 ins. as deep as it is intended to have the ballast, spread over the roadbed and leveled off smoothly before the track is laid. As a general thing it can be placed more cheaply in this way than by hauling it with the train and shoving it under the ties after the track is laid, because then the track must be raised so much the higher. There is also a further advantage in that, from being driven over by teams, the bed of ballast becomes quite compact, whereas ballast placed under the ties after the track is laid will always settle a good deal at first. On dry roadbed it is quite customary to first place a layer of stones broken to the size of cocoanuts, or a paving of flat stones laid shingle fashion (standing at an angle of about 45 deg. and leaning against one another), and then lift the track 6 ins. when placing the gravel, broken stone or other ballast. Track laid on loose rock not broken up should be chinked in or roughly blocked at the ends of the ties before the outfit train is allowed to run upon it. This work is quickly and easily done, as the stones for blocking are close at hand. Where gravel ballast varies in size the coarser material should be put underneath. Sometimes in working out a gravel bank the run of the strata is such that the coarse material may be separated from that of finer quality and taken out first. In such event the track should be raised to grade in two stages, using the coarse gravel at the first lift (say 6 or 8 ins.), without dressing off, and then top out with the finer material when the track is surfaced to the final grade line. It is advantageous to give the track a little time to settle before raising it the second time, for the consolidation of ballast in any considerable depth must come about by settlement under the traffic.

33. Rail Grade Stakes.—The grade for top of rail in ballasting is indicated by stakes about 4 ft. from the rail at one side of the track, opposite every full station, and wherever there is a change of grade. These stakes are set after the track is laid. The stake is driven or sawed off to bring its top to grade. If the foreman in charge of the work is experienced at raising track it is useless to set stakes closer than 100 ft. apart, except where there is a change of grade; and there is no necessity, either, for setting stakes both sides of the track.

Vertical Curves.—Where a considerable change of grade occurs stakes should be set for a vertical curve. The length of this curve should be proportional to the amount of change in the grade—20 to 50 ft. for each one-tenth of one per cent change being customary practice. Engineers should explain to foremen who are unacquainted with these curves their nature, so that they will get the rails to a curved surface instead of making of them a series of grades. Stakes should be set every 50 ft., or even closer, always putting a stake at the middle point of the curve—that is, at the vertex or point of meeting of the two grade lines—and then they should be spaced equally each way from this point to the ends of

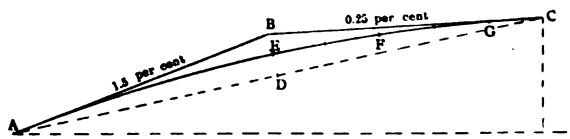


Fig. 42—Vertical Curve.

the curve, without regard to the established stations of the center line of the track. Instructions for setting these stakes are given in field books, but for the benefit of trackmen an example of the kind will here be considered. Referring to Fig. 42, let *A B* represent a grade of $1\frac{1}{2}$ per cent and *B C* a grade of $\frac{1}{4}$ per cent. The change in grade at the point *B*, the vertex, is then $1\frac{1}{4}$ per cent, and if 40 ft. be selected as the length of the curve for each tenth of change the curve will then be 500 ft. long and run 250 ft. each way from *B*. Set a stake then at *B* and every 50 ft. (or some multiple distance of half the length of the curve, not exceeding 50 ft.) each way, it not being necessary to designate the stakes by marks or numbers any more than to show that they are rail grade stakes. The point *D* is half way between *A* and *C* on the straight line *A C*, and its elevation is readily found from the known elevations of the points *A* and *C*, being higher than *A* by half the difference of level between *C* and *A*. Of course *B* is not vertically over *D*, but no perceptible error is made by assuming it to be such. The point *E*, on the proper grade for the curve, is half way between *B* and *D*; and any point between *E* and *C*, or between *E* and *A*, on the curve, is at such a distance from *B C* or *B A* that its ratio to the distance *B E* equals the ratio between the square of the distance of the point *C* or *A* and the square of the distance *B C* or *B A*, according to which side of *B* it happens to come. For instance, the distance of the point *F* below the line *B C* (call it x) would be found by the equation

$$\frac{x}{BE} = \frac{(FC)^2}{(BC)^2} = \frac{(\frac{3}{5})^2}{(^5/_5)^2} = {}^9/_{25}\text{; or } x = {}^9/_{25}\,BE.$$

In the same manner the distance of the point *G* from the line *B C* would be $(\frac{1}{5})^2\ B\ E = {}^1/_{25}\ B\ E$. Where the grades meet in a sag the curve is located above the two grade lines, of course, and the distance of any point on it from one of the grade lines is found in the same way as has just been described. The distance thus found is additive and gives the same result as though the figure (Fig. 42) was inverted. It is usual to grade the roadbed to conform to the same vertical curve, but more care should be taken in setting stakes for the rail grade than is necessary for the sub-grade. Foremen are not apt to run in a vertical curve very well by the eye; that is, to surface the track well at such a point without stakes. A change of grade should not occur on a horizontal curve in the track if it can be avoided.

Mr. Wellington's rule for the length of vertical curves is based on the following consideration: "The rate of grade on which the head of the train stands must in no case exceed that on which the rear of the train stands by more than the grade of repose* of the last car." For sags Mr. Wellington's rule is: "The curve should be 400 ft. long (that is, 200 ft. on each side of the vertex) for each tenth in change of rate of grade, making the change in rate of grade per station not over .025 per station, if all possibility of bringing the draw-bars of any part of the train into compression while passing over it is to be avoided. With half this length of curve, which is considerably more than is usual in laying out vertical curves, all danger of 'taking out the slack' in the front half of the train, where there is most danger of breaking in two, will be avoided." It is thus seen that the idea in the mind of the author quoted was to so limit the change in rate of grade that in passing over sags the cars in the rear of the train would have no tendency to run into those in front. But since the long coupling of former days has gone out of use there is now far less cause for trouble in sags, and accordingly vertical curves are now made much shorter than this rule requires. To always follow this rule would give some lines a very sinuous appearance, indeed, while in many cases it would be impracticable.

The best method of making the transition between grades of varying inclination was one of the subjects reported upon at the sixth session of the International Railway Congress, held in Paris in 1900. As a great deal of mathematical learning has been brought to bear on this question in times past the information produced by the reports presented is of particular interest. One of the reports was prepared by Mr. Van Bogaert, chief engineer of the Belgian State Ry., and covers the practice of 67 railroads in Europe, Great Britain, the British colonies and the United States. The report reaches the conclusion that, from theoretical considerations and from practical experience, a vertical curve of 16,000 ft. radius is quite sufficient to prevent severe jerks in the draw-bar pull resulting from sudden change in the tractive effort of the locomotive due to a change of grade even as great as 2 per cent. A sag between two grades is not considered dangerous even if the connecting curve is of a radius considerably less than 16,000 ft. This is the radius (5000 meters) adopted by a large number of roads, none of which reported trouble as having arisen from the radius of the connecting curve being too short. The minimum radius prescribed by the German Railroad Union is only 2000 meters (6500 ft.). This is the radius in use on a number of European roads in hilly country, with results reported to be entirely satisfactory. In sags between opposing grades the tendency of the cars is to bunch together and drive the buffers in, but on vertical curves of

*By "grade of repose" is meant the minimum grade upon which a car will start itself without assistance. This is not the same as the minimum grade upon which a car will keep moving after it is once started; such is not nearly so much as the grade of repose. The grade of repose (proper) is about 0.4 per cent and the grade on which a car will continue to move after being started is about 0.3 per cent for box cars, in each case, depending always on the amount of journal friction.

any considerable radius such action takes place gradually and no harm results. On summits between opposing grades, or where the grade changes from a rise to a level or from a level to a fall, the draw-bar pull is subject to sudden changes, at high speed, and break-in-twos occasionally take place, although the jerk at such points is nothing nearly as great as is liable to happen from the action of the brakes. The report recommends that for changes of grade greater than 1 per cent, passing from a rise to a level or from the level to a falling grade, or over a summit between opposing grades, it is advisable to ascertain by means of a dynamometer car whether the curve used in any case has a radius of sufficient length to prevent sudden jerks in the draw-bar pull. For changes of grade less than 1 per cent the report maintains that the question is not of any importance. It is not desirable, however, to have a change of grade occur where there are horizontal curves of short radius.

Replies to a list of questions making inquiry for the details of practice on the different roads indicate a great diversity as to the form of curve used. Although the circular arc is the form most commonly found, nevertheless a considerable number of roads use parabolic curves, some roads introduce a piece of level track at the summit of opposing grades, several roads make the transition by means of a series of inclines, each of 20 to 30 ft. length and changing one tenth of 1 per cent. On the other hand, some roads having grades as steep as 2½ and 3 per cent do not use vertical curves connecting changes of grade. The radii of vertical curves used on different roads, as noted in the report, vary from 3000 to 33,000 ft. The practice of running out the vertical curves also varies greatly. On many roads there are no definite rules regarding vertical curves, and in surfacing the track reliance is placed upon the judgment and the eye of the section foreman, who puts in such a curve as he thinks will answer the purpose. Of course the most careful practice is to establish the curve by setting grade stakes instrumentally. In some cases the roadbed is graded to the vertical curve, while in others the curve is introduced only as the track is ballasted, the grades in the roadbed, in that case, continuing to an apex or to the point of meeting. In some cases where opposing grades are steep, however, as at a summit, the roadbed is graded level at the summit and the curve is introduced when the track is being ballasted; in other cases the roadbed is graded to the curve only where the difference in the grades amounts to as much as 1 per cent.

The facts set forth in the report show that general practice in the use of vertical curves is much simpler than some theories would lead one to suppose. For convenience of surfacing the track the curve should be as short as will conduce to safe operation. A curve of 16,000 ft. radius connecting grades where the change amounts to 2 per cent is only 164 ft. long each side of the vertex, or 328 ft. in total length. To follow some rules requiring a curve of very long radius, on roads where the grades are much broken, there would not in some cases be room enough between the points of change to get in the curve. It seems to be proven in practice that vertical curves of considerable length are not required where the change in rate of grade does not exceed ½ of 1 per cent.

34. Raising the Track.—A jack is a better tool for raising track than a lever, because it requires only one man to operate it, whereas a lever usually requires three or more; the jack can also lift through a greater vertical hight without changing, and it does not throw the track out of line so much as when raising with a lever. If the roadbed is soft, so that the jack sinks in too much, it may be stood upon a piece of plank. Using the level board, the rail is raised to surface opposite each rail grade stake, and then at the joints and centers, blocking them to place, or shovel-tamping if the ballast is at hand. It is an advantage to have ballast on hand in sufficient quantity to tamp the tie ends, because blocking will settle when the train comes on, and the track will have to be raised again; besides, it is not altogether desirable to leave blocks, stones, etc., under the track so near the bottoms of the ties. With rails of heavy section the stiffness of the rail will usually hold the quarters to surface if the joints and centers are supported. On track laid with rails of light weight a quarter now and then will sag and require raising to surface. In a high lift light splices are in danger of being bent by taking hold of the rail at the joint. It is better in a case of this kind to take some point 2 or 3 ft. to one side of the joint as the raising point. Track usually settles as soon as the jack lets go, and allowance should be made accordingly. It is a good plan to raise every joint somewhat higher than the point to which it would naturally settle back, so that it will stand striking down. The usual arrangement is to have a man carry a 16-lb. sledge along and strike down on the tie tamped. In this way a good surface can be had without taking so much pains with the raising, and the ballast under such ties gets hardened to a considerable extent by being struck down.

It is well to raise and hold the rails on both sides to surface before tamping the ends of the ties, because where one rail has been raised and the tie ends have been tamped, when it comes to raising the rail on the opposite side the rail first raised will rise with it an eighth to a quarter as fast and leave the ties which have been tamped bearing only at their ends, with a clear space under the tie at the rail seat. The side last tamped will then hold up better than the side tamped first, and the track will settle more on one side than on the other; but this is not liable to happen where neither side is tamped until after both sides have been raised and held. Unless the side first raised be blocked, and that directly underneath the rail, it will rise a little with the second side when it is raised, as just explained, and after the track is leveled across or elevated it will be somewhat higher than the grade stakes. There is no objection to this excess, because it provides an allowance for settlement and does not usually leave the surface of the side first raised uneven; should it do so occasionally, a few strokes from the sledge on the high ties will usually put it right. Some make it a practice to set the jacks outside the rails and raise both sides of the track at the same time. Where the lift is high this is a good plan.

The man who sights the rail should be at least 60 ft. back of the point which is being raised, so that his eye can catch a good stretch of rail between. It is well to designate each point which is raised opposite a grade stake by placing a pebble or chunk of dirt on the rail, for it is an aid in sighting other points on the rail with reference to it. One man can sight for two jacks—one at raising joints, the other at raising centers. About the utmost speed attainable in raising track at one place would be had by using five jacks; one crew with jack and level board could put both rails to grade opposite grade stakes; a man behind, sighting for two jacks, could follow and place one rail, that is one side, to surface; and behind him, on the opposite side, a crew with jack and level board could raise the joints, and another jack with a man to sight for it could be used in putting up the centers. The best sighter should be put on the side which is in the advance. It requires a little genius as well as judgment to sight rails well and rapidly. Young or inexperienced foremen use various devices as an aid to sighting the rails. One of the simplest of these is three blocks, all of the same thickness or hight. Two of the blocks are placed on the rail at points where it is at the proper hight, at any convenient distance apart within sighting range; the third block is placed upon the rail at the point which is being raised, and when it is brought up into the line of sight with the other two the rail at that point is at the proper surface. Another device consists of sighting blocks and boards, worked on the same principle. There is a thin plank or board usually painted white, with a black stripe running longitudinally its whole length. The board has L-shaped irons or feet to steady it in an edgewise position, and when the track opposite a grade stake has been raised and blocked or tamped to surface and leveled, this board, called the "hight board," is placed to stand edgewise across the rails; or it may be set at proper hight, across the track, on heaps of ballast in advance of the work. By means of two other boards or blocks, called "sighting boards" or "sighting blocks," as the case may be, one placed on the rail at the observer (where the track is in surface) and the other at the point where the track is being lifted, the rail is sighted to surface. The thickness or hight of the "sighting" boards or blocks corresponds to the hight of the stripe on the "hight board." Foremen experienced at sighting rails can get along without these devices and do the work just as well and just as rapidly. In fact, some foremen, in raising new track or any track where the top faces of the ties are clean, do not sight the rails at all, but stand back a little way in the middle of the track and judge of the rail surface by the appearance of the ties. When the rails are out of true the ties appear to form the elements of a warped surface. On curves the rails are sighted along the inside of the curve.

Track on tangents should be raised and tamped level transversely. There are those who claim that a train will run more steadily on straight line if the rail on one side is about $\frac{1}{4}$ in. lower than the other, than it will on track which is level transversely. This claim is based on the idea that the wheel flange on the lower side will follow the rail instead of moving first toward one side and then toward the other, as it does on track which is level transversely. But the coning of the wheels would not in all probability allow this steadiness of movement on straight line; and if it did, more power would be expended in hauling the train, because if the same wheel flange followed one rail all the time, either one or both wheels would have to slip a little almost constantly.

In ballasting new track it is desirable, especially when working a large crew, to have the track where raising is in progress entirely free from passing trains. In case the ballast must be hauled from the rear the best plan, if practicable, is to first unload ballast along the track for several miles in sufficient quantity to tamp the ties outside the rails; on fills where the track is to be raised 6 ins. or higher there is not usually room for more material than this. Then everything is ready to begin with part of the crew to raise the track and tamp the ties outside both rails; this will hold up a train without settling to hurt, and the train should follow to haul what ballast is needed to complete the work. The remainder of the crew should follow the first party and tamp the ties between the rails, line the track and fill it in.

35. Tamping.—Except where broken stone or slag is used for ballast the shovel is the best tool for tamping new track. Tamping bars are not effective in such work. The tamping bar is intended to be used only where ballast can be confined in a small space, such as is found between the bottom of a tie and a hard bed, when the lift is small. In raising new track, where the lift is usually several inches, the ballast must necessarily be put in loose; and it can become hard and compact only after time and by pressure from trains running over it. The range of action of a tamping bar is only an inch or two in depth below the bottom of the tie at the most, and consequently it is a waste of time to attempt to harden several inches of ballast under the tie with such a tool when the ballast between the ties is in a loose condition. The shovel does just as good work and is far more rapid. In shovel tamping, the gravel or other ballast is first shoved under the tie with the shovel blade, and then crowded, the latter effect being produced by putting the foot on the shoulder of the blade and driving it under the bottom of the tie, at the same time prying backward a little on the handle, thus enabling the lower edge of the blade to pry forward and crowd. Before placing the foot upon the blade, ballast should be filled in between the ties as high as an inch or two above the tie bottoms, so that a fulcrum may be had for the back of the shovel blade to pry against. The thin edge of a shovel blade, even when new (being only about $^3/_{32}$ in. thick) is not worth much for a rammer; it is, therefore, the prying and ramming combined which crowds or tamps the ballast under the tie, but principally the prying. This is the reason it is so important that ballast between the ties should all the while be kept somewhat higher than their bottoms, and that the edge of the shovel blade should penetrate under the lower corner or edge of the bottom face, instead of against the side of the tie. It is somewhat difficult to describe just exactly how shovel tamping is rightly done; it is easier done than said. It is work which requires judgment, and that must be acquired by experience. New men seldom if ever do it properly on the start. An intelligent man may soon learn it, but some never do.

In starting out at tamping the foreman, who by all means should at some time have worked at shovel tamping himself, should take a shovel and show each man individually how it is done. After he has gone through the crew in this way he will usually have occasion to come right back and, with as much emphasis as possible, inform about 49 out of every 50 men that they are not doing it properly; for, invariably, instead of tamping the ballast *under* the tie, nearly all will be found trying to pack it *against the side* of the tie. More money is wasted in paying for poor tamping than for all other poor work on track put together. The man in charge of a surfacing or ballasting crew must therefore be vigilant. Men should be given to understand that as soon as a tie is properly tamped the work on that tie should cease, since there is not the slightest necessity for tamping against the side of it; that is to say, above the edge of the bottom face; that as soon as one is through tamping under the bottom of one tie further effort can most profitably be expended under the bottom of the next tie ahead; that to the laborer the physical exertion must, in any case, be the same whether he remains hopping up and down on his shovel, spudding it against the side of the tie, or whether he moves to the next tie ahead as soon as the tamping of the tie is properly finished. The foreman's command of language cannot be used too vigorously in bringing these points to the notice of his men. Shovel tamping when well done will give good results, but when poorly done it is much expense laid out for little or nothing in return. Foremen should not forget this.

Most kinds of dirt ballast cannot be well tamped with the shovel blade. Cast ends are sometimes provided for shovel handles, so that the tamper may take the edge of the blade in his hand and use the handle as a rammer, and in some kinds of dirt ballast they do pretty good work. A tool called a puddle is sometimes used for this purpose. It resembles very much a tamping pick with the pick end of the tool cut off near the eye.

Stone and slag ballast are tamped with tamping picks. Each tamper works by himself, stooping over the tie and driving the rock into the space underneath it. In order to do this work uniformly, more or less care must be exercised, for, if not mindful, one may, in striking with a tamping pick, easily wedge parts of the track up above its proper surface. The material is first thrown into the track loosely and pushed under the ties with shovels, and then thoroughly packed with the tamping picks. After a few days the track should be carefully resurfaced, taking out the rough spots, tamping the raised ties and filling in and dressing off. As already stated, rock to be broken for ballast is sometimes thrown into the track and broken up there. This is not a good plan to follow, however, since the ballast is liable not to be broken finely enough to the proper depth, unless the rock be thrown in a piece at a time; it gives the men a chance to break the material finely on the top and leave larger pieces underneath where they cannot be seen. The ballast, if broken on the spot, ought, therefore, to be broken up on the shoulder, outside the track. It should be thrown in with forks rather than shovels, since with the latter it is difficult to handle rock ballast lying on the ground without taking up some dirt with it; and of course it is desirable to keep rock ballast clean, in order to prevent the growth of vegetation and the churning of the ties.

Shovel tamping is done on both sides of the tie simultaneously. Outside the rails two men work together, on opposite sides of the same tie; between the rails four men—two on each side of the tie—usually tamp together. Ties should be well tamped directly underneath the rail seat. This can always be done to best advantage by getting the tool in there at the start. A shovel blade must be thrust in cornerwise in order to do it, and such cannot be done after the tie has already been tamped farther out toward the end; or farther in toward the middle, if tamping be done inside the rails. When tamping either outside or inside the rails one should aim to tamp the tie directly underneath the rail from that side. It is an easier matter to tamp the ties at this point when using a tamping bar or tamping pick than when using a shovel. When tamping new track for the first time, the middle of the tie may, without ill effect, be tamped as firmly as the ends, but after that the middle should never be tamped quite as solidly as the ends.

36. Ballast Cars.—In handling ballast for new track two kinds of ballast car, or a car which combines the typical features of both kinds, can be used to best advantage. Reference is intended to cover cars which can be unloaded from the side and those which can be dumped from underneath. The latter saves the expense of once handling part of the ballast, for otherwise it must be cast into the track from the outside. As is well known, cars are made which combine these two features in one. While cars which dump by careening to the side may be made to do good work at filling in a trestle, they do not answer well for dumping ballast, because the momentum with which it leaves such a car will sprawl it over the shoulder and down the slopes, on fills of ordinary width, much being thereby wasted; and again, wherever a car is dumped a whole load must go, whether all is needed there or not. For unloading to the side it is more economical of ballast and more convenient to unload off ordinary flat cars by hand than to use careening side-dump cars. The cheapest method of unloading flat cars, however, and the one most extensively in service, is by the use of the unloading plow and cable. The various devices of this kind and their manner of operation are described and illustrated under the subject of "Handling Ballast and Filling Material," § 148, Chap. X.

A very common type of side-dumping ballast car is built on the gondola style, with a crowning floor (running to a peak in the middle of the car) and swing side doors hinged at the top. When the doors are unlatched the ballast slides out by gravity, close by the side of the track. The Pratt side-dumping car, in use on the New York, New Haven & Hartford R. R., is an 8-wheel car of about 25 cu. yds. capacity and 28 ft. length inside. The sides of the car are divided horizontally into two parts, or with one swinging door above another, so that, if desired, only half of the load on each side of the car need be discharged at one dumping. The upper door is released first, and if it is desired to carry the remainder of the load a car's length ahead, the lower door is

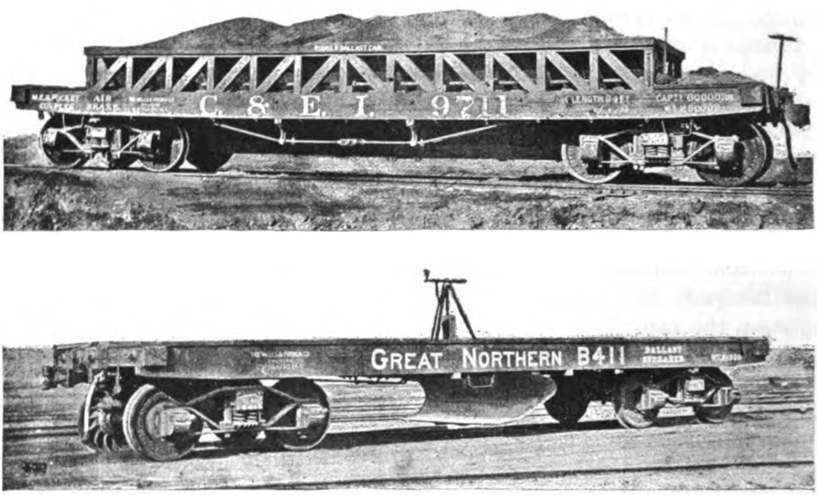

Fig. 43.—Rodger Ballast Car and Spreader.

held closed until the car is moved, when the remainder of the load is dumped. The Womelsdorff gondola ballast car, used on the St. Louis Southwestern Ry. of Texas, for cinders, has a deck inclining each way from the middle, and a side drop bottom. This drop bottom is in four sections on each side of the car, and consists of wrought iron plates $^5/_{16}$ in. thick and $2\frac{1}{2}$ ft. wide, hinged to the bottom edge and inside face of the intermediate sills. Two of the sections or aprons are each $12\frac{1}{4}$ ft. long and the other two are each 4 ft. 2 ins. long. The drop aprons are held in position by chains winding upon a $1\frac{1}{4}$-in. shaft extending the length of the car (inside) at the top of each side and operated by brake wheels on vertical shafts connecting by means of worm gearing at the top, while at the bottom the wheel shaft has the ordinary ratchet and pawl. The aprons drop through an angle of about 40 deg. and permit the ballast to slide freely from the car, under the side sill, onto the shoulder, close by the track. The car is $34\frac{3}{4}$ ft. long over end sills and 8 ft. $10\frac{1}{4}$ ins. wide.

For unloading ballast between the rails, cars are made with hopper bottoms. A well-known car of this type is the Rodger ballast car, shown in Fig. 43, as constructed by the Chicago & Eastern Illinois R. R. The length of the car is 32 ft., the width 8 ft. 9 ins. and the hight of the top of the car above the rails 6 ft. 1½ ins. The capacity of the car level full is 14.6 cu. yds., and when heaped 18 to 20 cu. yds.; as it appears in the view the car is loaded with 22 cu. yds. of gravel. The capacity of the car is 60,000 lbs. and it is equipped with air brakes. These cars are hoppered at the sides and ends, the hopper extending between and slightly below the inner axles of the two car trucks. The hopper has a door at the bottom 17 ft. in length, which is opened and controlled by chains winding upon a shaft. There is a lever and ratchet attached to the shaft at the end of the car, outside of the hopper, by means of which the door in the bottom of the hopper can be opened any desired width, so that the amount of ballast discharged is under control, being regulated by the amount by which the door is opened and the speed of the car. In unloading ballast from a train of these cars only one car is opened at a time and a ridge of ballast is deposited between the rails. If it is desired to unload ballast outside the rails a distributing car or spreader is coupled on at the rear of the train. This car consists of an ordinary flat car carrying a plow underneath, as shown in the lower view of the figure. This plow can be adjusted to any desired hight, but in service it is lowered by the screw and handle until it scrapes the rails. It plows all the ballast down to a level with the top of rail and flanges the track, leaving the excess material outside the rails, upon the ends of the ties. The quantity of ballast delivered is limited, necessarily, by an amount sufficient to pour over or cover the rails. Where the lift is not high, however, enough ballast may be plowed out across the rails to tamp the ends of the ties without unloading any outside the track from cars of other type. As used on the Union Pacific R. R. the wings of the plow were extended to spread enough gravel to make a 6-in. lift by putting all gravel unloaded under the ties. After this first raising enough material is plowed off to finish a 9-in. lift, fill in between the ties and trim out to the standard cross section.

This ballast car is used on a large number of roads. When not in use as a ballast car it can be put to service as a coal car. The Grand Rapids & Indiana Ry. has these cars built with a capacity of 100,000 lbs.; and when not in service in handling ballast they are used for transporting coal or ore. The Illinois Central R. R. also has combination cars of the Rodger type. In the summer the cars are used for hauling ballast and in the winter they are fitted with removable extension sides and ends and used in the coal traffic. The cars are 40 ft. long over end sills, 9½ ft. wide, outside, with a hopper 30½ ft. long on top and 24½ ft. long on bottom. The capacity of the car level full of ballast is 22 cu. yds. and 28 to 30 cu. yds. when heaped. The coal capacity is 40 to 42 tons. When used for carrying ballast the top part of the coal box, which is an extension of the hopper of 30 cu. yds. additional capacity, is removed. The weight of the car is 36,900 lbs. and the nominal weight capacity is 80,000 lbs.

The Rodger ballast car of improved design is convertible into a flat-bottomed gondola car. The car of improved design is similar to the old car, but having the addition of removable sloping ends and foldable longitudinal sections attached to the intermediate sills, which may be swung over to form a tight flat-bottom gondola car, overcoming the objection to the old-style Rodger ballast car, namely, that it was not available for ordinary freight service, although extensively used for carrying coal. The convertible car contains every feature of the old Rodger ballast car, having the same slope at the sides and a larger capacity, at the same time being convertible at the end of the ballasting season into a gondola car. A still later design is convertible into either a flat car or a flat-bottom gondola car.

Ordinary hopper-bottom gondola coal cars are frequently used for distributing ballast between the rails by skidding a square stick of timber ahead of the front wheel of the rear truck of each car dumped, to level down the ballast and spread it out across the rails. On the Lehigh Valley R. R. 160 "quarter" coal-car loads of slag measuring 1000 cu. yds. have been unloaded in this manner by a crew of 18 men in $\frac{1}{2}$ day, the men being employed, for the most part, in pushing the slag down into the hoppers with bars. After raising the track to grade and tamping it with slag that material was leveled down even with the bottoms of the ties, and cinder ballast for filling was dumped in the same manner.

Another very well known car for hauling either ballast or filling material is the Goodwin car, in use on a large number of roads. This car is made to dump either at the side or from the center or from both

outlets at the same time. The car as now built is constructed entirely of steel and iron. As shown in the cross-sectional view, Fig. 44, the body of the car is built upon two plate-girder sills 21 ins. apart. These girders are 18 ins. deep at the middle and $9\frac{1}{2}$ ins. deep at the ends. The space between the sills is left clear for dumping the load between the rails, and from each sill there is an apron or floor inclining downwards. The two ends of the car are connected by top side plates 18 ins. deep and the car is divided at the middle by a transverse bulkhead, so that either of the two compartments can be dumped independently of the other. To the top side plate on each side of the car, in each compartment, there is hinged a swinging door which, when the car is loaded, rests upon the projection of a movable section in the bottom of the hopper. This bottom is composed of two narrow movable sections hinged to a longitudinal shaft. Each bottom section is held in position by a tripping device, by means of which the said movable section on either side of the car may be released, when it swings downward, inclining toward the apron, thus releasing the swinging door and permitting the discharge of the load. The apron is hinged along its middle line (longitudinally), so that the upper portion can be swung upward, as shown by the broken lines at the left side of the figure. When the upper section of the apron is set in this position and the swinging door released, the latter strikes against, and is held by, a spring on the raised portion of the apron and the contents of the car are discharged between the sills and inside the rails of the track. The dumping devices are arranged to be operated either by hand or by compressed air. A view of the car with the swinging doors open is shown as Fig. 45. Hand dumping is accomplished by the wheel at the end. When equipped for pneumatic dumping an air cylinder is attached to the end of the car, on the outside, beside the hand wheel. This car can be made to discharge half of its load on one side and half on the other; or half in the center and half on the outside; all on one side or all in the center, as is desired. The car is 35 ft. 11 ins. long over the end sills, 8 ft. 10 ins. wide over all, and the extreme hight above top of rail is 8 ft. 6 ins. The carrying capacity is 80,000 to 125,000 lbs. or in volume, with the load heaped, it amounts to about 29 cu. yds. As shown in Fig. 45, the ends of the car are of wood construction, but in later designs the ends are constructed entirely of steel. These cars are constructed with a view to turning them to service for carrying coal, ore, grain and other bulky freight. For grain service the car is provided with an adjustable steel top for protecting the grain from the weather, and for carrying coke there is a top crate which enlarges the capacity to 37 cu. yds.

There are other ballast cars of well known patterns, used either in supplying ballast for new track or for renewing the ballast on old track, described in the chapter on "Work Trains" (§ 148, Chap. X). In ballasting, or, rather, surfacing, track with dirt but little or no hauling is

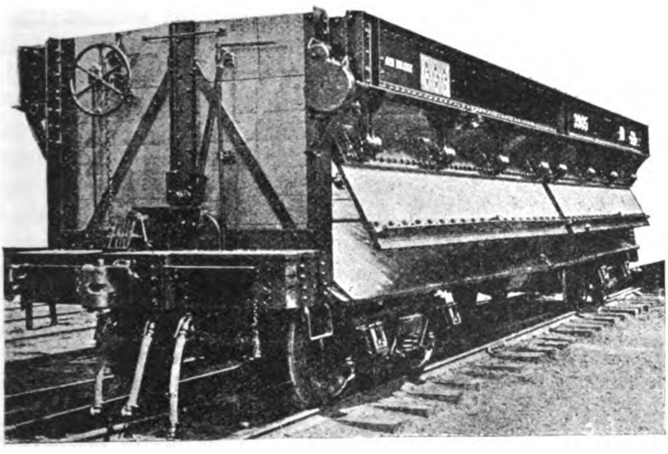

Fig. 45.—Goodwin Dump Car with Swinging Doors Open.

usually done, as in such material the track is not usually raised very high above the sub-grade, and enough material can in most places be had by casting up from the side or from the ditch; but holes should not be dug out of embankments for this purpose nor should irregular enlargements be made in the ditches, where they will hold water in puddles.

37. Lining.—After the track has been tamped, and before it is filled in, it should be lined. It can be easier thrown before it is filled in than afterward, as there is then not so much material to hold the ties, and besides, the rail is more free to align itself farther from the point at which it is thrown, thereby lessening its tendency to kink and require throwing at more frequent intervals. The foregoing applies to track in most kinds of ballast, but in stone or slag ballast the track should be lined before it is tamped the last time, because when track is thrown on freshly placed ballast of these kinds the pieces of stone will roll and raise it out of surface. As a guide in throwing the track to the center stakes a tack is driven in the middle of the gage, or it is notched at that point. The gage is then placed across the rails at each center stake and the track is thrown to bring the mark on the gage vertically over the tack in the stake. It is well to place pebbles or other small objects on the rail at such points to designate the place. The crew then goes back and throws the joints, centers, and quarters if need be, to line with the rail at these designated places. Six men will usually be a large enough force to handle it easily, and in some cases four will be sufficient. They should all throw together, at the word, with a rather steady pull or heave, not trying to jerk too quickly. At some places where there is a short kink the rail must be held at one place while throwing it at another, so as to avoid throwing out of line the portion which is so held.

One often sees in railroad periodicals inquiries after the best method of lining track. All there is of it is simply the use of a fair "mechanical eye" to put the rail in line over stretches of 50 or 100 ft., although, for that matter, center stakes on tangents need not be nearer than 200 ft. apart. It is the practice with some young engineers to line tangents by sighting along the rail with a transit. Possibly such work may convey the impression of accuracy, but it cuts no figure in track work. When the unaided eye cannot detect any portion of a rail out of line it is certainly not going to affect the running of trains; moreover, in curves, where good alignment is most needed, the transit can be of no use in this way, and the eye must be, and has always been, depended upon.

38. Filling in and Dressing.—After the track is lined it is filled in and dressed off. The manner of filling in depends a good deal on the quality of the ballast. Track in broken stone, ordinary gravel, cinder and like kinds of ballast should be filled in full, even with the tops of the ties inside the rails, but not over the tops. For a distance of 6 ins. inside the rails, however, and from there on out to the end of the tie, the ballast should be just enough lower to nicely clear the rail base. If the ballast be even with the rail base, sand or dirt will be sucked in between it and the tie face, as the rail springs up and down under trains, and in winter the flange of the rail between the ties will lie in a frozen rut which will be a hindrance to shimming and other kinds of work which must sometimes be done. The expansion or heaving of the ballast is also liable to lift the rails from the ties and start the spikes. Beyond the ends of the ties the ballast should be shouldered out full depth a distance of at least 8 ins., and better if 10 or 12 ins. Ballast banked against the ends of the ties helps very much to hold the track in line. It also keeps the ground from freezing that much deeper in winter, and in case of derailment gives some aid to the wheels and protection to the ties. The portion just outside the ends of the ties is usually called the ballast shoulder. From the top of the shoulder the ballast may be sloped off gradually toward the ditch or edge of fill; broken stone ballast is usually sloped off more abruptly—something like 1 to 1, say. Figures 3 and 4 illustrate the manner of filling for different kinds of ballast. If too much ballast has been left during construction it may remain to be used in repairs later on, but no material should remain piled in a ditch or in a cut.

In all kinds of loose ballast through which water soaks away readily little attention need be given to dressing the material with a view to draining the water off the top; but in dirt ballast, and, to some extent, in sand ballast also, the conditions are different. In those cases the ballast must be so dressed that it will run all water possible off the top and keep it from getting underneath the ties. The only thing which makes dirt a practicable ballast is good surface drainage. Dirt and sand ballast should be rounded up 2 or 3 ins. higher than the tops of the ties in the middle of the track, covering the ties over a strip about 3 ft. wide, and then sloped down to the bottoms of the ties at their ends, passing 1 or 1½ ins. under the rail base. The standards of some roads require that between the rails the ties shall be covered as far as a line 3 ins. from the rail base, from which point the ballast shall be sloped down to the bottoms of the ties at their ends, "care being taken to leave an opening under the rail for drainage." Outside the ends of the ties the surface should slope away gently out over the shoulder. Engraving *G*, Fig. 4, shows the arrangement. On quite a number of roads, one of which is the Illinois Central (Fig. 5), it is the practice to fill in and dress off cementing gravel ballast in this manner; that is, to heap it up in the middle of the track and slope it down to the bottoms of the ties at their ends. Cementing gravel does not pass water freely, and it is so difficult to work that much labor is saved by leaving the ends of the ties uncovered, so that they may be readily opened out for tamping.

There are several objectionable effects from the banking of ballast inside the rails, two or three of which it may be well enough to remark upon. Where ballast is dressed in this manner there is always a tendency to center-binding of the track. In the first instance, as elsewhere stated, the ballast or earth under the exposed ends of the ties is not as well retained as it is under the middle of the track where there is a full depth of filling. When the ground is thawing the frost leaves from under the ends of the ties before it does the middle of the track. The effect of this condition is inequality of support and a slight rocking of the track which causes it to settle out of surface. Nevertheless, in the qualities of ballast under consideration, the advantages obtained by covering the ties in the middle of the track outweigh the disadvantages. Aside from the superior drainage effected, the heap of ballast in the middle of the track assists materially in holding the track in alignment. When heaping the filling in curved track it is usual to crown it on the outer side of the center line, which brings the highest point of the filling nearer the outer than the inner rail; otherwise it might not be possible on track highly elevated to make the filling slope both ways.

When dressing off filling for the first time, except in dirt ballast, it is not worth the while to spend any time at work intended merely to make a neat appearance, because the track will soon settle and have to be raised. At the first dressing merely "cuff" it over roughly with the shovel, but after the track has been put in good surface the second time, it may be dressed off more carefully. In dressing off stone ballast it puts a "finishing touch" on appearances to lay a margin of stones to line on the shoulder, parallel with the rails, but opinions regarding the utility of such work are likely to be influenced by personal tastes.

On double track, where the ballast is retentive of water, a ditch becomes necessary between the tracks. It should be provided at intervals with lateral drains or outlets under one of the tracks. Where the ballast is of good quality, however, such as gravel, broken stone, or of any porous material, the space between the tracks is usually filled in full and a ditch is not needed. On this question, however, opinions seem to differ, for on a number of double-track roads where gravel ballast is used the filling between the tracks is depressed to drain toward a center ditch. On the gravel-ballasted road of the New York Central & Hudson River R. R. the filling between parallel tracks on the same roadbed is depressed 7 to 9 ins. and cross drains are placed at intervals of 400 to 500 ft. apart, to drain the depressions. These drains are 6x6-inch boxes made of 2-in.

plank treated with three coats of Woodiline or Fernoline, or creosoted with dead oil of tar. The cross drains are run each way from the center line of the roadbed, deep enough to permit tamping, and at an inclination of at least 1 in 12. Use has been made of center drains 8 ins. lower than the bottoms of the ties, with tile drains leading under the track at intervals of 500 ft., but the results of this style of dressing track have been reported unfavorably. In the first place, the ditch was too low and it was found that the gravel from each side was shaken into the ditch, obstructing the same; and lumps of coal, leaves and other rubbish had obstructed the tile drains. A scheme of tile-draining the roadbed to carry off the water which soaks through the ballast is elsewhere referred to (§ 3, Chap. I).

39. Quantity of Ballast Required.—To fill in track properly with ballast, between the ties and for a foot outside the ends, even with the tops of the ties, requires about 16 cu. yds. of material per 100 ft. of single track. For every inch below the bottoms of the ties, about 4 cu. yds. of ballast is required per 100 ft. of track. For double track, 13 ft. centers, filled full between the tracks evenly with the tops of the ties, about $2^1/_5$ times the above amount will be required for filling down as far as the bottoms of the ties—that is, about 35 cu. yds. per 100 ft.; for ballast below this point, double the figure, or 8 cu. yds. per 100 ft., per inch in depth.

How Track is Ballasted in Baluchistan.

In the above scene native laborers are ballasting track with broken stone, on the Muskaf-Boulan Ry., in Baluchistan. The ties are of pressed steel, weighing 160 lbs. each. These natives have but little strength in their arms, and it takes two of them to work a shovel—one pushing on the handle and another pulling on a rope tied to the tool near the blade.

CHAPTER V.

CURVES.

40.—Track can be made to change direction either by an angle or by a curve. When direction is changed by an angle it changes suddenly, as it were, and at a point, or all at one place; when by a curve, it changes gradually at every point along the curve. The first method is occasionally resorted to for main track where the change in the direction is small, but is most frequently employed at split switches, the angle commonly used being about 1 deg. 40 min. In changing the direction of track by a curve it is laid to form part of the circumference of a circle, or parts of the circumferences of two or more circles. The first mentioned arrangement is called a "simple" curve; the second, a "compound curve" when the different parts turn in the same direction, and a "reverse curve" when they turn in opposite directions. The use of the circle applies to the main portion of practically all railroad curves, but curves more complicated than the circular one, for the purpose of an easement at the ends of the circular portion, are largely employed. Such curves change direction by a gradually varying rate instead of a uniform rate, and are known by various names, such as "spirals," "transition" curves, "easement" curves, "tapering" curves, etc.—all meaning about the same thing. In laying out curves of any kind it is well to avoid, as far as possible, locating them on bridges; and where too much will not be sacrificed the grade of track should not be changed in a curve.

41. Simple Curves.—The circumference of a circle is the simplest curve because it is the easiest drawn or laid out, and because its form is everywhere the same. Any straight line which touches the circumference of a circle without cutting it, however far the straight line may be produced, is called a *tangent*. At the point of contact the tangent has the same direction as the curve, and it is perpendicular to the radius drawn to that point. Likewise a straight line touching any curved line without intersecting or cutting across it, however far produced, is called a tangent, and two curves are tangent to each other when they are both tangent to the same straight line at the point of contact. In railroading every piece of straight track is called a tangent, because it is supposed to meet tangent to a piece of curved track somewhere.

Circular railway curves are referred to by the length of radius or by the degree of curvature. By the *degree of curve* is meant the degree of the angle included between two lines drawn from the center of the circle to any two points on the curve 100 ft. apart, measured in a straight line; or, more concisely stated, perhaps, the degree of a curve is the angle which a chord of 100 ft. subtends at the center. For curves of radius less than 50 ft., such as are found on street car tracks, this definition obviously fails, for in that case there is no chord of 100 ft., but very sharp curves are usually designated by the radius. There is another definition that makes no reference to the center or radius, which describes the degree of curve as the change in the direction of the curve between two points 100 ft. apart. In foreign countries the curvature is expressed by the length of radius. In English practice the chord length in railway curves is one chain, or 66 ft., and the curvature is referred to by the length of the radius in chains. Where the metric system is employed the chord length is 20 meters or 65.62 ft. In speaking of curvature in track reference is always made to the center line of the track. Neither rail has exactly the same degree of curvature as the center line, or as the other rail—the outer rail is of longer radius and less degree than the center, and the inner rail is of shorter radius and greater degree than the center. On double track, the two tracks being the same distance apart everywhere, or parallel, both tracks cannot have exactly the same degree of curvature. For instance, if the outer track be a 10-deg. curve and the tracks are 14 ft. between centers, the inside track will have a curvature of 10 deg. 15 min., or 10¼ deg.

To make these matters clearer to persons not familiar with the mathematics of railroad curves, let us refer to Fig. 46, not drawn to scale. From a point *c* draw two straight lines making with each other

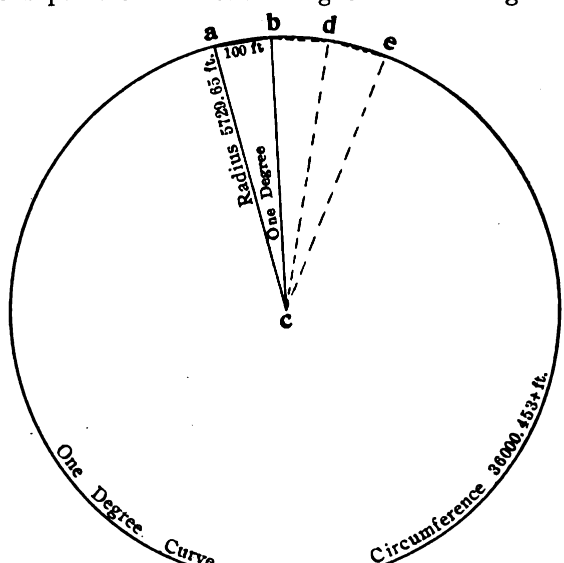

Fig. 46.—One-Degree Curve.

an angle of one degree, and let them diverge until they are 100 ft. apart at points *a* and *b*, equally distant from *c*; this occurs when *a c* and *b c* each becomes 5729.65 ft. in length. We then have the isosceles triangle *a b c*. Now it is plain that around the point *c* there can be drawn 360 such triangles, thus filling up the whole angular space about it. We shall then have a 360-sided regular polygon, the total length of whose sides will be 360×100 ft.=36,000 ft. If now a circle be circumscribed about this polygon it will have *c* for a center and 5729.65 ft. for a radius; and any portion of its circumference will constitute what in railway engineering is called a 1-degree curve. The sides of the polygon so nearly coincide with the circumference of this circle that the difference between the total length of all sides of the polygon and the circumference is only a very small amount, comparatively (really 0.453+ft.). The radius of a 1-deg. curve is then 5730 ft., very nearly; and, nearly enough for practical purposes, the radius of any curve used on steam railroads is 5730 ft. divided by the degree of the curve. Table VI. gives the radii of curves up to 50 deg. There is nothing concerning the ordinary use of simple curves that is complicated, and any roadmaster or section foreman who has been so fortunate as to have gained a knowledge of the geometry of the circle and a smattering of trigonometry can easily acquaint himself with the necessary knowledge concerning them, and should by all means do so.

42. Some Ways of Laying Out Curves.—No man who is not able to master an ordinary book on field engineering should, as a rule, be given charge of locating and laying out curves; yet there are times when exigencies arise such that a man competent to do a little calculating may not have a transit at hand, but is able to lay out curves quite accurately without the transit if he has at hand a field book or the necessary tables. For this reason, then, two methods of laying out curves by the use of a tape line or chain, as the only instrument, will be given. These methods are useful in rerunning or relocating old curves or in laying out short stretches of new track or side-track, when a surveyor with transit cannot be had. There are many railways of short length in this country which cannot afford to retain a regularly employed surveying party in idleness a large part of the time, and so occasionally these "unprofessional" methods come handy. I have seen many examples of very creditable work done in this manner, where stretches of track over considerable distances were laid out anew or relocated, and which checked up closely enough with transit work afterwards.

Method of Middle Ordinates.—The problem most frequently arising is that of laying out a curve between two tangents meeting at a given angle. Let, in Fig. 47, *A B* and *C D* be the two tangents. The angle *B C D* is the intersection or Δ (delta) angle, as it is generally called. Find Δ by laying off with tape line the right triangle *B C E,* and compute *tangent B C E* or *tang.* $\Delta = B\ E \div C\ E$. The angle corresponding to this tangent value can be picked from a table of tangents (Table V. See in-

Table VI.—Tangent Offsets, Chord Deflections and Middle Ordinates for 100-ft. Chords.

dex). The length of tangent for the curve is $T = R \times tang.\ \frac{1}{2}\Delta$, where R is the radius of the proposed curve. Lay off the tangent length each way from C, to F and to G. Let an example be taken. In order to draw $B\ E$ perpendicular to $C\ D$, take any point B, on line AB, and from B as a center and with $B\ C$ as a radius cut the line $C\ D$ at N; E will then lie half way between N and C. Now suppose that $B\ E$ measures 7.5 ft. and $C\ E$ 12 ft. Then $tang.\ \Delta = 7.5 \div 12 = .625$, which value corresponds to the tangent of 32 deg. within a half minute; Δ then $=$ 32 deg. Suppose it is desired to lay off an 8-deg. 30-min. curve (8° 30′ being the conventional way of expressing it). From Table VI we find the radius of such a curve to be 674.7 ft. The tangent length for the curve will then be $T = 674.7 \times tang.\ 16° = 674.7 \times .28675 = 193.5$ ft. $F\ C$ and $C\ G$ then each equal 193.5 ft. Having now the starting point and ending point of the curve, it may be laid off by the method of middle ordinates or by the method of deflections from tangent and chords produced.

The middle ordinate of a chord is the perpendicular distance from the middle of the chord to the curve; it may be found very approximately

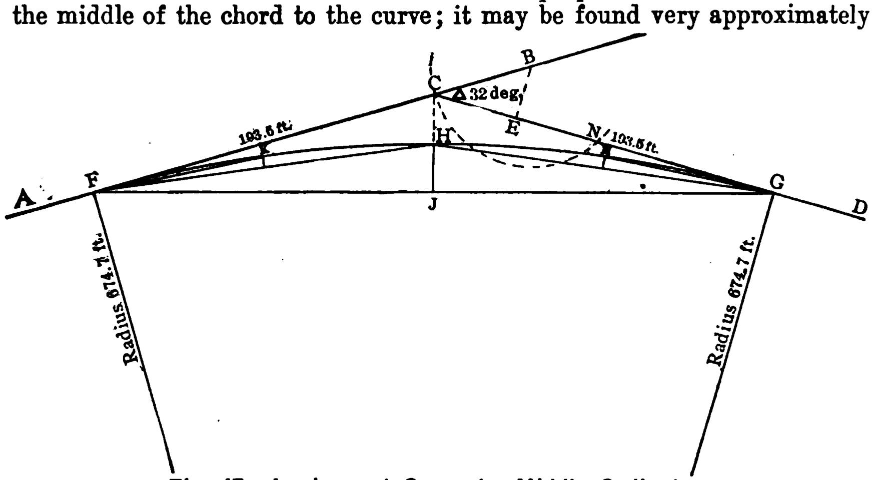

Fig. 47.—Laying out Curve by Middle Ordinates.

by dividing the square of the chord length by 8 times the radius of the curve. For a 100-ft. chord the middle ordinate is equal to the radius multiplied by the versed sine of half the degree of the curve. In Fig. 47, JH, the middle ordinate of the long chord FG, is $R \times vers.\ \frac{1}{2}\Delta$, and, as a check, the distance $C\ H = R \times Ex.\ Sec.\ \frac{1}{2}\Delta$. The middle ordinate of the chord $F\ H = R \times vers.\ \frac{1}{4}\Delta$; of chord $F\ K$, $R \times vers.\ \frac{1}{8}\Delta$, and so on as far as it is desirable to go. For the long chord $F\ G$ a wire may be stretched. The length of curve in 100-ft. stations and fractions therefore, is Δ divided by the degree of the curve or, in this case, it is $32 \div 8\frac{1}{2} = 3.76$ stations$=$376 ft. From Table V and the foregoing formulas, then, we get:

$J\ H = R \times vers.\ 16° = 674.7 \times .03874 = 26.2$ ft.

$C\ H = R \times Ex.\ sec.\ 16° = 674.7 \times .04030 = 27.2$ ft.

Middle ordinate of $F\ H = R \times vers.\ 8° = 674.7 \times .00973 = 6.56$ ft.

Middle ordinate of $F\ K = R \times vers.\ 4° = 674.7 \times .00244 = 1.65$ ft.

The middle ordinate of $K\ H$ is the same as that of $F\ K$. The middle ordinates for chords between H and G are the same as for corresponding ones between F and H. Without appreciable error the middle ordinate of $F\ H$ may be taken at $\frac{1}{4}\ JH$, and the middle ordinate of $F\ K$ at $\frac{1}{4}$ that of $F\ H$, or $^1/_{16}\ J\ H$. This is the most accurate method of laying out curves by measurements alone, because no sighting is required. The point J may, however, be located by measuring and sighting, without stretching a string or wire.

Method of Tangent Offsets and Chord Deflections.—Where it is not feasible to stetch a wire, the distance being too long, or the ground inaccessible, or where the two tangents are not located, or where the intersection point is inaccessible, the curve may still be laid off quite readily by tangent offsets and chord deflections. Starting on the tangent (Fig. 48), set a stake at B, 100 ft. from A, the point of curve. An offset to C, equal to the tangent offset, will give the first station on the curve. Then by producing the chords 100 ft. beyond the last point of curve found each time, and setting off the chord deflections $F\ D$, $G\ E$ etc., successive points around the curve can be found. To get on tangent again, as at E, a full station, produce the chord $D\ E$ one station beyond E and lay off the tangent offset $H\ I$, which is always $\frac{1}{2}$ the chord deflection. If the last chord be less than 100 ft., the tangent offset for it may be found by multiplying the tangent offset for 100 ft. by the square of the sub-chord and dividing by 10,000.

The chord deflection for a 100-ft. chord may be found by dividing 10,000 by the radius of the curve. It is not necessary, however, to use a chord of 100 ft. The chord deflection for a chord of any length may be found by dividing the square of the chord by the radius of the curve. It should be noted that, to be exact, the tangent offset $B\ C$ is not laid

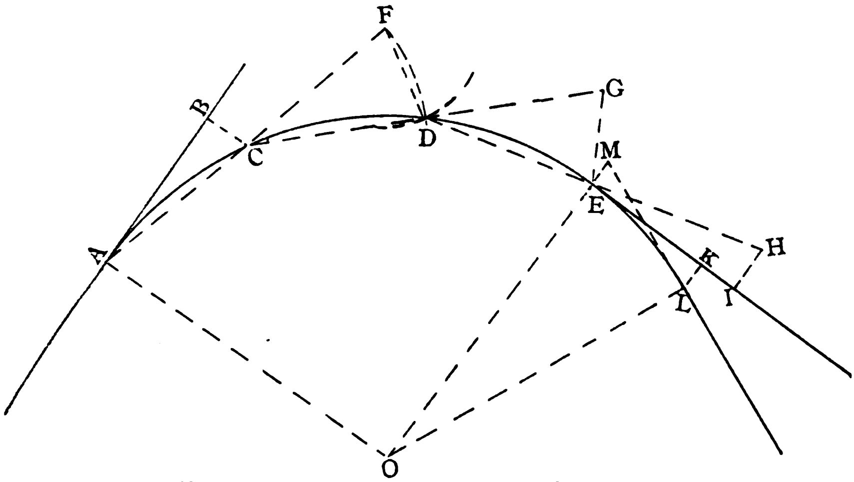

Fig. 48.—Tangent Offset and Chord Deflection Method

off from B, but perpendicular to $A\ B$ in such manner as to meet the line $A\ C$ 100 ft. (or whatever chord length) out from A. No noticeable error will arise, however, in making $A\ B$ equal in length to $A\ C$, for curves of small degree. It must also be noted that $F\ D$ is not perpendicular to $C\ F$, but is so measured that $C\ F$ and $C\ D$ are equal; that is, having measured off and set the stake at F, swing the tape with a radius $C\ D = C\ F$ and set a stake at D, the intersection of the two radii $F\ D$ and $C\ D$.

In the example at hand, we find, in Table VI, the tangent offset $B\ C$ corresponding to 8° 30′ to be 7.41 ft., and the chord deflections $F\ D$ and $G\ E$ to be 14.82 ft. As the curve has been found to be 376 ft. long, the last chord is a sub-chord of 76 ft., for which the tangent offset required will be $(76^2 \div 10{,}000) \times 7.41 = 4.28$. In this case, then, we would make $E\ I$ tangent to the curve at E just as has been done in the figure for a full station. Then, measuring off $E\ K$ equal to 76 ft., make the offset $K\ L$ equal to 4.28 ft. L is then the end of the curve, and the direction of the tangent may be found by laying off $E\ M$ from E equal to K L, or 4.28 ft. A line drawn through M and L gives the direction of the tangent. Points on the curve midway between A and C, C and D, etc. may be set by the foregoing method of middle ordinates. Middle ordinates for 100-ft. chords are given in Table VI.

In order to lay off a curve so as to pass through a given point, which is a problem often arising, draw a tangent through that point to intersect the tangent on which the starting point is situated and connect the two tangents with a curve. For example, suppose it is required (Fig. 49) to reach the point B by a curve starting from A on the line $A\ E$. Connect $A\ B$ and find C, its middle point, by sighting or by stretching a wire, and measuring. Draw through B a line to meet $A\ E$ in D, so that $B\ D = A\ D$. The point D may be found by drawing from C a line perpendicular to $A\ B$ to intersect AE; or it may be found quite readily

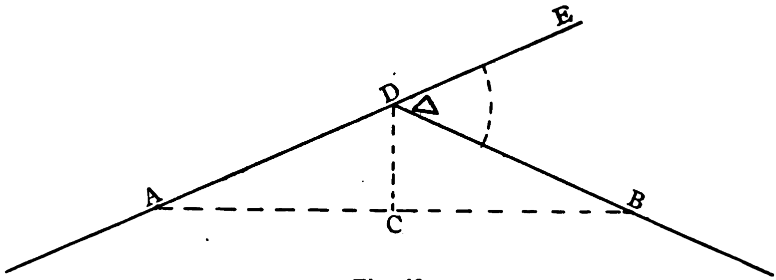

Fig. 49.

by estimating the length $B\ D$ and "cutting and trying" once or twice. Having the two tangent distances and the intersection or Δ angle $E\ D\ B$, the radius for the proper curve to connect A and B will be

$$R, = \frac{\textit{tang. dist.}}{\textit{tang.}\ \frac{1}{2}\Delta} = \frac{AD}{\textit{tang.}\ \frac{1}{2}\Delta}$$

Having the radius we can now lay off the curve by the method of middle ordinates or by tangent offsets and chord deflections, as best suits the case.

43. To Find the Degree of Curve.—Where there are not marked monuments or records of some kind at the curve it often becomes necessary to measure the degree of curve. The middle ordinate of a 62-ft. (more exactly 61.8 ft.) chord, measured in inches, gives the number of degrees curvature. That is, stretch tightly along the gage side of the outer rail a string or chord 62 ft. long. The number of inches from the middle of the string to the rail is the degree of the curve. If, however, the curve be out of line at the place where the string is stretched, there is liable to be quite a large discrepancy, if so short a chord be taken. It is always best, therefore, when using such a short chord to get a mean of several measurements taken at different places in the curve; but if a long chord be used, the fact that a rail or two is out of line does not so much affect the result. The middle ordinate for a chord of other length is approximately the length of the chord squared, divided by 8 times the radius of the curve. If the values in this computation are expressed in feet the result—that is, the middle ordinate—will be in feet.

There is always a middle ordinate of 4 ft. 8½ ins. available without making a measurement. That is the gage of the track; and by sighting across the rails, the length of arc for the chord of which the gage of the track is the middle ordinate may be known by counting the rails. By the use of a short table it is a very convenient way of getting at the degree of curve, either with the transit or by the eye unaided. Not so much as a tape line, string, or rule is necessary, for ordinary degrees of curvature. By sighting over a joint on the outer rail of the curve, on a line of sight which just touches the gage side of the inner rail of the curve, and counting the number of rails from the point where this line of sight intersects the outer rail beyond, back to the joint sighted across, gives a length of arc which corresponds to a certain degree of curve. On curves of over 10 deg., one should sight quite carefully. Figure 50 will explain the method more clearly, perhaps. Sight across some joint, as at C, on a line of sight which just touches the gage side of the inner rail at D; this line of sight cuts the outer rail again at A. Count the number of rails from A

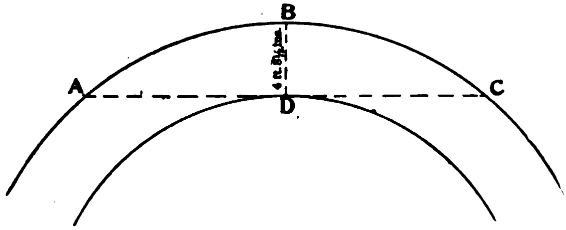

Fig. 50.—To Find Degree of Curve.

back to C or measure the distance; and opposite this distance in Table VII (shown with Fig. 44) pick out the degree of curve. This method and the table are credited to Mr. Wm. A. Pratt, formerly division engineer with the Baltimore & Ohio R. R.

44. The Action of Car Wheels on Curves.—On curved track car wheels meet with certain constraints and resistances to movement which cause them to take definite and peculiar positions with respect to the rails. An understanding of the characteristic behavior of wheels on curves assists very much to account for the various conditions imposed upon the track maintenance and also to devise methods of work and standard rules governing such conditions. The unequal wear of the rails, the spreading of the rails, the canting of the inner rail, the superelevation of the outer rail and the question of widening the gage, all stand in an important relation to the action of the wheels on the curves.

The immediate effect of joining two wheels solidly with an axle is that both wheels must turn together through equal angular distances. The consequence is that if both wheels have the same diameter they tend to run equal distances, and hence the tendency to run straight ahead. The additional force which it takes to haul cars around curves, above that required to haul them along tangents, is used up in three ways: (1) A force to all times keep the two wheels turning through equal angular distances, which force is transmitted from wheel to wheel through the axle and continually keeps one or both wheels slipping on the rail; (2) a force to keep constantly swinging the axle into its proper position radial to the curve, or nearly so, thus opposing the tendency for the wheels to run equal distances; and (3) a force to overcome the retarding tendency in the rotation of the wheel due to the friction of its flange against the rail. With a single pair of loose wheels the last force (3) is the only one adding to the resistance on curves above that on tangents; but with four loose wheels joined as in a truck, both (2) and (3) enter into the curve resistance fully as much as though the wheels were solidly attached to the axle. The resistance which curves offer to the movement of trains is of course widely recognized, it being customary, where curves occur on grades of considerable importance, to compensate for the increased resistance by easing the grade .02 to .05 per cent per degree of curvature. In average practice the rate is .03 to .04 per cent.

Consider the simple case of a single pair of car wheels and an axle, supposing them to be pushed around curved track in the same manner that one would push a lawn mower; and let Engraving *G*, Fig. 51, represent such a contrivance in diagram. A device built on this principle is actually used for the forward truck of two classes of locomotives. Let the axle in starting have a position (*A B*) radial to the curve. The direction of the handle by which the wheels are pushed is then, to start with, tangent to the center line of the curve at the axle. Now if the axle is to remain radial to the curve, it is plain that the two wheels cannot travel equal distances, because the outside rail in track of standard gage is the longer, between radial lines to the curve 100 ft. apart, by over an inch per degree of curve. The two wheels, then, if of equal diameters, cannot run equal distances for a single revolution and maintain the position of the axle radial to the curve; but unless the axle can in some way be swung, the farther they run, the farther will the axle depart from a

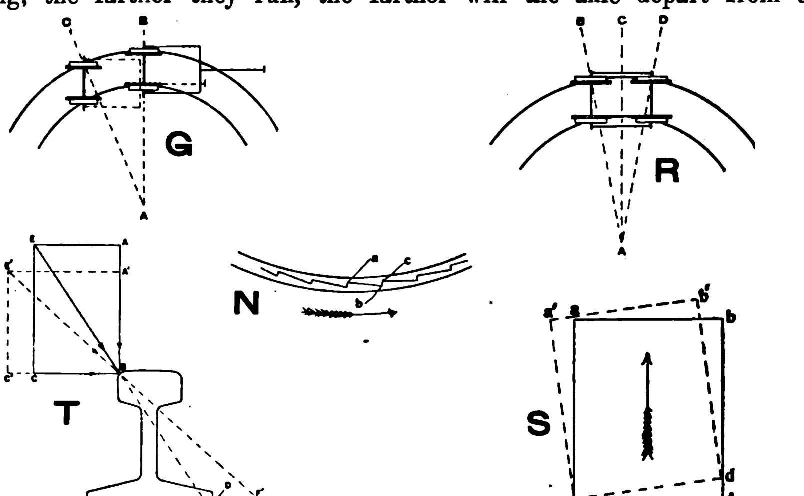

Fig. 51.

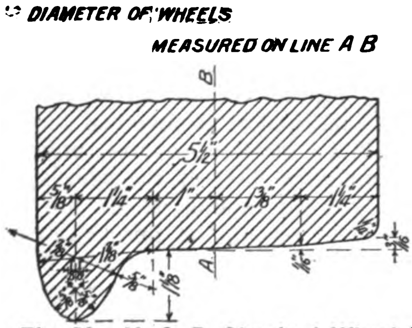
radial position, until it becomes so skewed to the rails that either the outside wheel will mount the rail or else the inside wheel will drop between the rails. It must be plainly seen that to keep a pair of wheels on the rails the axle cannot depart from a position radial to the curve by more than a limited amount; and it will subsequently be shown that the nearer to the radial position the axle is kept, the less will be the resistance which the curve will offer to the passage of the wheels.

It is apparent that if the inner wheel referred to in the figure was smaller in diameter than the outer one, by a certain amount fixed for the special curve on which they are rolling, the axle would maintain its position radial to the curve unaided. Of course this supposition has no application to track, but the principle is applied in car wheel design and has some effect, with new wheels at any rate, toward lessening resistance on curved track. Both wheel treads are of the same diameter with respect to corresponding portions of each; but the tread of each, $2\frac{3}{4}$ ins. from the flange, is smaller in diameter than the part next the fillet by $\frac{1}{8}$ in.; that is, the wheel tread is coned $^1/_{16}$ in., as shown in Fig. 52. (The increased coning of the wheel for $1\frac{1}{4}$ ins. on the outside of the tread is to reduce the tendency of the wheel to drop between the rail heads at frog points and at the heels of frogs, and into the flared opening at the stock rails of point switches, after the wheel tread becomes hollowed out by wear.) The gage of the wheels is also made $\frac{3}{8}$ in. less than the gage of the track, permitting that much play in the wheels across the track. On a curve, then, the outer wheel, the flange of which will crowd the outer rail, will roll on a periphery of greater diameter than that upon which the other wheel is rolling, and produce the same effect as though the inside wheel was of less diameter than the outside wheel by some certain amount. As to just how much this increased diameter is, is difficult to tell, because it is not known just how far up on the flange fillet the wheel rolls, when running at any given speed. But with a new wheel the increase of diameter due to the coning, at slow speed, is at least $^1/_{50}$ in., thus enabling the outer wheel to gain $^1/_{16}$ in. on the inner wheel per revolution and hence adapting it to a curve of about $\frac{3}{4}$ deg. At higher speed the degree of curve for which this amount of coning ($^1/_{16}$ in.) would adapt itself must be larger.

By widening the gage of the rails this speed difference of outer and inner wheel is increased: for every $\frac{1}{4}$ in. the gage is widened the wheels become adapted to a curvature greater by about $\frac{1}{2}$ deg. By heavily coning the wheels the gage of the track on any curve might be so adjusted that curve resistance could practically be overcome, but neither scheme is practicable or desirable. By heavily coning the wheels more tractive power would be wasted in the increased resistance and unsteadiness of motion on tangents than would be saved on curves, unless the gage of the track on tangents corresponded to that of the wheels; and this is not a practicable proposition. For this reason wheels are coned but very little, and consequently nothing of account on this score can be gained by widening the gage of curves. The degree of curve to which a $^1/_{16}$-in. coning of the tread is adapted is so small and the coning disappears from the tread so rapidly, that, taken all in all, the part which coning of the wheels and widening of the gage plays in decreasing the resistance of wheels to rolling around curves must be very little. In fact, any advantage which accrues from the coning of wheels is soon lost, for on car and locomotive wheels which have seen much service the conicity will usually be found reversed; that is, the wheel will usually be found smaller in diameter near the flange than on the outside of the tread, thus giving exactly the opposite effect that coning is intended to produce. It has also been pointed out by Mr. M. N. Forney that coned wheels on axles held rigidly parallel do not roll as freely as a pair of coned wheels on a single axle. A model consisting of two wheels $1^7/_{16}$ and $1^5/_{16}$ ins. in diam., respectively, on the same axle rolled freely in a circle of $26\frac{3}{4}$ ins. radius. When two such models were joined together with the axles parallel and $1\frac{1}{2}$ ins. apart the combination model rolled in a circle of $33\frac{1}{2}$ ins. radius. With the axles 4 ins. apart the model rolled to a circle of 169 ins. radius, and with the axles 5 ins. apart it rolled to a circle of 322 ins, radius, showing that the tendency of coned wheels on parallel axles to roll in a circle is counteracted by spreading the axles farther apart. Reasoning from experiments with models the conclusion was reached that a freight car truck with axles 5 ft. apart and wheels coned $^5/_{16}$ in. in 3 ins. would have to be given lateral play of $\frac{3}{4}$ in. on the rails in order to roll freely to a 1-deg. curve.

There is a popular but erroneous impression that the outer wheel on curves is enabled to keep abreast of the inner wheel by a rotative slipping of one or the other, or both. It must be apparent that the action of slipping in rotation can effect no advance for either wheel, for when one wheel slips its mate must slip also. If a pair of wheels rigidly fixed to an axle which is not attached to anything be set rolling on a curve and left to themselves there will be no slipping of either wheel and the pair will not keep to the track. The outer wheel can keep abreast of the inner one only by ***swinging about it,*** and this is true whether there be only one pair of wheels, or two or more pairs joined together, as in a truck or as the connected drivers of a locomotive—the outside wheels must swing about the inside ones, and it will now be shown how this occurs.

Referring again to the pair of wheels pushed lawn-mower-fashion (Engr. *G*), suppose that no attempt is made to keep the axle radial to the curve and that the wheels are pushed forward apace. It will soon be seen that the inner wheel has gained a little on the outer one with respect to a radial line (*A C*) drawn to the outside wheel in its new position. The wheels have run equal distances, but not straight ahead; the axle in its new position is parallel to its old position; and with respect to the curve the handle has swung inward. This fact goes to show that in order to keep the axle always radial to the curve, or at a constant angle with a radial line, there must be a force outward at the end of the handle



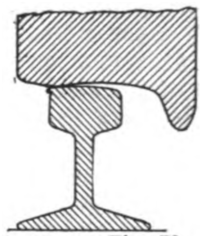


Fig. 52.—M. C. B. Standard Wheel Tread and Flange. Fig. 53.

to oppose the inward swing; or, in other words, the tendency of the axle to swing out of a radial direction, or out of a position having some constant angle with the radial direction, exerts a force tending to swing the handle inward with respect to the curve. Now this is exactly the action of the front wheels and axle in any four-wheel truck. In place of the handle there is the truck frame attached to both axles, holding them parallel to each other and rectangular to itself. In place of the hand guiding the handle or frame, as in the lawn-mower affair, the trailing wheels and axle hold the rear part of the frame to a position constant in direction with respect to the curve, or at least very nearly so (see Engr. *R*). The force which, with the single pair, swung the handle inward still acts and tends to swing the rear pair of wheels inward. This accounts for the fact that in passing around curves the front outer wheel of the truck crowds against the rail continually, while with the rear wheels the tendency appears as though to crowd the pair toward the inner rail.

Aside from the swinging force exerted on the truck by the tendency of the front axle to move parallel to itself, another partial cause for the inward swing of the rear axle is a considerable force tending to swing the truck as a whole, which is due to the retardation of the front outer wheel in consequence of the friction of its flange against the rail. The tendency of movement of the wheels on the rear axle is the same as that of the front pair, namely, to run straight ahead and follow the forward pair, but the motion of the outer rear wheel is not in a direction to crowd the outer rail at the point of contact (Engr. *R*). Any inward swing of the rear axle moves it into a position approaching that of a line radial to the curve. With the axle radial the movement of the wheels is, of course, neutral respecting the two rails; that is, they tend to crowd neither rail. Hence it occurs that every force acting upon the rear axle which can affect its position with respect to the curve tends to cause the outer rear wheel to run clear of the outer rail. Observation of a train passing a curve will show that the flange of the rear inner wheel on some of the trucks crowds the inner rail, while in other cases the rear wheels take an intermediate position respecting the rails. According to Mr. Wellington the flange of the outer rear wheel of a four-wheel truck is supposed to stand away from the outer rail a distance equal to the versed sine of a chord having twice the length of the wheel base. This is the same as saying that the rear axle maintains a position radial to the curve, if free to do so; but he gives no reason why this should necessarily be the case. As the shape of the wheel tread must be an important factor of the behavior of the wheel on the rail one can readily understand how the position of the rear wheels relatively to the rails is not fixed, as is proved by observation. It is readily imaginable how a pair of trailing wheels the treads of which are in a condition of reversed conicity might take a position different from that of a pair of wheels newly coned. The degree of the curve, the elevation of the outer rail and the length of the wheel base are also effective on the behavior of the trailing pair of wheels. Other conditions remaining the same, the shorter the wheel base the closer should the flange of the inside wheel on the rear axle run to the inside rail. And then, it might be expected that the position of the rear wheels of a truck would be quite dependent upon the relative freedom of action under the side bearings. Where the body bolster is down hard on the side bearings the truck may not be free to align itself in accordance with the tendency of the wheels.

It is now opportune to consider how both outer wheels of a four-wheel truck do actually swing about the inner wheels and keep abreast of them on the curve, or how the truck as a whole is guided or kept straight with the track. With a four-wheel truck standing on the track so that the flanges of both outer wheels touch the rail neither axle can be radial to the curve, because radii cannot be parallel. In this position a line drawn parallel to the axles half way between them is radial to the curve (*A C*, Engr. *R*), and the position of each axle deviates from that of a radial line by a very small angle which varies with the degree of the curve. The nearer the truck can be kept to this position the less will be the resistance to its movement. Start the truck around the curve. Immediately both inner wheels turn equally with those on the outside, and will run an equal distance (neglecting the effect of coning) unless held back; but they are held back. The tendency of the leading inner wheel to get farther away from, and of the rear inner wheel to approach, a line radial to the curve swings the trailing pair of wheels inward to the curve about the outer front wheel as a center (for the instant). Of course the limit of this movement is when the inner rear wheel flange meets the rail, and frequently a truck will be seen running in this way, as already stated. There being no external force exerted to move the leading wheels and axle laterally or in a direction endwise to the axle, the outer leading wheel always tends to roll straight ahead and its flange, of course, cannot depart from the rail.

The truck moves continually in a position askew to the curve, being so compelled by the constant tendency of the inner wheels to outrun the outer ones with respect to a line drawn radial to the curve. The truck, as a whole, swings about its inner rear corner as a center—that is, about the point where the inside rear wheel touches the rail. As the two sides of the curve are unequal in length the outer wheels must swing through the distance necessary to keep them opposite their mates on the inner rail, the tendency of which is to keep in the advance. Hence in passing around a curve the whole load on the outer wheels must be dragged a distance equal to the difference in the length of the two sides of the curve. The action which causes the truck to swing is the lateral sliding of the front wheels across the rails toward the inside of the curve, due to the constraint of the outer front wheel flange. In Engraving *S*, Fig. 51, the four corners of the rectangle *a, b, c, d* represent diagrammatically the points of contact of the four wheels of a car truck with the rails, *a* and *b* being the points of contact of the leading pair of wheels and *c* and *d* those of the trailing pair. If *b* be pushed or shoved in the direction of *a*, then *a* must move also in that direction; and the side *b d* of the rectangle will be moved ahead or swung around *c* as a center, and the direction of the truck will be changed by the angle *a c a'*. This lateral sliding of the leading pair of wheels is caused by the circular path to which the wheels are constrained. The wheels at any instant actually move in a different direction from that of the plane of their rotation. The movement is the resultant of a lateral skidding combined with longitudinal progression. In order that the truck may curve, both the outer wheels must slide along the rail and both leading wheels must slide laterally; the outer leading wheel therefore slides both longitudinally and laterally respecting the rail. What is true of the action of a single truck applies to both trucks of a car and to the trucks of all the cars in a train. The effect of the "indraught" of the locomotive—that is, the tendency in the pull of the locomotive to straighten the train—in reducing the crowding action of the front outer wheel flanges against the rail is not perceptible, even in the longest train. The front outer wheel of a car or truck persists in flanging with the outer rail against all forces acting upon the car in consequence of being coupled in a train.

The tendency of the two wheels on the front axle to run straight ahead crowds the flange of the outer wheel hard against the rail, and the wheel is continually tending to roll on the fillet or side of the flange and lift the tread from the rail. At slow speed, when the rails are dry, the wheel on the outer rail may sometimes be seen to rise and roll along on the fillet or side of the flange, while the inner wheel may be seen to spread or spring slightly outward the top of the inner rail; until suddenly the wheel on the outer rail will drop down to a bearing on its tread and, by this wedging-like action of its flange, transmitted through the axle, shove the inner wheel squarely across the top of the inner rail; this rail, as soon as the wheel lets go, tilts suddenly back to its normal position. The tendency of the wheels is thus to spread the rails apart. A movement of the inner rail relatively to the inner wheel a full $\frac{1}{4}$ in. has been observed to suddenly take place at slow speed. At higher speeds both the rail and the wheels move relatively just the same, in a direction crosswise the track, but more continually, and with an amplitude decreasing with increase of speed, until a point is reached when both the inner wheel and the top of inner rail are in a state of continual vibration back and forth. At good speed the outer front wheel will sometimes roll on the fillet or side of the flange, with the tread lifted clear of the rail, for long distances. The path of contact of the inner wheel with the rail is a zigzag line like that shown in Engr. *N*, Fig. 51, exaggerated and distorted for sake of clearness. The portion *a b* is supposed to be a movement in the direction of the rotation of the wheel, and the shorter portion, *b c*, the movement across the rail top. The arrow denotes the direction in which the wheel is moving. This vibration of the inner wheel sometimes sets up a ringing sound not unlike the squealing of a pig, but it varies in pitch all the way from a coarse, grating sound to a howl, and up to a sharp or shrill ring. The explanation of this phenomenon is that the wheel is in principle a flattened-out bell kept in continual vibration by the rapid alternate catching and slipping of its tread in contact with the rail.

Canting of the Inner Rail.—The action of wheels on curves enables one to account for the canting or tilting of the inside rail. On curves where the ties are soft or old the inside rail will sometimes cant or tilt over, more or less, the top of the rail canting outward; and frequently it will spread the spikes. This action is most pronounced where the traffic is heavy and speeds, as a general thing, are slow. Some students of the question attempt to explain it on the claim that the increased weight which the inside rail sustains at slow speed causes the canting and that the spreading is caused by the tight running of locomotive wheel bases on track not gaged widely enough. There is, on elevated curves, at slow speed, an increased weight borne by the inside rail over what it sustains at higher speeds, and the greater weight thrown to that side increases the friction between the wheels and the rail and consequently the force of the overturning component on the inside rail; and there is a corresponding decrease in the overturning force on the outside rail. This overturning force is greatest when the car is standing still, because when in motion it is counteracted by centrifugal force, more or less, and may be entirely overcome. The principal cause of canting, and which is independent of centrifugal force, is the lateral sliding of the inner wheel across the rail top, as hitherto explained. Its effect is somewhat dependent upon the elevation of the outside rail and the speed, because the greater the weight which is thrown upon the inside wheel the greater will be its tendency to travel tangent to the curve and the greater the skidding friction. When it is considered that while a long freight train is passing around a curve all the inside wheels on that curve are exerting a reactionary crowding force across the top of the inside rail it is not difficult to understand how it is tilted outward, and the phenomenon is explained.

It may be asked why the outside rail is not tilted outward, inasmuch as it would seem that both outside and inside wheels must crowd outward across the rails with the same force tending to spread them apart, the action of each and the reaction of the rail against each, being equal and opposite in direction. Against the head of the outside rail there is acting a force due to the crowding of two wheels on each axle, but (leaving for the moment centrifugal force due to speed out of the question) the crowding of the flange of the outside wheel alone is a binding action, taking place simply between the tread, flange and rail; and, having no reaction against any object exterior to the rail, it cannot exert a force tending to overturn that rail. The tendency of the outside wheel and flange is to continually run tangent to the curve and against the rail. The tendency of the inside wheel, on the contrary, is to run tangent to the curve, but away from the inner rail. It is this tendency of the inside wheel to run away from its rail which produces a lateral force through the axle tending to overturn the outside rail, because it is reacted against by an object exterior to that rail; and the object reacting against this lateral force is the inside rail, so that the same force acts equally against both rails. In other words, the force exerted by both wheels, in being turned from a straight path and constrained to a curved path, as far as it can act toward overturning either rail, must tend to overturn both rails with the same force. It is also clear that this force can be no greater than the friction between the inside wheel and the rail top; that is, the friction opposing the lateral sliding of the wheel across the rail. The fact, then, that the outside wheel acts against the side or corner of the outer rail head by flange pressure, while the inside wheel acts against the inner rail only by sliding friction between tread and rail top, does not render the outside rail the more liable to overturning. Just why the flange pressure from the outside wheel alone has no tendency to overturn the outside rail may be more clearly understood, perhaps, if it is reflected that, with some means to steady it, a single wheel, not attached to an axle, will roll along the outside rail and keep to the rail. The flange will, of course, crowd the rail, but, as the wheel can react against nothing exterior to the rail, it can at slow speed have no tendency to overturn the rail. On the other hand, a wheel rolled similarly along the inside rail, having no axle or other thing to react against, would not keep to the rail, for it would roll straight ahead, of course. So much for the front pair of wheels. But with the rear pair of wheels the case is different. As has been shown, the rear pair of wheels serve to guide or steer the truck frame straight with the track; and the tendency of the front axle to skew swings the rear end of the frame so as to oppose the tendency of the rear axle in an endwise direction, sufficiently, almost always, to keep the flange of the outer rear wheel from crowding the rail. In exerting a force outward to the curve, by which the rear wheels and axle oppose and balance the inward swing of the rear of the truck frame, the wheels must necessarily react against something exterior to the frame, and that which they react against is the two rails. In other words, and to use a familiar picture, for illustration, the force exerted by the tendency of the inside rear wheel to run away from the rail, reacts outwardly against that rail and exerts itself in crowding against the rear of the truck frame as a man would in "beaming" a plow. Likewise, the force exerted by the outside wheel is also a force crowding against the frame, but reacting against the outer rail in a direction inward to the track or curve. Thus, while the reaction of the front pair of wheels against the rails has a tendency to spread the rails apart, the tendency of the reaction of the rear pair against the rails is to overturn both those rails, not in opposite directions, so as to spread them apart, but in the same direction, and that toward the inside of the curve. If the force required to keep the truck gradually swinging, as it moves along the curve, be greater than this tendency of both the rear wheels, the flange of the inside wheel will seek its rail; if such required force should be equal, the rear wheels will take a mid position respecting the two rails; while if it should be less, the outside rear wheel flange will crowd the rail. As stated, however, such last condition is not usually the case with a truck of ordinary length. So, regarding the tendency of the rear pair of wheels to run in a straight line, the reaction of the inner wheel is always against the rail, tending to spread it or overturn it outward to the track. With the outer rear wheel, if its flange be not against the rail, its tendency to run straight ahead is exerted as if to overturn the outer rail inward to the track, and it thus balances the force exerted on the rail at the outer front wheel in the outward direction. The resultant overturning force against the outer rail thus becomes nil, while the crowding effect of these two forces forms a couple tending to move the rail both out and in—outward at the front wheel and inward at the rear wheel. In no case, except in the very exceptional one where the outer rear wheel flanges with the rail, can there be any resultant overturning force acting on the outer rail, and even in that case it would but little exceed that of the front pair of wheels. To sum up, then, the combined resistance offered by both inner wheels, to being constrained to keep their positions opposite the outer wheels, relatively to the track, in traveling a curved path, acts with full effect, at all speeds, toward overturning the inside rail outward; while with the outside rail it is only the very exceptional case where there is any resultant overturning force against it at all. Hence it is that at slow speed the inner rail is sometimes tilted while the outer rail is not.

The manner in which the wheels bear upon the rails will also account in some measure for the unequal tendency of the inner and outer rails to tilting. The manner of bearing is indicated by the rail wear. Thus the top of the outer rail wears down most rapidly at the gage side of the head, showing that the preponderance of weight bears upon that side, at least until the rail becomes considerably worn, the effect of which is an unequal distribution of the weight on the rail base and a tendency to tilt the rail inward to the track. On the inner rail, however, one will usually find the wear most rapid on the outside of the head, caused by the bearing from the least worn portion of the wheel tread, as shown in Fig. 53. The tilting effect due to the unequal distribution of weight in this case is toward the outside of the track, or in the characteristic direction for the inner rail. It may be noted in passing that a condition favorable to the bearing of the wheel in the manner shown is widened gage, since it permits more lateral movement in the wheel. Another commonly observed effect from this manner of wheel bearing is the flowing of metal and the formation of "fins" along the edges of the rail top.

There is, nevertheless, a force having an overturning tendency upon the outside rail, namely, centrifugal force, due to speed. For any given speed there is always a certain amount of outward force exerted by a body traveling a curved path, such force being due to the persistence of the body in tending to travel in a straight line. In curved track without elevation all this force is exerted against the outer rail of the curve. For any given speed this force against the outer rail may be overcome by elevating the outer rail, so that a horizontal component of the force of gravitation caused by the tendency of the load to slide in the direction of the inclination of the track, will balance it. As is discussed in connection with the subject of curve elevation, this balancing can be accomplished for but one speed only, so that at higher speeds than the one calculated upon some overbalance of centrifugal force will still act against the outer rail; but at slower speeds, for which the elevation is excessive, the horizontal component of the force of gravitation overbalances the centrifugal force and the resulting force becomes centripetal, or against the inner rail.

The forces acting against the rails have thus far been spoken of as having an overturning effect. Such is the tendency, but the extent to which overturning or tilting of the rail actually occurs depends largely upon the condition of the ties. The inside rail is subject to both tilting and spreading, the former more especially after the ties become somewhat unsound. The outside rail is subject to spreading but seldom or never to tilting, the reason being, perhaps, that while the force which causes the spreading of the outside rail—the centrifugal force—is acting with maximum effect at high speeds, at the same time also the weight or forces acting vertically downward upon the rail have been largely increased, because the centrifugal force acting upon the upper (and heavier) portions of the car and its load tends to relieve the inside wheels of load and throw it upon the outside ones. Also, any tilting outward of the car body on its springs actually moves the center of gravity of the load nearer the outside wheels. Resistance to spreading is the resistance offered by the spikes and the friction between tie face and rail base; while resistance to overturning or tilting is weight to be actually lifted; for, in being tilted, the rail must revolve about one corner of its flange and thus cause the inner corner of the head to rise. If the weight or force acting vertically downward be great relatively to the outward or centrifugal force the resultant force acting on the rail may fall within the outer corner of the base, thus operating to increase the stability of the rail instead of producing an overturning effect. This action may be understood by referring to Engr. *T*, Fig. 51. If *A B* represents the direction and intensity of the force due to the weight of the wheel and its load, and *C B* the direction and intensity of the centrifugal force, the resultant force acting on the rail will be indicated in direction and intensity by the line *E B*. If this line produced falls within the corner *D*, as at *F*, there can be no overturning tendency; but if the two forces acting were in the ratio of *A'B* to *C'B*, then the resultant *E'B* produced would fall without *D*, and an overturning tendency would result.

In what has been said with reference to the wheel flange, it has been supposed to be of standard form and not worn. A section of the Master Car Builders' standard wheel tread and flange is shown in Fig. 52. It will be noticed that the flange slopes away from the tread by a gradual curve or fillet, the object being to avoid having the flange make with the rail a surface contact. The greater the surface between the parts in contact, the greater is the grinding action between the two. There is also another reason for having a curve of comparatively long radius between the tread and flange. It has been stated that the front axle of any wheel base or truck must run askew to the rails when passing around a curve. Now, with the axle in this position, with the wheel flange against the head of the outside rail, suppose that a vertical plane be passed through the axis of the axle and the point where the tread meets the rail head. It must be seen that the shape of the flange determines whether or not the point where the flange touches the rail lies in this plane or outside of it. Suppose, for sake of illustration, that the flange is perpendicular to the tread, or that it is in shape the reverse of the rail head, as it practically does become when badly worn. Place the axle radial to the curve, with the flange of the outside wheel against the rail head. A plane passed as stated will now contain the points of contact of both tread and flange. But swing the axle into a skewed position, as it must take when running, and it will be seen that effectually the wheel is rolling with the outer edge of the flange grinding against the rail at a point some few inches in advance of the vertical plane in which lie the axis of the axle and point of contact of the tread; in short, the flange touches the rail at a point in advance of that at which the tread touches, and consequently the wheel makes contact with the rail by parts of unequal diameters. To properly understand the increased resistance caused by this action consider that the force exerted by the locomotive in hauling a car wheel acts about the point of contact of tread and rail with a lever arm equal to the radius of the wheel, and that just so far as the flange meets the rail in advance of this point, with just that length of lever arm is the friction of the flange against the rail acting against the force exerted to roll the wheel.

It is well known that enormous resistance is offered by car wheels with flanges which meet the tread more or less squarely. The flange, meeting the rail in advance of the point where the tread does, makes contact at a periphery of larger diameter, and produces an effect similar to that which would obtain if the wheel was skidding a block or chock in front of itself. But a well-shaped flange, which curves gradually back from the tread, cannot come into contact with the rail far in advance of a plane containing the axis of the axle and point of contact of tread, and so whatever friction exists between flange and rail has a very small lever arm with which to oppose the force which is rolling the wheel. When the wheel is rolling partly on the tread and partly on the side of its flange there is, of course, in any case, some grinding action of the flange against the rail, owing to the differing diameters of the parts of the wheel in contact; but if the wheel is rolling on the side of its flange against the corner of the rail head there is no grinding and consequently no opposition to the rolling of the wheel.

Widening Gage on Curves.—In connection with the action of car wheels on curves arises also the question of widening the gage. Since the standard wheel gage is $\frac{3}{8}$ in. less than the gage of the track it is impossible for the flanges of both wheels on the same axle to crowd both rails, and therefore impossible for a four-wheel truck to bind in any curve used in steam railway track. It must therefore be clear that there is not the slightest necessity for widening gage for four-wheel trucks. The question regarding the widening of gage on curves must arise with vehicles having more than four wheels in the same base, especially as is the case with locomotives having six or more drivers.

The question of widening gage on curves involves a discussion of two features of locomotive running gear, namely, the arrangement as to the flanging of the driving wheels, and the design of the forward truck respecting provision for lateral movement of the locomotive frame. As to either of these matters there is as yet no widely prevailing settled understanding between the track and motive-power departments. The wheel base details of the locomotives on each railway are usually designed to suit the ideas of the motive-power management respecting the features here considered, and the official responsible for the maintenance of the track studies the conditions of running as they appear in the spreading of the rails and in rail wear, and then adopts some try-and-fit rule for gaging the curves. To summarize the situation generally, it may be said that it is not customary for the two departments concerned to study the matter from a mutual point of view.

In considering the matter of driving wheel flanges it is well to begin with a case which fairly approaches the extreme of ordinary conditions. The longest driving-wheel base used to an extent which might be termed general is that of consolidation, and mastodon or 12-wheel locomotives, measuring 16 ft. Let it be supposed that the rails and wheel tires are new or not worn and that the rails are laid snug to gage, and then ascertain how much, if any, the gage should be widened in order to pass such a driving base freely around a sharp curve, the total wheel base (which includes the forward truck) not being considered in this instance. On a 15-deg. curve the middle ordinate of a 16-ft. chord is almost exactly 1 in., and a side ordinate corresponding to the position of one of the intermediate drivers is $^{57}/_{64}$ in. Taking account of the usual $\frac{1}{8}$ in. of side play in the journal boxes (it is frequently as much as $\frac{1}{4}$ in., and sometimes more, in new locomotives), it is clear that if the tires of the two intermediate drivers are flanged, the flanges of these wheels must stand at least $^{49}/_{64}$ in. clear of the outer rail and 4 ft. $7^{47}/_{64}$ ins. from the gage side of the inner rail. But the gage of the wheels is 4 ft. $8\frac{1}{8}$

ins., or $^{25}/_{64}$ in. more than the available room. Apparently, then, the gage of the track should be widened $^{25}/_{64}$ in. or about $\frac{3}{8}$ in.

Under ordinary conditions, however, it would not be necessary to widen the gage that much, for it is quite commonly the practice to make the gage of the front and rear pairs of drivers $\frac{1}{4}$ to $\frac{3}{8}$ in. less and the gage of the intermediate pairs of drivers $\frac{1}{8}$ in. less than standard, without extra side play in the axle boxes. If such was done in the case here considered the required amount of widening of the track gage would be reduced to $^{13}/_{64}$ in. By a "tight squeeze" this wheel base might pass safely around the curve without widening the gage, but the wheels would either ride high on their flanges or else some springing of the parts (such as the rails or the locomotive frame) would have to take place. With rails or wheels considerably worn, however, such a wheel base should freely pass the curve referred to. It takes but little wear at the corner of the rail head and in the fillet of the wheel flanges to increase the free side play of the wheels to $\frac{3}{4}$ in. In fact, one can find but few wheels, even among those considered to be in good condition, with which the side play is less than 1 in. on rails laid to standard gage. With new rails or rails not worn at the top corner of the head, it would seem advisable to widen the gage of the curve for such a wheel base as is above considered.

On a 10-deg. curve the middle ordinate of a 16-ft. chord is $^{11}/_{16}$ in., and a side ordinate at one of the intermediate drivers about $^{39}/_{64}$ in. Taking into consideration the $\frac{1}{8}$-in. side play in the journal boxes and the $\frac{3}{8}$ in. in the wheel flanges, as before, we find the required amount of widening of the gage to be $^{7}/_{64}$ in.; on an $8\frac{1}{2}$-deg. curve the wheel base under consideration would just pass around the curve freely without widening the gage. Substituting a set of six-coupled flanged drivers, with the usual wheel base of 14 ft., for the eight-coupled set already considered, and assuming similar conditions of side play, the required amount of widening of the gage for a 15-deg. curve is found to be $^{9}/_{32}$ in.; on a $9\frac{3}{4}$-deg. curve the wheels will just pass freely without widening the gage.

In considering the length of driving base on very sharp curves the measurement should extend to the point of contact of the wheel flange, which is some little distance beyond the point of contact of the tread. In other words, on very sharp curvature the length of the driving base exceeds the distance between centers of front and rear axles by the length of the lap to the contact points of the flanges. On main-track curves this length of lap need not be considered, but on some side-tracks it is a matter requiring attention, as the length which it adds to the effective wheel base causes binding in the curves. This lap extension of the wheel base occurs on all curves with sharply-worn flanges, but in ordinary cases the wear of the flanges is sufficient allowance for the extra length of base produced. Another instance in which it is important to take account of the lap of the wheel flanges is in considering the width of flangeway at guard rails on sharp curves.

It is entirely clear that with flangeless, "blind," "bald" or "plain" tires (as they are variously known) on the intermediate drivers in the foregoing examples no widening of the gage would be required; that is, so far as the driving base alone is considered. And really, for roads of sharp curvature there is no necessity for more than two flanged drivers on each side of ordinary locomotives, for not more than that number can flange with the rail on curves sharper than about 5 deg. for a 14-ft. wheel base and about 4 deg. for a 16-ft. base, even when $\frac{1}{8}$ in. is allowed for side play in the boxes and $\frac{1}{8}$ in. more for the set-in of the leading and trailing driving tires, or half the amount by which the gage of the intermediate drivers exceeds that of the forward and rear pairs. With all but four of the drivers flangeless the question of widening the gage on curves then depends upon the manner in which the locomotive frame is attached to the pilot truck (and in some cases the trailing truck).

In this country locomotives are classified according to the number of driving wheels and truck wheels, and the following is a description of the types most commonly in use:

American or 8-wheel,	4	drivers	and	4	pilot truck	wheels.
Mogul,	6	"	"	2	" "	"
10-Wheel,	6	"	"	4	" "	"
Consolidation,	8	"	"	2	" "	"
Mastodon,	8	"	"	4	" "	"
Decapod,	10	"	"	2	" "	"

Atlantic,	4	drivers,	4	pilot truck wheels,	2	trailing	wheels.
Chautauqua,	4	"	4	" " "	2	"	"
Prairie.	6	"	2	" " "	2	"	"
Pacific	6	"	4	" " "	2	"	"
Mikado,	8	"	2	" " "	2	"	"
Trailer Decapod,	10	"	2	" " "	2	"	"

A pilot truck of two wheels is called a "pony" truck and one of four wheels a "bogie" truck. Respecting its connection with the frame, a bogie may be either a "rigid-center" or "swing-center" truck. The former arrangement is where the frame is so pivoted to the truck that there can be no lateral movement, any more than is usually allowed in journal boxes. The swing-center arrangement is one whereby the frame is attached to the truck by means of swinging hangers, which permit lateral motion of a few inches in the front end of the frame. A pony truck must necessarily be of the swing-center pattern. It is guided by a "radius bar" pivoted at a point near the forward end of the driving base, which keeps the axle radial to the curve, and in this respect its similarity of movement to that of a lawn mower is striking, as hereinbefore alluded to. Swing-motion devices take various forms, but the most frequent arrangement is to support the center casting on four links of 6 to 9 ins. length, usually splayed or hung out of the vertical, so that they will not swing too freely on straight track. In other cases "controlling" springs are set to oppose the sway of the links, the tension being such that a side pressure of 1 to 1½ tons must develop before lateral motion of the frame can take place. These springs serve to steady the motion of the engine on straight track but do not prevent the desired lateral swing on curves. Lately the use of heart-shaped or "three-point" hangers seems to be gaining favor. This style of hanger in its normal position hangs upon two points of support, at the top, the load being carried at the bottom from a point central to the two upper supports, thus maintaining stable equilibrium, as in the case with diagonally-hung links. As the hanger moves to either side it swings clear of one of the upper supports and the effect of a diagonally-hung link is immediately produced. As the ordinary link hanger swings from the vertical it offers more and more resistance to swaying as it swings farther out, and does, therefore, in a measure, enable the truck to do something toward guiding the engine. The chief advantage with the three-point device is that all of the hangers supporting the center casting swing parallel, thus equally distributing the load and the resistance to swaying; and therefore the part which the hangers take in the guiding of the engine is very considerable from the instant lateral motion begins; whereas, with the ordinary link hanger the guiding action does not become important until the hanger has swung far out of the vertical.

The pilot truck of a locomotive may serve two purposes: (1) It supports part of the weight of the locomotive, but (2) it may or may not guide the forward end of the frame. In the locomotive wheel base, as in the four-wheel truck, the flange of some one wheel must do the entire work of guiding all the rigidly connected wheels around sharp curves. One object of the pilot truck may, therefore, be to keep the front driver flange from the rail. As the rigid-center truck is fixed so as to swivel only, it accomplishes this by force exerted through the center pin of the truck. While the swiveling of the truck obviates to a considerable extent the grinding action of the front outer wheel flange against the rail, still the pressure of that flange against the rail is greater than is due merely to the load carried by the truck, for it must serve to guide the whole base, driving wheels and all. (This statement and a preceding one to the same effect may not be strictly correct in all cases. For instance, it might occur that with a locomotive concentrating an undue proportion of its weight on the driving wheels the force exerted by the resistance of the driving wheels to being guided with the curve would hold both outer pilot wheel flanges to the rail in spite of the tendency in the truck to swing the rear wheel away from the rail. In a case of this kind the flanges of both truck wheels would necessarily take part in the work of doing the guiding.) It is not considered good practice to allow sufficient side play in the truck journal boxes to permit the forward driver, if flanged, to assist in the work of guiding, because an abnormal amount of side play in the truck allows too much swinging of the frame when the locomotive is pulling hard on tangents.

The swing-center truck principally bears up weight, and takes but comparatively little or no part in guiding or swinging the driving base, except within certain limits. It does, of course, as already shown, exert a guiding influence to the extent of the resistance of the forward end of the frame to sway on the hangers, and in the case of a pony truck its resistance to being turned by the radius bar places some restraint on the outward tendency of the front drivers; but, in the main, the first flanged driver must guide not only the driving base but the locomotive entire. With a swing-center pilot truck the front driver is nearly always flanged, because it is the one which can operate with the longest leverage to force the base around. It will readily be seen that if the front driver is blind, the next driver behind must crowd the rail with much greater force in order to keep the wheel base swinging with the curve, than would be the case if the front driver did the guiding, because it not only is operating on less leverage to swing itself and the drivers following, but has also to swing the driver in front of it on the principle of a force acting on a lever of the third class; that is, the force acts between the fulcrum and the load. Even at the front driver there is required a much greater crowding force than at the pilot truck, to produce the same turning effect on the locomotive, owing to the fact that the frame projects some distance ahead of the drivers. It ought to follow, then, that the nearer the guiding flange can be to the front of the locomotive the less will be the wear on flange and rail and the less the tendency of the locomotive to spread the outer rail. This would seem to be a point in favor of the rigid-center pilot truck respecting the relative ease of service on curves.

Having investigated the behavior of the driving and truck wheels separately it now remains to consider the action of these two sets of wheels taken together. The wheel base of a locomotive includes, of course, both the driving wheels and the truck wheels. The rigid wheel base includes such wheels as are connected with the locomotive in a manner not to permit side swinging of the frame (play in the axle boxes excepted). On a locomotive with a swing-center pilot truck the rigid wheel base comprises only the driving wheels. Such is necessarily the case with all mogul and consolidation locomotives. On a locomotive with rigid-center pilot truck the limits of rigidity are the center pin of the truck and the axle of the rear drivers. It should be noted that such does not cover the total wheel base of the locomotive, because the truck is free to swivel into line (that is, into its natural position) with the curve. For convenience of reference the distance from rear driving axle to the center of a bogie truck will be called the *long base;* the corresponding distance where a pony truck is used is, of course, the total wheel base.

The question of widening the gage of curves is easily answered in any case, and the amount of widening may be determined either by computation or graphically. By applying the rectangle of the rigid wheel base of each type of locomotive to a diagram of the curve the ruling type is at once discoverable and the proper amount of widening may be scaled off, or it may be computed from the chords and ordinates. For the purpose of direct calculation of limiting curvature passable by six or eight flanged wheels, and the amount of widening required for stated conditions of wheel base and curvature, Mr. Wm. H. Searles has worked out formulas of convenient application. In the case of three pairs of flanged wheels in the same rigid base the limiting curvature on which the wheels will run without widening the gage is expressed by the formula

$$D = \frac{3825\ p}{l^2}$$

in which D represents the degree of curve sought, p the flange play in inches, and l the length of the rigid wheel base in feet. If the intermediate axle be not at the middle of the base let the distance from it to the two end axles be represented by a and b, in feet. The limit of curvature then becomes

$$D = \frac{956\ p}{a\ b}$$

In the case of eight flanged wheels in the same rigid base the formula is applicable by considering the intermediate axle nearest the middle and ignoring the other.

In the case of a locomotive with a swing-center truck and not more than four flanged drivers the limiting degree of curve that will pass the engine without widening the gage is expressed by the formula

$$D = \frac{956}{a\ b}\left(p + \frac{b\ s}{a + b}\right),$$

in which a represents the distance in feet from center of truck to axle of the leading pair of flanged drivers, b the distance in feet between the axles of the two pairs of flanged drivers, p the play at the flanges in inches, and s the side motion of the swing hangers from center, in inches. The total clearance required to pass an engine through any curvature, the degree of which is represented by D, is found by the formula

$$P = \frac{D\ a\ b}{956} - \frac{b\ s}{a + b}$$

To find the amount of widening required subtract from P the play at the flanges; that is, *widening of gage* $= P - p$. This formula is general and applies to a single rigid base as well as to a locomotive with swing-center truck. In the case of a rigid-center truck or in that of a single rigid base s becomes zero and the last term of the equation disappears. For curvature of 20 deg. or more the numerical coefficient in the above formulas should be 960 instead of 956; for 30 deg. it should be 966.

Bearing in mind, then, that the matter of widening the gage of curves on any road is a special problem to be solved from the data of the locomotives in service, it may nevertheless prove instructive to investigate in a general way a common example of each type of wheel base. In every case the gage of the wheels will be taken at the standard 4 ft. 8½ ins. and the side play in the axle boxes ⅛ in.; in the case of swing-center trucks the permissible sway will be assumed at 3 ins. from center. This amount of lateral movement has been found to take place on a number of roads. The most common example of American or 8-wheel locomotive has a driving base of 8½ ft. and a long base of about 20½ ft. For this engine with a swing-center truck it is unnecessary to widen the gage on curves not sharper than 16½ deg.; but if the truck has a rigid center the sharpest curvature on which the engine will run freely without widening the gage is 4½ deg.

The average driving-wheel base of mogul locomotives seems to be about 15 ft. and the average total wheel base of engine about 23 ft. On engines of this class the pilot truck is of the radial swing-center type and the forward driver must do the guiding, and therefore that driver should be flanged. With the middle drivers flangeless there is no necessity for widening the gage of curves not sharper than 19½ deg., but with all of the drivers flanged the sharpest curvature on which the engine will run freely without widening the gage is 8½ deg. A 6-coupled switching engine without truck behaves on curves like a mogul with unlimited sway on the pilot truck, but as the wheel base is usually but 11 to 12 ft. in length it is not necessary, even if all the drivers are flanged, to widen the gage of curves not sharper than 13 deg. (for 12-ft. base) to 16 deg. (for 11-ft. base). The Columbian type of locomotive, which has four coupled drivers with a pony radial truck in front and a pair of trailers behind, behaves on curves like a mogul; unless the trailing truck should be swing center or provided with excessive lateral play in the boxes, in which case it would behave like an 8-wheel engine with swing-center pilot truck.

The average driving base of 10-wheel locomotives is 14 ft. and the average long base is 21 ft. 9 ins. With swing-center pilot truck and the middle or main drivers flangeless the gage of curves not sharper than 21½ deg. need not be widened; with all the drivers flanged the gage of curves exceeding 9½ deg. should be widened. With a rigid-center truck no advantage to speak of is gained by omitting the flanges on any of the drivers, as with the leading drivers flangeless, or with the main drivers flangeless, or with all drivers flanged, the sharpest curvature on which the engine will run freely without widening the gage, in any of the three cases, is 4 to 4½ deg. The Atlantic type of passenger engine, which has four coupled drivers with a bogie truck and a pair of trailing wheels, may be considered a 10-wheeler, so far as the matter of taking curves and the widening of gage are concerned; unless the trailing truck should be radial and swing center (Chautauqua type) or have excessive lateral play in the boxes, in which case it would behave like an 8-wheel engine.

An ordinary (although seldom exceeded) driving-wheel base for consolidation locomotives is 16 ft., with a total wheel base for the engine of 24 ft. As the truck in this case is of the radial or swing-center type the front driver is flanged and must do the guiding. With bald tires on the intermediate drivers the gage need not be widened for this engine unless the curvature exceeds 18½ deg., but if all the drivers are flanged the gage should be widened on curves sharper than 8½ deg. No advantage is gained by omitting the flanges on only one pair of intermediate drivers. The prairie type of locomotive, which has six driving wheels with a pony radial pilot truck, besides a pair of trailing wheels, behaves on curves like a consolidation engine; unless the trailing truck should be radial and swing center (as it is in some cases) or provided with excessive lateral play in the boxes, in which case it would behave like a mogul.

The average driving-wheel base of 12-wheel or mastodon locomotives is 15½ ft. and the average long base is 23 ft. With a swing-center pilot truck and the intermediate drivers blind tired the gage of curves not sharper than 20½ deg. need not be widened, but with the same truck and all the drivers flanged the gage should be widened on curves sharper than 9 deg. No advantage is gained by omitting the flanges on only one pair of intermediate drivers. With a rigid-center truck the second or main driver comes nearest the middle of the rigid wheel base and it should have the blind tire; and, thus arranged, the gage should be widened on curves sharper than 4 deg. Although a flange on the front driver of this engine with a rigid-center truck is not a necessity, still nothing is gained in freedom of movement by omitting it, because that driver is farther from the center of the rigid wheel base than the driver following. Neither is anything gained by omitting the flange of the third driver when there is a rigid-center truck, because it is farther from the middle of the rigid wheel base than the first driver, the flange on which should be retained if the flange of the second driver is dispensed with. With all the wheels on this engine flanged the sharpest curvature on which it will run freely without widening the gage is 3¾ deg.

From the foregoing it will be seen that as between the various types of locomotives having rigid-center pilot trucks and all drivers flanged there is but little choice, 4 deg. being about the sharpest curvature any such locomotive will run around freely without widening the gage. As to the location of the flangeless drivers there is no uniformity in general practice, the flanges in some cases being omitted from one or more pairs of the intermediate drivers and in other cases from the front pair. Likewise with the manner of truck suspension: the swing-center truck is sometimes used in connection with flangeless drivers and sometimes not, while in other cases it is used with a wheel base all the drivers of which are flanged. It is a rule pretty well established, however, that with a swing-center truck the leading pair of drivers should be flanged. Cases are on record of mogul, consolidation, and 10-wheel locomotives with swing-center truck, and 8-wheel passenger engines with rigid-center truck, which were built and run in regular service with the leading drivers flangeless, but few or none of these engines are now in use. They are not regarded as safe on curves, and some prefer flanged front drivers with rigid-center pilot trucks also, for the reason that they hold to the rail better than bald drivers in case the pilot wheels become derailed. For security in running backwards the rear driver must, of course, be flanged.

As to the rate of widening gage for curvature exceeding the limit for which the wheel base is designed to run freely, that depends upon whether the widening is required for the driving wheel base, as in the case of locomotives with swing-center pilot truck and flanged drivers, within the limit of curvature on which the swing-center truck is effective; or whether the widening is required for the longer wheel base extending from the rear driver axle to the center of the pilot truck. In either case the theoretical widening would increase practically as the middle ordinate of a chord equal in length to the wheel base considered. In some cases the arrangement of the drivers might make it seem desirable to consider ordinates at points other than the middle of the chord, but the difference in any case is comparatively slight, and, for the sake of a general discussion, may be neglected. The middle ordinates of 12-ft., 14-ft., 15-ft. and 16-ft. chords, which may be taken to represent the lengths of driving-wheel base of various types of locomotives, increase at the rate of .04 in., .05 in., .056 in. and .07 in., respectively, per each degree of increase in curvature. The middle ordinates of 21-ft., 22-ft., 23-ft. and 24-ft. chords, which may be taken as representing the long base measurements for various types of locomotives, increase at the rate of 0.115 in., 0.128 in., 0.14 in., and 0.15 in., respectively, per each degree increase of curvature. It thus appears that for the driving base alone the rate of widening required varies, according to the length of the base, from $^1/_{25}$ to $^1/_{14}$ in. for each degree increase of curvature, while for the long base the rate varies from $^1/_9$ to $^3/_{20}$ in. per degree, according to length of base. In practice, however, a rate as large as that in the latter case is seldom applied. A few roads widen the gage at the rate of $\frac{1}{8}$ in. per degree above a certain limit at which widening is supposed to begin, but the rate used in the largest practice is $^1/_{16}$ in. per degree above the limit at which widening is supposed to begin, which is usually 4 to 6 deg. The maximum amount of widening with roads of moderate curvature is $\frac{1}{2}$ in. With roads of heavy curvature the maximum amount of widening is $\frac{3}{4}$ in. to 1 in.; but very few roads exceed 1 in.

The explanations necessary to reconcile practice with the foregoing theoretical requirements have already been indicated. On many roads the driver tires are set in to permit more play at the flanges than is provided for in the M. C. B. standards, $\frac{5}{8}$ in. play being common for front and rear pairs of drivers and $\frac{1}{2}$ in. for the middle or intermediate pairs of drivers. And then it should be noted that rails with side-sloping head, or a head with a long radius at the top corners, or with the top corner on the gage side considerably worn, conform more nearly to the shape of the wheel tread and flange than is the case with rails of American Society section, and therefore permit more lateral play of the flanges. In some cases, also, it is the practice to set the tires of the middle drivers of mogul and 10-wheel engines and of the intermediate drivers of consolidation and mastodon engines $\frac{1}{8}$ to $\frac{1}{4}$ in. closer between backs than on the front and rear drivers. So far as curves are concerned this is a better arrangement than to narrow the gage of the front and rear drivers, but it is hard on frog wings and on guard rails opposite frogs, and the practice should not be permitted. Any deviation from the M. C. B. standard wheel gage is bound to result in blows to guard rails and frog wings. This matter is more fully discussed under the subject of Guard Rails, § 59, Chap. VI. On roads of heavy curvature it is quite customary to leave more play between axle boxes and wheel hubs than is told of, since if the side play is not provided for in the shops the locomotive will soon make the play for itself, because on engines which bind in the curves the hub wear is very rapid. It is quite usual to leave side play of $\frac{5}{8}$ in. and even $\frac{7}{8}$ in. between wheel hub and journal box. Furthermore, the side wear of the outer rail is rapid on sharp curves, particularly if there is insufficient room for the wheel flanges, and of course such wear amounts to widening of the gage. All these discrepancies of what is considered standard practice assist in getting engines around curves in some cases where the widening of the gage seems clearly to be far too small. Investigation will usually disclose that the apparent disagreement between theory and practice in such cases is easily accounted for. Lastly, whether from the absence of these compensating features or their existence to an insufficient degree, there are instances where the inadequate widening of the gage is only too evident from the excessive crowding of the flanges, resulting in rapid flange and rail wear, spreading of the rails, and, in extreme cases the refusal of the engine wheels to follow the track. In cases where the engines bind extremely hard in the curves one may sometimes find long shavings of steel cut from the rails by the wheel flanges

Regarding the practice of widening gage on curves it may be said that no rules approaching uniformity are widely established. Some roads widen the gage on comparatively easy curves, while others adhere to the standard, even on very sharp curves. Out of 104 replies to inquiries on this point, addressed to railway officials by the American Railway Association, in 1897, 25 roads reported no increase of gage on curves. The other 79 roads reported numerous rules of increase, beginning at limiting degrees of curvature which vary widely. Table VIII is a summarized statement of these replies in condensed form.

It is remarkable that in reports and discussions on this subject, mention of the type of locomotive used, on the road reporting a particular practice respecting the widening of gage on curves is seldom made. Many persons who attempt to give reasons for widening the gage seem to think that all locomotives having long driving-wheel bases are equally severe on curves, quite ignoring the fact that the arrangement of the flangeless drivers and the method of truck suspension may make all the difference conceivable. Some study of the subject will convince any person that the type of locomotive wheel base has all to do with the question of widening the gage. Locomotives having rigid-center pilot trucks are perhaps easier on curves than those having the swing-center trucks, but they require more room on the track. On ordinary curvature the former require an increase in the gage and the latter do not, if the middle or intermediate drivers are flangeless.

Amongst railway mechanical officials the opinion is to some extent prevalent that the omission of the flanges on the intermediate drivers of a locomotive increases the resistance to traction, and the practice of flanging all the drivers of locomotives of all classes seems to be growing. Of course such practice compels the widening of the gage on curves of longer radius than would be necessary if the case was otherwise, and the claims in support of flanging all the drivers should therefore be zealously scrutinized by maintenance-of-way men. According to currently reported observation on the part of mechanical men the wear of the flanges on the front drivers of mogul, 10-wheel, consolidation and mastodon locomotives takes place more rapidly when the middle or intermediate drivers are flangeless than is the case when all the drivers are flanged. With roads of light curvature, where the ordinary side play in the boxes is sufficient to permit the intermediate drivers to flange with the outer rail, this may be true, and, of course, it might be supposed that flanges on the intermediate drivers take their share of the wear on straight track, but it is not easy to see how they can be of assistance to the front drivers on sharp curves.

This question of flanged drivers has twice been the subject of investigation and report by the American Railway Master Mechanics' Association.

Table VIII.—Practice of 79 Roads in Widening Gage on Curves.

Increase Commencing with	—Range of Increase—	Maximum Increase
1° on 18 roads	1°, increase 1-32-in. to ¼-in.	¼-in. on 5 roads.
2° " 5 "	2°, " 1-16-in. " ¼-in.	⅜-in. " 2 "
3° " 15 "	3°, " 1-16-in. " ⅜-in.	2-5-in. " 1 "
4° " 10 "	4°, " 1-16-in. " ½-in.	½-in. " 30 "
5° " 16 "	5°, " 1-16-in. " ½-in.	⅝-in. " 5 "

The method of testing was to measure the drawbar pull in hauling the same locomotive around a curve, first with the usual arrangement of blind-tired drivers and then with all the drivers flanged. The main rods and valve rods were disconnected and a dynamometer car was coupled in between the locomotive under test and the one which did the pulling, to measure the tractive resistance. In the first report, submitted in 1899, the committee found no practical difference in the power required to pull a consolidation locomotive around the curve selected, with the different tire arrangements. The second report, however, presented in 1900, purported to be more decisive. This time the same committee reported to have found that it took less power to pull a locomotive (around the same curve on which the experiments of the previous year were conducted) when all drivers were flanged than when some of the drivers had blind tires. The conclusion of the report is that it is desirable to have flanged tires on all the drivers of mogul and consolidation engines and on 10-wheel engines which have swing-center trucks; furthermore, that the tires of mogul and 10-wheel engine drivers and of the second and third pairs of drivers of consolidation engines should be set 53¼ ins. back to back (⅛ in. less than M. C. B. standard), and the tires of front and rear drivers of consolidation engines 53⅛ ins. back to back. The report makes no reference to any requirements as to the gage of the track, neither is the proper relation of the wheel gage to the gage of the track on curves considered in any manner. Apparently the only aim considered was to save flange wear, whether or not at the expense of the track.

A review of the tests on which this report was based is important, because it shows such a variation in the conditions of the different tests that the conclusions of the committee appear groundless and misleading. The tests were conducted on a 14½-deg. curve on the main line of the Lehigh Valley R. R., on an ascending grade of 56 ft. per mile. The track was laid the same year with 100-lb rails, to a gage of 4 ft. 8¾ ins., on good ties with tie plates, and the elevation of the outer rail was 5 ins. The particular part of the curve on which the observations were taken was 476 ft. in length. The engines tested were a 10-wheeler and a consolidation just out of the shop, with a lateral motion of ⅛ in. between wheel hub and axle box. The gage of truck wheels and of driving wheel tires in all of the tests except one was 53¼ ins. between backs, which, considering the gage of the track, would give ¾ in. play at the flanges. Three series of tests were made with each engine, with a different tire arrangement each time, each series of tests comprising three runs at speeds intended to approximate ten, twenty and thirty miles per hour; that is to say, there were nine runs with each engine, or one run at each speed for each tire arrangement. The same two engines were used in all of the tests.

In the first test with the 10-wheeler it had a rigid-center truck and the front drivers were flangeless; in the second test it had a swing-center truck and the middle drivers were flangeless; in the third test it had a swing-center truck and all of the drivers were flanged. In the first test with the consolidation the intermediate or second and third pairs of drivers were flangeless; in the second test the second pair of drivers were flangeless and in the third test all of the drivers were flanged. In this last test with the consolidation the tires of the leading and trailing drivers were set 53⅛ ins. between backs of flanges, or ⅛ in. closer than the gage of the intermediate drivers. The results of the test in which all the drivers were flanged, in the case of both engines, show a smaller average drawbar pull than was registered in either of the tests on each engine with the other tire arrangements, but the variability of the conditions divest the entire series of tests of any meaning. The rigid-center truck in the first test with the 10-wheeler eliminates that test from consideration, and in the tests with the consolidation the gage of the front and rear drivers was not the same in all cases. But the irregularity which completely defeated the purpose of the experiments was the fact that the tests with both engines when all the drivers were flanged were conducted on a wet rail, in a light rain, whereas all the other tests were made in clear weather, on a dry rail. The effect of such a conspicuous disparity the committee assumed to dispel by sanding the rail before the test, but the efficacy of such an expedient is certainly conjectural. Moreover, the scheme of the tests was badly planned, in that only one run was made at each speed for each tire arrangement, and the speed recorder showed too much variation in the speeds actually made to admit of fair comparisons. For instance, the speeds made in the second run in each of the three tests with the 10-wheeler were 16.2, 22.95 and 24.5 miles per hour, respectively, and in the corresponding run in the three tests with the consolidation they were 18.6, 22.7 and 18.6 m. p. h., respectively, when they were supposed to approximate 20 m. p. h. The corresponding other runs in the tests with each locomotive were equally variable as to speed, as were also the averages of the three runs in each of the tests, the same for the 10-wheeler being 17.8, 21.2 and 22.2 m. p. h., respectively. It would have conduced better to the usefulness of the results had it been attempted to make all of the 18 runs of the series at the same speed. Lastly, some inconsistencies appear in the results figured from the dynamometer records and spring curve, which reflect badly upon the calculations.

The reason for criticising the work of this committee thus in detail is the fact that the conclusions of the report have been quite widely accepted as final, by both mechanical and maintenance-of-way men, when really the report, for the purpose intended, is of but little or no value. In any event, however, the resistance of the drivers to passing a curve when the engine is hauled loose, at the end of a train, as in the case of these experiments, may not be the same as that which obtains under service conditions, when the same engine is under the strain of hauling a train around the curve.

The effect of flanging all the wheels of such locomotives as are covered by the conclusions of this report reaches farther than the matter of widening gage on curves. In the case of a frog or guard rail on the outside of a curve, the channel or flangeway, which is supposed to be but ⅜ in. wider than the thickness of a wheel flange, is parallel to the curve, whereas the intermediate driver or drivers must run on the chord of the arc which terminates at the end drivers. Unless, in such cases, where the curvature is heavy, the channel of the frog or the flangeway of the guard rail is made to special order the backs of the flanges of the intermediate drivers will impinge heavily upon the wing of the frog or the guard rail—it is a "tight place" for an engine to "worm" itself through. The conclusions of the report as to the gage of driving-wheel tires are at variance with the M. C. B. standard wheel gage and therefore open to the criticism already referred to respecting blows to guard rails and frog wings. A supposedly better arrangement for the variation of flange play with the drivers is that which has been in vogue for many years on the Delaware, Lackawanna & Western R. R. On that road the driving-wheel tires are all set to the M. C. B. standard distance, 4 ft. 5⅜ ins. back to back, and increased lateral play for the front and rear drivers is provided by varying the thickness of the flanges. On mogul engines the play at the flanges of the front drivers is ¼ in., at the main driver flanges ⅝ in., and at the back driver flanges $\frac{1}{2}$ in. On consolidation engines the play at front and back driver flanges is $\frac{7}{8}$ in. and at second and third driver flanges $\frac{5}{8}$ in. The lateral motion between hubs and axle boxes is $^3/_{16}$ in. But this arrangement is hardly an improvement, from the track standpoint, because the thinned flange permits the back of the flange on the mating wheel to strike that much deeper into the guard and wing rails on that side.

The prevailing tendency is to widen the gage of curves too much or to widen it where the necessity for doing so does not exist. One of the objectionable features, or supposed evil effects, of widening the gage of curves is that it permits car trucks to slew more on the track and hence to run with greater obliquity of flange contact with the outer rail, resulting in excessive side wear to the rail and to wheel flanges, waste of tractive force and increased tendency for wheels with sharp flanges to climb the rail. Particularly is such the case with the forward truck of cars which are hard down on their side bearings. With the running gear in this condition the resistance of the truck to adjust itself to its natural position on the curve will cause it to run with the wheels on opposite corners crowding the rails with excessive pressure, and the wider the gage the greater is the slewing angle, as just stated. Then, after passing out of the curve the truck will continue to run cornerwise and cause the forward wheel in flange contact to grind against the rail. Trucks out of true also tend to run in the same manner, and the situation is all the worse for widening the gage. In numerous instances abnormal side wear to the outer rail of curves laid to widened gage has been observed to cease upon drawing in the rails to close gage, and the usual explanation is that on rails laid to close gage car trucks run in a position more nearly parallel with the track.

The effect which widening the gage has upon flange wear and train resistance, or the resistance of car trucks, does not appear to have been well investigated, experimentally. From all the indications which trend in that direction, however, it seems reasonable to raise the question whether it might not be more important to pay heed to the proper relation of the track gage to the car-wheel gage, as affected by curvature, than to seek to reduce flange wear and the resistance of locomotive drivers by some tire arrangement that compels a sacrifice in the way of increased car truck resistance by reason of an enforced widening of the track gage. The car wheels in an average train are many, whereas the locomotive wheels are comparatively few, and it is well worth the study to determine which demand the greater consideration on curves. As an illustration, it is probably true that engines with rigid-center trucks and a suitable arrangement of flangeless drivers, with sufficient room in the gage of the curve, are easier on the track than engines of the same type with swing-center trucks and any possible tire arrangement. Nevertheless the greater widening of the gage required for the engines with rigid-center trucks on the sharp curves may cause extra resistance from, and wear to, the car wheels which will more than offset any advantages with that arrangement for the truck.

From the trackman's point of view the moral effect of widening gage is questionable. It usually occurs that any departure from the general standard in this respect leads to a good deal of looseness; for where a curve is supposed to be spiked $\frac{1}{4}$ or $\frac{1}{2}$ in. wide, one is quite likely to find almost any variation up to $\frac{3}{4}$ in., and, if not, the rail will soon wear enough to make the gage excessive for the needs. These discrepancies lead to carelessness in gaging tangents, and the matter of close gage gradually ceases to be regarded cautiously for either tangents or curves. Therefore gage should not be widened unless it is absolutely necessary that it should be done. It is a very important question whether rolling stock should be built for the track or whether the track should be gaged to suit rolling stock built to arbitrary standards respecting curvature.

Sharp Curves and Curve Guard Rails.—For standard-gage main-track service curvature exceeding 4 deg. is considered sharp, 10 deg. is very sharp and 15 deg. (radius 383.1 ft.) is a limit at which the great majority of railway engineers will stop if the situation will permit. The sources of danger to train operation on curves are bad surface and alignment in the track, hard-swiveling trucks, sharply worn wheel flanges and unequally loaded or top-heavy cars. With one or more of these conditions present the chances of derailment increase with curvature and, in most instances, with speed also. On curves so sharp that danger of derailment from any of these defects is thought to be threatening it is quite commonly the practice to lay a continuous guard rail around the curve on the gage side of the inner rail. The most usual limit of curvature at which the need of guard rails is supposed to begin seems to be about 16 deg., although they are used to some extent on curves of less degree. Such a guard rail should be laid to bring the service side 4 ft. 6¾ ins. from the gage side of the outer rail, regardless of any widening of the gage or of the width of the flangeway between it and the running rail. A notable example of sharp curvature in main-line service is the curve around the abandoned "Mud Tunnel" on the Pacific division of the Canadian Pacific Ry., in the Kicking Horse pass, between Golden and Field, B. C. The radius of this curve is only 262 ft., which corresponds to curvature of 22 deg. The curve is 755 ft. in length and is guard-railed on the gage side of each running rail the whole distance. The purpose of the guard rail on the inner side is to prevent wheels from mounting the outer rail, and the purpose of the guard rail next the outer rail is to carry blind drivers. The running rails are laid broken joints, to a gage of 4 ft. 9¾ ins., and the guard rails break joints with the adjacent running rail. The flangeway between guard and running rail in each case is 2¾ ins. Both the running rails and the inner guard rail are backed by rail braces on every third tie, and on every third tie there is a piece of plank fitted between the two guard rails. The outer rail is not elevated, the omission of this feature being necessary to prevent the roof projections of passenger cars from "cornering," which would result if the car bodies were tilted.

Another notable example of sharp curvature on standard-gage main track is found with the Rossland branch of the Canadian Pacific Ry., from Trail to Rossland, B. C., originally known as the Columbia & Western Ry. In its length of 13.6 miles the road rises 2300 ft., and there are thirty 20-deg. curves having an aggregate length of 3 miles. The grade on tangents is 4 per cent and on curves it is compensated .04 per cent per degree. The rails are laid on Servis tie plates with three spikes in each, which hold the track to gage without using rail braces. The gage is widened one inch and there are no guard rails except at three trestles located on these sharp curves. The outer rail is elevated only 2 ins. Originally it was only 1 in., but after two years it was increased to prevent the track, which is filled in with light ballast, from getting out of line. Heavy consolidation and other locomotives of ordinary type have been operated on this line successfully. The average traffic has been four trains each way per day. Passenger trains make 12 miles an hour and freight trains 8 miles per hour over these curves. The Mexican Central Ry. has a 3-per cent mountain grade with curves varying from 15 to 24 deg., there being only one tangent in 30 miles, and that only a few hundred feet long. The gage of the track on the sharp curves is 4 ft. 9 ins. and the maximum elevation on curves is 3 ins. There are guard rails on all curves exceeding 17 deg. The rails are of 75-lb. section. Consolidation engines with 15-ft. driving wheel base, total wheel base 23 ft. 5 ins., all drivers flanged, the drivers carrying 80 tons, are operated on this line. The lateral play between wheel hub and driver box is $\frac{1}{4}$ in. for the front drivers, $\frac{1}{8}$ in. for the second and third pairs of drivers and $\frac{1}{2}$ in. for the rear drivers. The relatively small superelevation on the foregoing curves deserves notice, as it is on the side of safety of operation where guard rails are not used. Increase in elevation of the outer rail on sharp curves decreases the proportion of the load on the outer wheels and increases the tendency of those wheels to climb the rail when moving at slow speed.

The tires of blind drivers are usually $6\frac{1}{2}$ to 7 ins. wide, or $\frac{3}{4}$ in. to $1\frac{1}{2}$ ins. wider than the tires of flanged drivers. This extra width is to afford a margin of wheel bearing to allow for the range of lateral movement possible for such drivers relatively to the rails on curves. Nevertheless on heavy curves, particularly where the gage is widened excessively and the outer rail is badly flange worn, a blind driver will sometimes drop inside the outer rail and derail the locomotive. Of course the chances of such an accident are greatest with consolidation or mastodon locomotives whereon both pairs of intermediate drivers are flangeless or with mogul or 10-wheel locomotives having a long driver base with the middle pair of drivers flangeless. Under fairly supposable conditions a derailment of this kind can be accounted for. For example, consider a driving base of 16 ft., on a 15-deg. curve, laid with 80-lb. rails to a gage originally widened 1 in., and suppose the outer rail to be flange worn $\frac{3}{4}$ in. If the flangeless tire is $6\frac{1}{2}$ ins. wide and is set to run centrally with the rail on straight track then it is necessary to find a lateral movement of $3\frac{1}{4}$ ins. + $1\frac{1}{4}$ ins. (half width of rail head) — 1 in. (middle ordinate 16-ft. chord) — $\frac{3}{4}$ in. = $2\frac{3}{4}$ ins. for the rectangle of the driving base in order to account for the dropping of an intermediate blind driver. The widening of the gage gives a play of 1 in., the standard play of the flanges $\frac{3}{8}$ in. more, a set-in of the flanges of leading and trailing pairs of drivers $\frac{1}{4}$ in. more, wear of the flanges $\frac{1}{2}$ in. more, play at and wear to the hubs and axle boxes $\frac{1}{2}$ in. more, or altogether about $2\frac{5}{8}$ ins. The remaining $\frac{1}{8}$ in. the drivers will find at some place where the spikes are spread or at some angling joint. This estimate does not take into account the "personal equation" of trackmen in widening gage, already explained, or as much play as might be figured if a lighter rail with narrower head was used, but it serves to show what is liable to happen under conditions which sometimes exist; and it also shows what a large factor the widening of gage is in trouble of this kind. The difference in the length of the middle ordinate of a 16-ft. chord on the curve considered, and a side ordinate at a point corresponding to the position of one of the intermediate drivers of an eight-coupled set, is only $^1/_8$ in. As the tendency with engine drivers is to run to the outside of the curve as long as traction is maintained, the danger with blind drivers dropping from the rail is greatest when they slip, as then they lose their grip on the rail and slide toward the lower side of the curve.

The necessity for some provision against the dropping of blind drivers does not usually seem to be taken into consideration until after a few derailments have happened. Then, to avoid further trouble, a guard rail is laid inside the outer rail and another outside the inner rail to carry the flangeless drivers. Such guard rails are usually laid as close to the running rail as requirements, such as room for the spikes and proper width of flangeway, will permit. For splicing guard rails fish plates are more convenient than angle bars, and the nuts should be on the side of the guard rail which is not in service—that is, on the side farthest from the running rail, so as not to come in the flangeway.

In the present connection it is proper to point out that blind tires should not be set to a closer gage between backs than that of the flanged tires, and, in any contingency, never closer than 53 ins. If the backs of the blind tires are set closer than the distance between the backs of the flanged tires the false flanges of the blind tires when badly worn will drop into the flangeway at guard rails and frog wings and heavy blows to those parts will result. The increment of width to blind tires should be made to the outside, because there is where it is most needed. The liability for a blind driver to drop inside the outer rail is always greater than for its mate to drop outside the inner rail. This is because the liability of a flangeless driver to drop outside the inner rail is not increased by widening the gage; in fact the probability is decreased. The liability of derailment to blind drivers on the outside of the inner rail depends only upon the thickness of the flanges, the play at the hubs of the blind drivers and the width of the rail head; it is even independent of the spreading of the spikes, however badly. Consider, as a presumably bad case of this kind, an engine having a 16-ft. driver base, with flanges worn $\frac{1}{2}$ in. and with $\frac{3}{4}$ in. play at the hubs of the blind drivers, passing a curve laid with 60-lb. rails. Then before an intermediate driver with blind tires set even with the backs of the flanged tires can drop off the inner rail there must be a middle ordinate of $1\frac{3}{8}-\frac{1}{2}-\frac{3}{4}+2\frac{3}{8}$ ins., $= 2\frac{1}{2}$ ins., to a chord of 16 ft., which corresponds to a 37-deg. curve. Even in the extreme contingency that the outer rail had been flange worn $\frac{3}{4}$ in. and changed over, the blind driver would still be safe against dropping off up to curvature the middle ordinate of which to a 16-ft. chord is $1\frac{3}{4}$ ins., or 26 deg.

Rail Wear, Sharp Flanges and Derailment.—The causes of derailment on curved track have not been investigated as extensively as the importance of the subject would seem to warrant. It is currently accepted that sharply worn flanges and the forces acting upon car or locomotive wheels are the causes which contribute to derailment on curves, but just what the conditions are when they reach the danger point is not so widely understood. So far as car wheels are concerned the code of rules of the Master Car Builders' Association specify that a flange worn to a "flat vertical surface extending more than 1 in. from the tread, or a flange 1 in. thick or less," are defects which justify removal. A noteworthy treatment of the general subject of derailments is to be found in a paper by Mr. J. H. Wallace, engineer maintenance of way of the Southern Pacific Co., presented before the Pacific Coast Railway Club, in January, 1900. The theory by which he explains the derailment of a wheel on a curve is based upon the ratio of the vertical force, due to the weight of the wheel and its load, and the horizontal force acting upon the wheel, due to the reaction necessary to curve the engine or truck combined with centrifugal force arising from speed. To show cause for the lifting of the wheel when it becomes derailed, account is taken of the shape of the wheel flange, but the shape of the rail head is left out of consideration, the claim being that the conditions are not essentially changed on a flange-worn rail. The theory propounded by Mr. Wallace concerning the position which a wheel will take on the outer rail of a curve is that the wheel makes contact with the rail on that part of its running surface which is perpendicular to the direction of the resultant of the forces acting upon the wheel. On straight-line track the resultant is, of course, vertically downward, and the wheel runs upon its tread; while on curved track, if the speed be sufficiently great, the relative magnitude of the centrifugal force will cause the resultant force to assume a direction approaching the horizontal, and in that case the wheel will rise from the top of the rail and run upon the side of its flange, against the corner of the rail head. The condition which obtains when the wheel is on the point of being derailed is that the direction of the resultant force becomes perpendicular to the face of the flange on that line where the curve of the flange reverses. Beyond this line the curvature of the flange approaches nearer and nearer to a horizontal direction; or, in other words, the slope of the flange becomes more gradual, thus facilitating the climbing action of the wheel. On a new wheel the resultant is supposed to have this direction when the horizontal force becomes equal to 2.4 times the vertical force.

Respecting the claim that the chances of derailment are no greater when the outer rail is flange worn than when it is new, opinions differ. Some authorities on the subject claim to have observed that the flange-worn rail is usually in evidence wherever derailments take place on curves. Numerous experiences have been cited to show that with locomotives having pilot trucks of both the swing and rigid-center type and front drivers with both flanged and plain tires no difficulty was had until the rails on the curves became flange worn. In fact there is much evidence on both sides of the question. In one case numerous derailments have been observed on new rails, while in the other case practically all of a large number of derailments have been observed only on flange-worn rails. To get at the merits of the contention it seems proper to inquire respecting the nature and effect of the friction of contact between wheel and rail. With a new wheel on a rail worn to almost any shape commonly found in service the friction of the parts in contact is mainly rolling friction, the condition least conducive to derailment, but as the rail becomes flange worn the side and corner of the head are reduced to an outline approaching that of the average wheel flange and fillet, and a sharply worn flange, which usually slopes back on a straight bevel from the fillet, will, by the slewing of the truck, on sharp curves, make a surface contact with the rail in advance of the line of contact at the tread. The result is a grinding against the side of the rail head, due to contact at peripheries of unequal diameter, which, in connection with the side thrust of the horizontal force, must exert a considerable lifting effect upon the wheel which Mr. Wallace's theory does not take into account. There is therefore room to doubt whether this theory applies as strictly to worn wheels and rails as it does to new ones.

Mr. Wallace's paper treats of another set of conditions which should not be overlooked when contemplating the safety of wheels in passing around curves. Reference is made to the change in the ratio of the vertical and horizontal forces due to the fluctuation of the weight on the wheels. This fluctuation may arise through oscillation on rough track; through uneven loading of the car; through top-heavy loads, which may set the car to rolling, or which, at slow speed, may cause the car body to incline to the inside of the curve and relieve the outer wheels of some portion of their load. The fluctuation of loading is an important matter affecting the design of locomotives for safe running. If the forward truck of a locomotive has a rigid center the truck should sustain a larger share of the weight of the locomotive than otherwise, for under this condition it becomes the duty of the truck to compel the locomotive to follow the curve, and it is not safe to take chances on a too great proportion of the weight being momentarily reduced by a teetering motion of the locomotive on rough track or by the upward reaction of the connecting rods against the guides. If the truck is provided with a swing center, however, the conditions are essentially different, for then the guiding of the locomotive is performed by the forward driver, which is not so subject to violent fluctuations of the loading.

45. Curve Elevation.—The purpose of elevating the outside rail of curves is to overcome or lessen the unpleasant tendency of the car bodies to swing and tilt outward from centrifugal force, and also to lessen the wheel flange pressure against that rail. The commonly accepted idea that elevation or "superelevation" in the outer rail lessens the tendency of the wheels to climb the rail does not always hold true. The action of wheels relatively to the rails on elevated curves is in nowise different from what it is on curves level across. The flange pressure of wheels against the outer rail of curves may arise from two forces, namely, centrifugal force. due to speed, and the resistance of the wheel to being turned from a straight course, which is independent of the speed. With proper elevation for the speed the centrifugal force may be counteracted, but the lateral pressure due to the tendency of the wheels to run straight ahead is always present. It is therefore impossible, by any known arrangement, to prevent flange pressure of wheels against the outer rail of curves.

While speed higher than that for which the curve is elevated does increase the flange pressure against the outer rail it also increases the weight or vertical force acting down upon the wheel, and there are conditions under which the vertical force may increase relatively faster than the horizontal or centrifugal force. The less the elevation the greater is the weight thrown upon the outside wheels, at any speed, and the less the weight on the inside wheels—the very condition which conduces to the easier turning of the car truck or wheel base, to cause it to follow the curve or to make derailment less probable. A car loaded unevenly, with the excess of weight on the inside of the curve, will, at slow speed, climb the outside rail more readily if that rail be elevated than it will if the two rails be on the same level, because there is an undue proportion of the weight on the inside wheels and less weight to hold down the wheel flanges on the outside. The resistance of the inside wheels to lateral sliding may then overcome the action of the force which tends to constrain the flanges of the outer wheels to follow the rail. Danger from this source is greatest on sanded rails. The same action holds true of cars with top-heavy loads—at slow speed the car body leans heavily toward the inside of the curve and tends to lift the outer wheels from the rail. If the curve was level transversely such would not be the case.

Reference is intended mainly to tendencies, for they do not reach the danger point except at limits which would indicate extremely careless running. It is not an easy matter to determine in any case whether the greatest source of danger in running around curves which are level transversely, at very high speeds, lies in the liability of upsetting the car, in the spreading of the rails or in the tendency of the wheels to climb the outer rail. It is the habit of mathematicians who attack this problem to consider the vertical force on the outer rail as constant, at half of the load, which is very clearly not the case; and then figure the speed at which the wheel may be supposed to mount the rail or overturn it. The premises in an investigation of this kind are necessarily uncertain. The moving car should not be considered as a whole. For the purpose of the investigation it is in two parts—the trucks constituting one and the body and its load the other—and within limits these parts act independently of each other. The center of gravity of the car body and load changes, with the speed, relatively to both the trucks and the track. At slow speed it is shifted toward the inner rail and at high speed it is shifted toward the outer rail. The fact that locomotives and cars running at high speed on curves have been known to completely overturn without first being derailed to the ties shows that the outer wheels hold down to the rail pretty firmly when centrifugal force is acting strongly upon the car body. In fact the source of greatest danger to the derailment of the wheels by mounting the outer rail is rough surface in the track.

The main advantages to be gained, then, by elevating curves are comfort to passengers, in traveling at high speeds, and less pressure of the wheel flanges against the outer rail. But while such advantages are feasible and very desirable for trains of the better class, still, where the slow-speed trains are comparatively numerous there are evil effects arising such as call for a compromise between the elevations suitable to each class. If the slow-speed, heavy-traffic trains are comparatively few in number the curves should be elevated for the high-speed trains. As regards traction at slow speed, more force is required to haul a car around an elevated curve than around one which is level across, owing to increased curve resistance. As the elevation increases there is an undue proportion of the weight shifted to the inside wheels, owing to the fact that the gage of the wheels, which is the base upon which the car stands, is narrower than the width of the body of the car. Since it has been shown that it is the tendency of the inner wheels to outrun the outer ones which causes the truck to run askew to the track, it must be clear that increase of load on the inner wheels will increase the tendency of the truck to slew, which, as previously pointed out, increases the curve resistance. The effect which is sometimes thought to be due to decreased tractive power of locomotives on elevated curves is really caused by increased curve resistance in the cars.

A general formula for curve elevation has been worked out upon the mechanical principle that by elevating the outside rail the force of gravitation, which may be considered to act vertically on the center of gravity of the car as a whole, is resolved into two components—one acting perpendicularly to the track, and the other across the track parallel to the plane of its elevation, in opposition to the centrifugal force, so as to hold it in check. This formula is

$$e = \frac{g\ V^2}{32.166\ R}$$

where e is the elevation in outer rail, in feet; g the distance in feet between rails, center to center of heads; V the velocity in feet per second; R, the radius of the curve, in feet. Taking the velocity in miles per hour, the formula becomes

$$e = \frac{.06688 g V^2}{R}$$

But such a formula cannot be rigidly applied to widely varying speeds and to curves of all degrees in common use, because in actual service it is not practicable to vary the elevation as the square of the velocity. To do that would, for speeds ordinarily made on some curves, require an elevation so high that to slow down upon it would throw too much weight upon the inside wheels, and in all probability run some of the cars off the track; or to stop on such a curve might put a top-heavy car in danger of tipping over. For speed of 60 miles per hour this formula requires an elevation of 2½ ins. per degree, which is far in excess of rates of elevation used in general practice for that speed. To find rates of elevation in common use for speed of 60 m. p. h., by this formula, the speed used therein must be assumed at 38 or 40 m. p. h. In practice it cannot be expected to entirely overcome centrifugal force at high speed. The car body is attached to the truck so as to act on springs, and any great pressure of the wheel flange against the outside rail, due to centrifugal force at high speed, is taken care of by the downward force which the car body exerts on the wheel tread, thus preventing the flange from climbing the rail, and also to some extent holding the rail more securely against spreading. It is readily seen how a downward force is exerted on the outside wheels of a car by centrifugal force acting on the car body, which is held to the truck only by a pin at the middle, thus allowing the center of gravity of the body to shift relatively to that of the truck, as already pointed out.

A formula which gives an elevation most suitable for any curve, for the different classes of trains, is necessarily empirical, for it cannot be derived by a strict application of mechanical principles. As a matter of fact curve elevation in practice is determined by trial and not by mathematical calculation; it is a "cut and try" process, pure and simple. After satisfactory elevation for a series of curves has been found it is customary to express the practice in some simple rule applying to various degrees of curvature, but the rule in all such cases is nothing more nor less than a report of experimental work. For the sake of preserving a scientific aspect by making the above general formula for centrifugal force seem to agree with practice, some keep twisting it by the introduction of constants to suit the case, but in this there is a good deal of nonsense—practice can be expressed by a simpler formula. Usually the outer rail is elevated according to some recognized rule, or not quite enough to meet the supposed requirements, and then, if necessary, it is later adjusted until the cars seem to ride satisfactorily. On the Chicago, Milwaukee & St. Paul Ry. an instrument made on the principle of the spirit level (§ 195, Chap. XII.) is used on the cars to indicate whether they are properly canted for the speed of the train and to show the excess or deficiency in the superelevation of the outer rail. Experience has taught certain "rules of thumb" which are reliable enough for trial and far simpler to use than any formulas which involve terms expressing centrifugal force. For level track these rules are about as follows:

On electric railways, logging roads, or on any road where speed of 30 m. p. h. is not often attained, it is customary to elevate the outer rail ½ in. per degree of curve, up to a maximum of 4 ins.

For roads on which the freight traffic predominates, the passenger trains being local only, and speed of 45 m. p. h., while running, is not often exceeded, the usual rate of elevation is ¾ in. per degree, up to a maximum of 5 ins.

On roads which handle a mixed traffic, operating through or express trains, where speed exceeding 45 m. p. h. is commonly made, the most usual practice is to elevate 1 in. per degree, up to a maximum of 6 ins. Where the freight traffic may be disregarded a rate of 1¼ ins. per degree, up to a maximum of 6 ins., is quite frequently employed; rates of 1½ to 2 ins., and even 2½ ins., per degree, up to a maximum of 7 or 8 ins., are also in use, but not so frequently.

The rules for usual conditions on the New York Central & Hudson River R. R., whereon two of the four tracks are given to passenger traffic exclusively, are as follows: For main passenger tracks curves of less than 1 deg. are elevated at the rate of 2 ins. per degree, and curves of 1 deg. and over are elevated 1 in. per degree, plus 1½ ins.; main freight tracks, ¾ in. per degree; combination tracks 1 in. per degree. The maximum elevation is 6½ ins. On some other roads the rate of elevation for passenger train speed is 1 in. per degree, plus 1 in. This use of a constant additional to a uniform rate per degree gives a relatively high elevation for curves of the smaller degrees, which seems to be a principle extensively followed. In a larger number of instances, however, this result seems to be attained by the addition of a variable which decreases with the curvature; as, for instance, the rule may be to elevate 1 in. per degree, adding 1 in. for a 1-deg. curve, $\frac{7}{8}$ in. for a 2-deg. curve, $\frac{3}{4}$ in. for a 3-deg. curve, $\frac{5}{8}$ in. for a 4-deg. curve, and so on, the elevation for 1, 2, 3 and 4-deg. curves then being 2 ins., $2\frac{7}{8}$ ins., $3\frac{3}{4}$ ins. and $4\frac{5}{8}$ ins., respectively. The justification for this practice lies in the fact that the fastest speeds on curves are made on the curves of small degree, and the elevation for these curves, though relatively high for the curvature, is still not high enough to be objectionable to the freight trains. The Philadelphia & Reading Ry. makes use of a rule derived with the idea of maintaining the proper relation between curvature and speed, by which the superelevation is taken as the middle ordinate of a chord equal in length to the distance run by the express trains in one second. The maximum elevation is fixed at 8 ins.

The foregoing rules show that under usual conditions in general practice there is a compromise of the requirements of slow-speed freight trains and of the speed of fast passenger trains. It is important also to note several of the widely prevailing abnormal conditions under which general rules are not followed. On curves at stations where all trains stop there is no necessity for elevating the outer rail, and in usual practice it is elevated but little or not at all. On sharp curves in front of stations where some of the trains do not stop it is better to slacken speed than to place full elevation in the curve, because the inward tilting of the cars which stop on such a curve fully elevated is an inconvenience to passengers getting on or off, and when the platforms are slippery from rain or snow the footing is very insecure and passengers are in much danger of injury from falling. Also in the vicinity of stations, water tanks, unprotected grade crossings, draw bridges, etc., where stops are made or speed habitually reduced, the elevation of the curves is governed accordingly. In some cases where turnouts occur on curves the ordinary rules for elevation are not followed, the speed of trains being reduced at such places. At a crossing on curved track it is not practicable to elevate the curve at the crossing, and speed should be reduced.

Local conditions of grade also govern the matter of curve elevation to a considerable extent. Thus, for example, the elevation of curves on summits is usually less, and that of curves in the hollows usually more, than the customary elevation in vogue for curves of the same degree on level road. Where heavy grades occur on double track the conditions of speed in the two directions are so essentially different that the requirements of curve elevation are not the same for both tracks—the curves on the up-grade track are necessarily elevated for a much slower speed than are the curves on the down-grade track. Where long, heavy grades occur on single track it is manifestly impossible to elevate the curves satisfactorily for the ascending and descending trains, the usual speeds of which may differ as widely as 10 or 15 m. p. h. up hill and 50 or 60 m. p. h. down hill. This is only going a longer way around to say that it is impossible to elevate a curve satisfactorily for more than one speed. On single-track mountain roads it is customary to reduce both the rate of curve elevation and the maximum elevation. As an illustration of this practice, the standard rule of the Southern Pacific road for main line, except on mountain divisions having grades over 1.8 per cent, is to elevate the curves 1 in. per degree, up to a maximum of 6 ins. The rule for all mountain divisions having grades exceeding 1.8 per cent (as also for all branch lines) is to elevate the curves at the rate of $\frac{3}{4}$ in. per degree, up to a maximum of 5 ins. On other single-track roads where long, heavy grades prevail a rate of curve elevation as small as $\frac{1}{2}$ or $\frac{5}{8}$ in. per degree, with maximum elevation as low as 3 or 4 ins., is extensively used.

Curves in yards and sidings, on which speed is necessarily slow, are, as a rule, not elevated at all. Where a considerable speed is liable to be made on such tracks, however, a reduced rate of elevation is quite frequently applied, as, for instance, rates of $\frac{1}{8}$ in. per degree to half the rate for main line, stopping at 2 ins., which seems to be the maximum elevation most commonly applied to side-track.

Concerning maximum curve elevation for main tracks the majority of roads, including roads which run fast express trains, place the limit at 6 ins. An important matter which has a bearing upon this question is the limitation of speed in relation to curvature. There is a decided and widely prevailing belief on the part of maintenance-of-way engineers, well supported by experience, that at limits of curvature quite closely agreed upon the speed of the fast trains should be restricted. Coming to actual figures the preponderance of opinion among maintenance of way men agrees that speed as high as 60 m. p. h. should not be made on curves sharper than 4 deg. There are more who place the limit lower than 4 deg. than there are who place it higher, and but few, if any, place it above 6 deg. The basis of this opinion rests in the fact that the speed conditions of mixed traffic do not permit the ideal elevation of any but curves of small degree to be practiced. Assuming maximum elevation at 6, or even 8 ins., any of the customary rules for the fastest traffic cannot be followed beyond a limit of curvature which is comparatively low. It is also taken into consideration that the liability of cars to derailment from the binding of side bearings, from broken wheel flanges or other defects of the rolling stock increases with the speed and curvature, so that, as between the question of exceeding the most generally accepted maximum elevation, in deference to sustained speed, and that of reducing the speed, the latter course is the safer. A rule covering the case which seems to meet with approval is to establish a maximum elevation for speed of 60 m. p. h. on a 4-deg. curve, say 5 or 6 ins. The speed for 4-deg. curves is then limited to 60 m. p. h. and reduced 5 m. p. h. for each degree above 4 deg.; i. e., the speed for 6-deg. curves is limited to 50 m. p. h., for 8-deg. curves to 40 m. p. h., for 10-deg. curves to 30 m. p. h. and so on.

The consequence of insufficient elevation for the speed is unpleasant riding, due to the listing of the car body, but on sharp curves the tilting of the car floor to the level position, for moderate elevation and the highest speed, is not considered objectionable. On the other hand the ill effects from heavy slow-speed freight trains on sharp curves fully elevated for fast passenger traffic are widely observed. The objectionable effects commonly referred to are excessive wear to the inner rail, canting of the inner rail, abnormal cutting of the ties under the inner rail, the tendency of the track to constantly increase its elevation, owing to the disproportion of weight bearing upon the inner rail; displacement of the track in line and surface; tendency to derailment, particularly at bad joints, owing to the tilting of the car body toward the inside of the curve, which relieves the outer wheels of an undue share of the load; tendency of top-heavy cars to capsize; and increased train resistance. The tendency of the inner rail to cut the ties and cant under excessive elevation for slow-speed trains is quite marked, and conditions of this kind sometimes require the use of tie plates where they would not be needed if the case was otherwise. Thus, on the Philadelphia & Reading Ry., where the maximum elevation is 8 ins., the use of "heavy" tie plates is necessary to overcome the tendency of the inner rail to cant under the slow-speed trains, but according to official report tie plates are not found to be necessary under the outer rail.

Where the roadbed is not sloped for the elevation it is well, when putting up the track for the first time, to allow ½ in. for the greater settlement of the high side of the curve.

Running Out the Elevation.—Concerning the manner in which the elevation should be run out at the ends of simple curves there is some difference of opinion, but in the largest practice full elevation is given at the points of curve and the run-off is made wholly on tangent. It is the practice to some extent, however, to make half or two thirds of the run-off on tangent and the remainder on the curve, and good results are claimed. The philosophy of this practice is that in approaching a curve the car begins to tilt toward the inside as soon as it strikes the elevated rail and continues to do so until after it passes into the curve; and that this momentum in a lateral direction counteracts the centrifugal force which develops upon striking the curve, even if there be less than full elevation at the point where the curve begins; and that before the centrifugal force can so far overcome the tilting motion as to produce an effect upon the car body the car will have reached the point of full elevation, where the two forces are supposed to come to a balance.

The rate of running out the elevation is another point on which men of experience differ, but in the great majority of cases in practice the length of the run-off is 30 to 60 ft. per inch of elevation, the preference seeming to lie with the 50-ft. and 60-ft. rates. As time is an element in the tilting of the car body to the inclination of the track it seems reasonable that the length of the run-off should bear some relation to the speed, while, on the principle that the car should not be tilted for an unnecessary distance or period of time before the centrifugal force begins to act upon it, the run-off should be as short as may be without being abrupt. The condition which would seem to govern in this respect is the distance between the trucks of the passenger cars, as one truck should not be tilted so much in advance of the other that the car body cannot readily adjust itself to the different inclinations of the two. As the distance, center to center, of trucks on passenger coaches and sleepers is 40 to 55 ft. (on standard sleepers it is 54½ ft.) it would seem that a run-off as rapid as 40 ft. per inch of elevation, which would permit a difference of only 1 to 1½ ins. of elevation at the two points at which the car is supported, should not be objectionable. In my own experience I have found this rate satisfactory for fast trains. On the other hand the practice of running the elevation out a long distance on the tangent presents an unsightly appearance and subjects the cars to tilting for an unnecessary period of time. On a few roads the length of the run-off is the same for all curves, of whatever elevation. One of these roads is the Atchison, Topeka & Santa Fe Ry., in which case the length of run-off is fixed at 120 ft. On the New York Central & Hudson River R. R. the rate of run-off for elevation of 3 ins. and under is 120 ft. per inch, but for elevation exceeding 3 ins. the length of the run-off is fixed at 360 ft. It is the opinion of some careful observers of train movements on curves that on double track the run-off for the elevation at the entrance to a curve should be longer than at the leaving end.

Any arrangement for running out elevation on tangent is not entirely satisfactory. Straight track out of level on the approach to a curve is just as objectionable as anywhere else. To test the truth of this proposition let the reader run around a corner and attempt to lean inward before beginning to make the turn. The unbalanced state of the runner in that case is the condition of a car which careens before the trucks are skewed, upon entering a curve, and remains careened after the trucks have straightened, upon leaving the curve, as must happen where the run-off is made on tangent. This careening of the car before it enters the curve causes the wheel flanges to seek the lower rail and the journal bearings to take up their lateral play by sliding over in the same direction, the result being that the wheel flanges do not meet the outer rail until they are some distance into the curve, where they, at about the same time as the journal bearings, are liable to bring up suddenly with a shock. A more desirable arrangement is to have the wheel flanges crowding the outer rail when they enter the curve, and one way in which this is accomplished is to compound the curve at each end with a piece of easy curve, usually ½ deg., just long enough to make the run-off. In this way the wheels can leave the tangent on level track and strike the curve, that is the main part of the curve, at full elevation, the flanges steadily crowding the outer rail all the while the full elevation is being attained. This is the most satisfactory way of running out the elevation of a simple curve. Of course the curve is in principle compound, but for the reason that the compounding is done primarily for convenience in arranging the run-off of the elevation, rather than for advantages in respect of curvature, the arrangement is not usually classified with compound curves. As the arrangement does not effect a gradual change of curvature it does not come within the meaning of what is ordinarily understood as an easement curve. For convenience of designation it might be called a "run-off" curve.

While fairly good results are obtained by the foregoing method of running out the elevation there still exists the undesirable feature that the largest portion of the run-off has an elevation not suited to the curvature, being far too much. The complaint is that this unfavorable condition gives rise to a centripetal force tending to hold the body of the car inward until it reaches the main portion of the curve, when the unbalanced centripetal force is suddenly changed to one that is centrifugal, with obvious consequences. The ideal method is to begin the change of direction with an easy curve having no elevation and develop the curvature gradually, or by a uniform rate of increase, to the point of full elevation, thus permitting the run-off at any point to be elevated to suit the degree of curve or radius at that point. This requires that the curve shall begin with radius infinity, or very long, and that the length of radius shall decrease gradually until the full degree of curve is reached. Such requirement is met by easement or transition curves, which are treated further along. In fact the only method of running out curve elevation that is entirely satisfactory is in connection with the use of easement or spiral curves, by which it is feasible to elevate with the curvature and maintain tangents level transversely their whole length. Wherever fast speed assumes importance practice is rapidly changing in the direction of spiraling the ends of the curves.

For a more detailed treatment of all the foregoing features of curve elevation, based upon an investigation of the practice of a large number of roads, the reader is referred to a paper by the writer included in the committee report on "Track," presented before the American Railway Engineering and Maintenance of Way Association, at the annual meeting in 1901.

Method of Elevating with Reference to the Grade Line.—Regarding the question as to whether the elevation should be made by placing the inner rail at the normal grade for top of rail and raising the outer rail the necessary amount, or by placing the outer rail at grade and depressing the inner rail, or making half of it superelevation in the outer rail, and the other half depression in the inner rail, it may be said that, as far as the running of trains is concerned, it does not matter; but for other considerations the best practice is to place all the elevation in the outer rail, leaving the inner rail at grade. Where there is a ditch at the curve one can readily see how this method of elevating will allow the same effective depth of ditch with less excavation than with either of the other two methods; and this advantage is all the more important if the ditch be continuous beyond the curve, out along an adjoining tangent. The practice of placing the outer rail above grade and the inner rail below it renders the surfacing of old track near the points of curves less satisfactory than is the case where one rail is placed at grade; because where grade stakes are lost—as they usually are on old track—it might be somewhat difficult to place either rail at point of curve to its proper hight; but it is always an easy matter to run either rail in at grade, because one has for reference the general surface of the adjoining rails on the tangent. It therefore simplifies the track work to either elevate the outer rail or depress the inner rail the whole amount of the required elevation. The term "depression," as used in the present connection, refers only to the position of the inner rail with reference to the grade line and does not necessarily imply that the inner rail is brought to position by lowering or cutting down the ballast or roadbed. As curve elevation is arranged when the track is ballasted it is usually the case that this rail must be raised some distance, the same as the outer rail.

There are three ways of elevating curves on double track with reference to the grade line. The most common of these, known as the "saw-tooth" method, is to have corresponding rails of each track on the same level. By this method the inner rail of the outer track necessarily comes in a depression, and drain boxes across one of the tracks are required at intervals to prevent the collection of water around that rail when a thaw occurs or when rain falls upon frozen ballast. The "step" method is that whereby the outer rail of the inside track and the inner rail of the outside track are placed at the same level (usually at grade), the elevation of the tracks then being arranged by raising the outer rail of the outside track and depressing the inner rail of the inside track. By the "plane" method the tops of all the rails of both or all tracks are placed on the same plane, so that there is an unbroken slope across both or all tracks. This is the best arrangement for draining the ballast and the one most favorable for laying a crossover, where such is unavoidable on the curve. A crossover is impracticable on tracks elevated by the "saw-tooth" method and it is not satisfactory if laid on tracks elevated by the "step" method. The "step" arrangement permits drainage without cross drains and for double track it is perhaps the preferable one. The objection to the "plane" method is that it requires the raising of the grade of the outer track or tracks, which must then be run off at the ends of the curve. On three and four-track roads the change of the grade at the ends of the curves in the outer tracks, required by this method, is considerable. This is the method of elevation adopted on the double, three and four-track lines of the Pennsylvania R. R. The standard of the Baltimore & Ohio and New York Central & Hudson River roads is the "saw-tooth" method, and on the Philadelphia & Reading Ry. the "step" method is standard. The New

England Roadmasters' Association, at its convention in 1897, voted in favor of the "step" method.

46. Reverse Curves.—A reverse curve is one formed by two curves turning in opposite directions and meeting tangent to each other. Two curves turning in opposite directions but having a piece of tangent between them do not constitute a reverse curve, although they are sometimes erroneously called such. Reverse curves are undesirable, but must sometimes be located. Speed should be reduced at such curves, because at the instant a car is leaving one curve and entering the other, centrifugal forces are acting in opposite directions on its two ends at the same time.

Elevation cannot be put in at the P. R. C. satisfactorily, because it is a point of curve for both curves. At the point of reverse curve the track should be level transversely, and the elevation run in both ways at the ordinary rate. If there is a short piece of tangent between two curves turning in opposite directions, and the piece is not long enough to allow for running out all the elevation from both curves, the full elevation should not be put in at the P. C. of either; but from a point between the two, distant from each in proportion to the elevation of each curve, run in the elevation of each at the ordinary rate until the full elevation is reached somewhere on the curve. This flattens out, as it were, the ends of the two curves, but it is better practice than to run out the elevation too suddenly. A piece of tangent between curves of contrary flexure, however short, is a good thing, for the opposite centrifugal tendencies of the cars at the point of reversal of a reverse curve is hard on draft gear.

47. Compound Curves.—A compound curve is formed where two or more circular curves, having radii of different lengths and turning in the same direction, meet tangent to each or one another in succession. The points of tangency are known as points of compound curve (P. C. C.). At such points the curve of shorter radius is usually given its full elevation and the excess gradually run out over the curve of longer radius, at the usual rate. On some roads, however, the run-off due to the change in elevation is distributed half on each section of the curve. The rule of the Atchison, Topeka & Santa Fe Ry. for running out the elevation between two curves, on a tangent which is too short to provide the usual length of run-off for both, is to divide the tangent into two parts in proportion to the degree of the curves which it connects (the longer part being next the curve of greater degree) and then make 90 ft. of the tangent "at the dividing point" level. From this piece of level track the length of run-off in each direction is 120 ft., using so much of the curve as is necessary for the purpose.

48. Curve Monuments.—A valuable aid in maintaining curves to good alignment is the ability to find points on the center line when wanted. While an experienced trackman in lining curves by the eye can keep them *smooth,* no man can keep a long curve *uniform* without reference points. A portion of the curve may get out of line slightly, and in lining it some other part may be thrown so as to conform to the portion out of line, perchance, instead of throwing the portion which is out of line back to place. In this way, after some years, it will usually be found that the curve has departed from the original center stakes, to one side or the other, and, even if by but long and gentle "swings", still the curvature cannot be uniform; some portions will be too sharp, others will not be sharp enough. At no place in the curve is this departure so noticeable and troublesome as at the point of curve. The "heavy shock," so called, experienced or felt when entering or leaving a circular curve, is often due to a failure to keep the P. C. or P. T. where it should be, and the ends of the curve in proper alignment. Moreover, all foremen do not understand that a simple circular curve cannot be eased off at the end without introducing at the curve end of the eased portion a longer or shorter piece of greater degree than the original curve, unless the whole curve be thrown in. Hence, when the end of the curve gets out of line, some foremen will attempt to throw two or three rails near the end in such a manner as to run the curve farther out from the old P. C., with a view to easing it off. This practice almost always results in a "bad job" affair, and the consequence generally is that the curve is never again got into good alignment without a new setting of stakes.

At the two ends, at least, of every simple curve, some monument of durable material should be set to mark the points. The expense of such provision will in the end be less than the cost of sending surveyors occasionally to find the points. It is also a good plan to have monuments every 50 ft. around the curve. On single track the monuments at the ends of curves are sometimes set on the center line, but usually a standard distance outside, say 7 or 8 ft. from the center; on double track monuments should be midway between track centers. The monument is often so placed that its top is made the grade for either the top or the base of the rail—better the base, as then it is lower and more out of the way. Stone posts cut square, about 3 ft. long, are extensively used and answer well for curve monuments. A cross is usually cut on top, extending from the four corners, to mark the center; or a drilled hole filled with melted brass or lead is sometimes used. The standard curve monuments of the Pennsylvania Lines West are iron pins 2 ins. in diam. and 4 ft. long, and dressed stone posts 6 ins. square on top and 3 ft. long. The stone posts are always used in slag ballast.

Short pieces of rail are also extensively utilized for curve monuments, and, considering that such short pieces accumulate rapidly and can otherwise be used only for scrap, they may be cheaper than stone. To make a rail monument more secure against disturbance or against being pulled up, the bottom end may be split along the web and the two parts bent out to form a "T", or an old splice bar may be bent at a right angle and bolted to the bottom of the piece of rail. In roadbed which is subject to heaving the monument should be set in cinders extending below the frost line. If the monument is a piece of rail which is also used to mark the grade, it should be stood on a flat rock in the bottom of the hole when it is set. Stone monuments placed at points where the curvature changes are usually smoothly faced, so that a record of the station number and degree of curve can be cut thereon. Monuments at other points on the curve, as at points 50 ft. apart, answer fully as well if only roughly cut or perhaps not squared or cut at all, and on single track they should preferably be set along the inside of the curve, just outside the ends of the ties,—say about 5 ft. from the center of the track—a few inches lower than the bottoms of the ties, covered up in the ballast. Being set a known distance apart they may be easily located and quickly uncovered when wanted. Pieces of rail or large stones of any shape, buried up and permitted to settle before the reference point is marked, are good enough for this purpose.

Compound curves should by all means be monumented at the P. C. C.'s and for some distance each way therefrom, if not all the way around the curve, so that at all times reference to the centers may be available. Transition or spiral curves are usually marked at both ends; that is at the point of spiral (P. S.), or the point where the spiral joins the tangent, and at the point of curve (P. C.) or point where the spiral joins the circular curve. Spirals should also be monumented for points on center not farther apart than 30 ft. The only way to maintain such curves in proper alignment is to have permanently established references to points on the center line. Without these references the section foremen cannot keep the spiral to its place as well as they can a circular curve without permanent reference points, and a spiral curve badly out of line affords no easement, so far as the curvature is concerned.

49. Rail Braces.—Rail braces, where needed, can render good service. There is usually more need of rail braces just a few years after track has been laid than there is with older track, for the reason that for the first few years after track is built the ties decay more nearly all at the same time. When double spiking on the outside will not hold, rail braces or tie plates must be used. They need not be applied, however, until the track begins to show signs of trouble from spreading. About five braces to the 30-ft. rail, on the outside, will usually be found sufficient for curves as sharp as 4 or 5 deg. On curves of 8 or 10 deg. and sharper, where braces are needed, it is quite commonly the practice to use them on every other tie, or eight or nine braces to the 30-ft. rail. These statements apply only in a general way, for the number of braces needed in any case necessarily depends a good deal upon the hardness of the ties. On hardwood ties braces are not usually needed unless the curvature is very sharp or the traffic heavy, while curves laid with softwood ties may need bracing for even moderate conditions of curvature and traffic.

Although the inside rail of curves is subject to spreading it is seldom, if ever, necessary to brace it. The most frequent cause of the spreading of this rail is that the gage of the curve is too narrow for the locomotives running over it. Undoubtedly some have noticed the inside rail spread slightly and then no farther, even though no attention was paid to bringing it back to proper place. The explanation of the phenomenon is simply that the locomotives made room for themselves. The inside rail may also spread slightly under the friction of the lateral sliding of the wheels, but not to do harm. In my own experience I have never seen an instance, where the gage was properly adjusted, that double spiking of the spread rails on the inner side of a curve failed to hold. A strange doctrine which has frequently been advanced to account for the spreading of the inner rail of curves is that the flange pressure against the outer rail pulls the ties through on their beds, the inner rail in some unaccountable manner holding fast and causing the spikes to be crowded out of place. When it is considered that each pair of wheels is tied together by the axle and that the rails are tied together by the ties, it would seem that any lateral action of the outer wheel should pull the inner wheel over with it and that any movement of the tie resulting from such action should bring the inner rail along. To any question, then, as to whether the lateral pressure of the wheels against the outer rail will pull the ties from under the inner rail, one may at least venture the proverbial argument of the old colored gentleman, that "such a case must be very rare." Those who think it necessary to brace both rails usually place the braces in pairs, opposite to each other, on the same ties.

It should further be said that the use of braces on the inner rail cannot prevent that rail from canting if the conditions are favorable to such action. A rail brace is designed to oppose lateral pressure, but not the vertical pressure which causes the rail to tilt and cut into the tie at the outer edge of the base. Where this tilting occurs the weight bearing upon the brace through the rail head tips the brace out of its adapted position, as shown in Fig. 54, loosening the spikes and readjusting the bearing of the brace against the rail. It is also to be noted that on rails which cut into the ties without canting the effectiveness of the braces, if used, is diminished in much the same manner. Where such are the conditions the costlier practice of using tie plates is a more satisfactory means of preventing the spreading of the rails. Combination devices embodying the features of both the tie plate and the rail brace are used to some extent, but experience with tie plates alone seems to demonstrate that they are able to take care of canting rails as well as to prevent the rails from cutting the ties; and where the rails cut the ties badly some means of protection should be afforded every tie.

It is better economy to use a few rail braces than to have to be pulling spikes, plugging the holes and redriving the spikes, as such weakens the tie and shortens its life. Frequently, however, double spiking every tie on the outside of the outer rail of the curve will hold it without rail braces, and it is a much cheaper method. As already stated, double spiking is always more satisfactory if done when the track is laid. Formerly, rail braces were pretty generally made of cast iron, thick and heavy, but late years cast steel and pressed steel braces of lighter weight have become standard. A pressed steel or cast steel brace is better than one of cast iron, since it is not broken by misdirected spike-hammer blows, and, being thinner, gives a spike more leverage or purchase with which to hold. It should be made to fit accurately the rail section with which it is used,

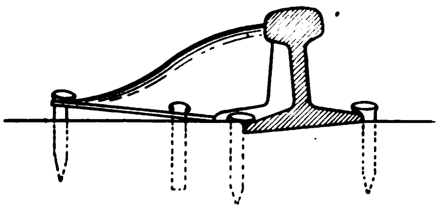

Fig. 54.

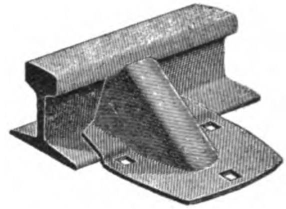

Fig. 55.

and it should extend well up against the rail head, but not higher than $\frac{7}{8}$ in. below the top of the rail for which it is designed, so as to allow $\frac{1}{2}$ in. for wear of rail and $\frac{3}{8}$ in. for guttered tires.

The principal patterns of rail braces now in use are shown by Figs. 55 to 60 inclusive. Figure 55 is the Alkins forged steel brace. The flange of the brace and the top fish into the rail like a splice bar, the wide bearing on the rail base being intended to hold the rail firmly to the tie, so as to prevent up and down motion in the same, and also to permit the first two spike holes to come close to the rail base, where their holding-down power is greatest. Figure 56 is the Elliot brace, of similar design in some respects, but having in addition a top shoulder, to fit against the head of the rail, and claws projecting from the base like those of a Goldie tie plate, to enter the tie and afford lateral resistance to assist the spikes. Figures 59 and 60 show two designs of the Weir die-formed steel braces. The flange of this style of brace is cut off at the edge of the rail base and abuts squarely against the same. The difference in the designs is that the one shown as Fig. 59 has open spike slots in the edge of the flange, while that shown as Fig. 60 has enclosed spike holes through the flange and affords more bearing surface upon the tie. In another design the side spike holes are enclosed, as in Fig. 60, and the place for the rear spike is an open slot in the edge of the flange, as in Fig. 59. Each of the designs is made with metal of either of two thicknesses—$\frac{1}{4}$ in. or $^5/_{16}$ in., as desired, the thicker brace being intended for rails of heavy section. The foregoing pressed steel braces of the box form are supposed to fit over the spike already in the tie when the brace is applied, but unless this spike happens to be at or near the center of the tie face (which is not likely to be the case) it comes in the way of the brace and it must be pulled and redriven

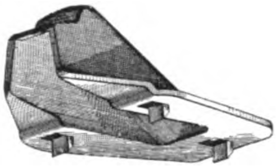

Fig. 56.

Fig. 57.

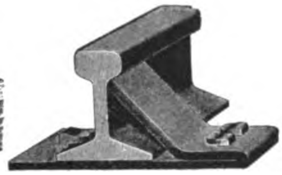

Fig. 58.

before the brace can be set. On the Southern Pacific road there is in service a forked rail brace made to fit around one spike set against the base of the rail. It is made of cast iron and is about 7 ins. wide.

Figure 57 shows the Ajax cast steel brace, designed to set over the spike already in the tie, as well as over the rail base, and fit against the web of the rail and side of the rail head. An excellent feature of this brace is that it can be set without interfering with the spike already in the tie in whatever position. For use on sharp curves this brace is sometimes ordered made with a $\frac{3}{8}$-in. offset to overlap the ends of tie plates. Figure 58 shows the Edwards combination rail brace and tie plate.

As the joint is the weakest place in the rail, it is spread the most easily; consequently there ought to be a rail brace designed to fit against the splice bar. In event such a design was gotten up it would be well to have about 25 per cent of the whole number ordered to fit the splice bars, as, if the joints could be made secure, the braces could in many cases be omitted from the quarters. The practical difficulty in designing a joint brace to fit against the web or vertical portion of the splice bar is the presence of the bolt heads or nuts and the creeping of the rails. In view of such conditions I would recommend a brace bearing only against the horizontal leg of the splice bar. Such a brace might consist of a flat plate punched for the spikes and flanged on the service edge to take the bearing of the splice bar. To provide against undercutting, through abrasion of the tie, this flange should project downward $\frac{1}{2}$ or $\frac{3}{4}$ in. into the tie.

Rails spread worst in winter, when the ground is frozen and the ties are held rigidly to their work. This is usually the busiest season of the

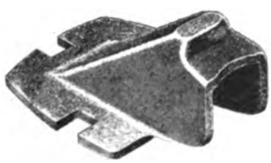

Fig. 59.

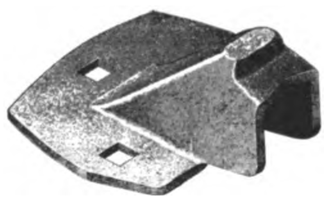

Fig. 60.

year for regaging and bracing spread rails on curves, and when the demand for braces is urgent it is frequently the case that some form of device must be improvised. Broken splice bars always come handy for this service, and, sometimes, even pieces of plank are used. In fact, a piece of 2-in. plank about 12 ins. long and, say, 4 to 6 ins. wide, makes a fair brace for temporary service. It should be set against the web of the rail and secured by at least two spikes against the end of it, the hook of the spike head being driven to sink into the block. Then to prevent the block from swinging out of place a spike should be driven through it. Good rail braces may be made of old fish plates by bending up one end so that it will fit under the rail head. There will then be left three holes for spikes, and a fourth spike can be driven at the end, if needed. In some cases the end of the fish plate is bent over against the web of the rail, something after the style of the Ajax brace. In setting rail braces all the old spike holes under the braces should be plugged.

In extremely bad cases, on very sharp curves, switch rods spaced a few feet apart are employed to prevent spreading of the rails. A bridle brace used at one time on the Stampede switchback of the Northern Pacific Ry. consisted of a bar with the ends bent around to clasp the flanges of the two rails on the outside only. They were easier to apply than switch rods and served the purpose just as well.

50. Transition Curves.—Easement, elastic, transition, parabolic, spiral, and tapering curves, as they are variously called, all signify the same thing—the gradual easing off or flattening out of circular curves at the ends, so as to make a gradual transition, as it were, from the tangent to the circular curve. It has already been explained that the transition curve enables a satisfactory arrangement of the run-off of curve elevation, since it affords a means by which the elevation can everywhere be adjusted to the desired relation with the curvature. A word further may be said by way of emphasis. After entering a curve a car has two movements relatively to the tangent behind: one progressively, that is, moving in the same direction as the tangent; and another normal or sidewise to the tangent. Now the car wheels begin their movement normal to the tangent the instant they strike the curve, and if at just this instant the car body could be tilted inward sufficiently by rail elevation, at just this instant its movement normal to the tangent would receive its initial impulse from elevation, and not from side pressure from the wheels; because in tilting inward from elevation in the track the car body, as a whole, actually moves inward as well. But such an arrangement in elevation cannot be had on simple circular curves, for the elevation must be developed gradually, in some considerable distance. With the spiral, however, the movement normal to the tangent can begin more gradually, because the track can be given its elevation so that at every point such elevation is adapted to the degree of the curve at that point; and hence at every instant leading up to the main part of the curve the car body is being gradually tilted inward by rail elevation at the same time that it is being accelerated in the normal direction—instead of being started by sudden pressure from the wheels, after the body has been already tilted while running over an elevated approach on the tangent.

The value of easement or transition curves is greatest where sustained high speed is practicable. Elevation for simple circular curves can be run in quite satisfactorily for good speed, and it is only where extraordinary results are desired that the greater expense and care necessary to maintain the easement curve can be justified. The most practical or satisfactory application of the easement curve is then not so much to curves so sharp that in any event speed must be reduced in running around them, but to those curves of comparatively smaller degree where, with the aid of the transition curve, the slackening of speed may be avoided; and while by using the transition curve a slightly higher speed on curves of, say, above 6 or 8 deg., might be had with a feeling of greater comfort or security, perhaps, still its use on curves less than 6 or 8 deg. must no doubt be the more justifiable practice. Not necessarily, then, are transition curves best suited to roads of heaviest curvature. Furthermore, it will usually be found that the surroundings which determine the location of a sharp curve will allow of but little room for easements. In any case the easement should be no longer than to give sufficient distance in which to run out the elevation. Any available room beyond this had better be used in reducing the curvature of the central or circular portion of the curve.

51. The Cubic Parabola.—A transition curve having a variable radius which gradually decreases in length from infinity, at the point where it meets the tangent, to a length equal to the radius of the circular curve, at the point where it meets it, is a desirable one to use, but it is also desirable that such curve should have an equation so simple that it readily adapts itself to easy calculations. A curve whose equation is of the form $y^n = A\,x$ is recommended, because of its simplicity and facility of application.

If some point be taken as an origin and rectangular axes of co-ordinates be drawn through this point, and points on the curve be plotted with reference to these two axes, the rate at which the curve departs from one of the axes, depends upon the power n, this power being given to the function which determines the position of any point on the curve with reference to the other axis. That is to say, the curve departs from one axis as many times as fast as it does from the other axis, by the n th power of its proportional distance from the other axis, at any point. But the scale to which the curve is drawn depends upon the value given to A; and by the scale is meant the relative length of the radius of the curve at any

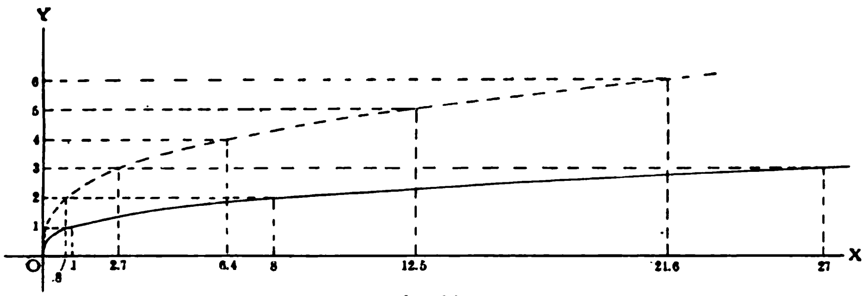

Fig. 61.

point. Thus the value of n determines the form of the curve, and the value given to A the size of it, as will be explained presently.

Now regarding the value of n, simplicity of calculation requires that it be an integral number and as small as can be used. To make it 1 would, of course, give the equation of a straight line; and to make it 2 would give a parabola, the maximum curvature of which comes at its vertex or origin, which is not a curve suitable for our use. The exponent 3 gives the *cubic parabola,* whose radius of curvature at the origin is of infinite length, being what is desired, and so to save complication no higher exponent need be used. To show to best advantage how this curve can be used we will plot it and point out its main features. In order to simplify matters suppose that at first we let $A=1$; then the equation of the curve becomes $y^3=x$. Let through the point O, Fig. 61, two axes of co-ordinates, $O\ X$ and $O\ Y$, be drawn at right angles to each other. Then all distances measured in a direction perpendicular to $O\ X$ will be denoted by y and distances measured in a direction perpendicular to $O\ Y$ will be x distances. Substituting different values for y we get: $y=0$, $x=0$; $y=1$, $x=1$; $y=2$, $x=8$; $y=3$, $x=27$; ....$y=10$, $x=1000$.

It is seen that the curve starts from O and after making a sharp bend rapidly flattens out; and that its distance from OY at any point, is, compared with its distance from OX, as the cube of its distance from OX. Thus the curve, while leaving OX gradually, leaves OY very rapidly, and the curve soon flattens out, so that it approximates to a straight line parallel to OX; or in other words it becomes a curve with radius rapidly approaching infinity. But let us consider the curve near the origin for values of y less than 1.

Let $y = .9$ then $x = .729$
$y = .8$........$x = .512$
$y = .7$........$x = .343$
$y = .6$........$x = .216$
$y = .5$........$x = .125$
$y = .4$........$x = .064$
$y = .3$........$x = .027$
$y = .2$........$x = .008$
$y = .1$........$x = .001$
$y = .01$.......$x = .000001$

While the curve makes a sharp bend between $y=0$ and $y=1$, it is seen that as y gets smaller in value the corresponding value of x gets smaller in proportion to the cube of the decrease of y. Hence, as the curve is followed toward the origin it approximates to a straight line parallel to OY, and at the origin it must be a straight line or curve of infinite radius.

Let this curve be cut into two parts or branches, call them for convenience, making the cut at the point of sharpest curvature. This point is at $y=0.3865$, $x=0.0577$ (see Fig. 62), at which point the radius of curvature is, of course, a minimum, and equal to 0.56744, or 1.46815 times

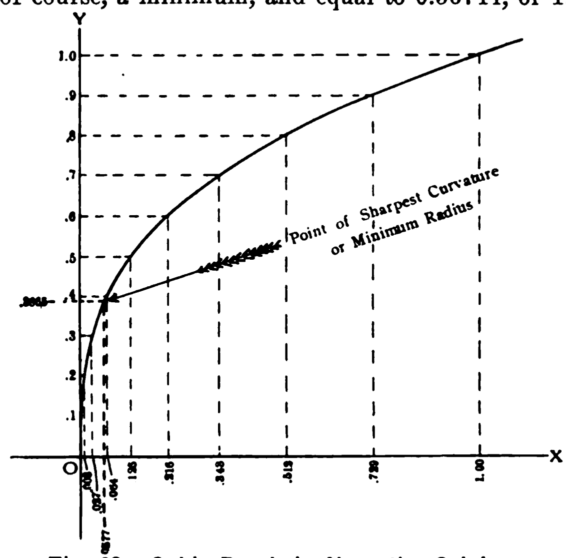

Fig. 62.—Cubic Parabola Near the Origin.

the value of y. By following the curve to the right from this point we pass from curvature of very short radius to curvature which rapidly approaches infinite radius, but reaches it only at infinite distance—that is, never reaches it; while if we go to the left, or toward the origin, we pass along curvature rapidly approaching infinite radius, which does actually reach infinite radius at a definite distance, that is, at the origin. So while the two parts of the curve under consideration vary in curvature according to the same law, each at the same rate relatively to itself, and while each branch passes through all degrees of curvature down as low as the minimum radius named, there is this difference: comparatively, the flattened portion in the right-hand branch is infinitely longer than the more curved portion of the same branch; while with the left-hand branch the flattened portion is, compared with the more curved portion of itself, infinitely times as short. It is, then, this latter branch or part of the curve which is the better suited for an easement curve, because the portion of the curve having radius very great, or infinitely long, is needed only for a short distance at leaving the tangent. The portion referred to is that between the origin and the point marked $y=0.3865$, $x=0.0577$, and is therefore only a small portion of the curve, as shown. This portion of the parabola can furnish a transition curve for any circular arc whose radius of curvature is not shorter than the minimum radius of curvature of the parabola. In practice, however, only part of this small portion considered is generally used, so that, to apply it to curves on the ground, its scale must be enormously enlarged. As stated previously, this is done by assigning a greater value to A.

Suppose, for the sake of discussion, that A be taken at 10. The values of x corresponding to values of y, taken in succession, will then be for $y= {}^1/_{10}$, $\frac{1}{2}$, 1, 2, 3, 4, 5: $x={}^1/_{10000}$, ${}^1/_{80}$, ${}^1/_{10}$, ${}^8/_{10}$, ${}^{27}/_{10}$, ${}^{64}/_{10}$, ${}^{125}/_{10}$, and when plotted gives the broken curve in Fig. 61, with minimum radius 1.7944, at $y=1.2222$. It might at first appear that the broken curve is of different form from the other. Such, however, is not the case, as both are identically of the same form, but one is simply drawn to a larger scale than the other. It is found that the scale of the plotted curve increases as the square root of A, the minimum radius always being equal to $0.56744\sqrt{A}$, and coming at $y=0.38650\sqrt{A}$; the minimum radius also equals 1.46815 times this value of y. So by assigning a suitable value to A in the equation we may start off with a curve leaving the tangent at radius infinity, and, at any desired distance out on the curve, obtain curvature which will coincide with that of any circular curve with which we wish to join it at that point.

Now it is found that for 0.45 of the distance between the origin and the point of minimum radius (p. m. r.) the cubic parabola follows almost precisely a curve the radius of which varies inversely as the distance measured along the Y axis (which, within the same limits, would be practically a measurement along the curve); and that up to 0.65 of the distance to the p. m. r. its departure from such a curve is inappreciable. For the remainder of the distance up to the p. m. r. the rate of change of curvature becomes less—that is, the radius of curve gets slightly longer than what would be its length did it decrease in exact proportion to the increase of distance along the axis. Coming down to fine points, then, this much may be said of the cubic parabola: If used within .45 of its length from origin to p. m. r., it gives a curve whose radius decreases almost precisely as length of curve increases, and up to .65 of its length to p. m. r. it does not depart appreciably from such curve; it is, therefore, to all intents and purposes, the ideal, within the latter limit.

Although beyond the .65 point the change of relation between the length of curve and radius does not to an appreciable extent render the curve less desirable for an easement curve, and although it does not usually happen that so much of the curve is needed in practice, still an important fact should here be noted. The formulas given further along for running out the curve, although very exact up to the .65 point, cannot be applied to the whole length, and cannot be depended upon much farther than this point. The effect of this discrepancy is, of course, that in order to use the full length of the cubic parabola to the p. m. r. more complicated formulas than those given must be used; and, furthermore, to get reliable results from the formulas given, the length of the easement curve used should not exceed 0.38 of the radius of the circular curve; which, as applying to circular curves above 11 deg., might make an undesirably short transition curve.

It now comes to settling upon a value for A, to suit any case in practice. At any point on the curve up to the .45 point the product of the radius at that point by the distance of the point from the origin (that is, the y distance) is almost precisely constant and is equal to $\frac{1}{6}$ A, for any value of A whatever; and between the .45 point and the .65 point this product is practically constant and always very approximately $\frac{1}{6}$ A. This relation holding true for any point, permits the use of a particular point, so that up to the latter limit, then, A for any particular curve may be considered to be the product of three quantities; viz., R, y_e and 6; and the equation becomes $y^3=6Ry_ex$,* R being the radius of the circular curve and y_e being the length of the easement curve, measured along the axis or tangent. As R and y_e are each constant for any chosen case, their product is then a constant, and it is usual to express the equation in the form $y^3=6Cx$, C representing the product of the radius of the circular curve (which is to be eased off) by the length of the easement curve desired. The formation of an equation for an easement curve in any given case becomes, then, a simple matter, and approximate formulas for laying it down by

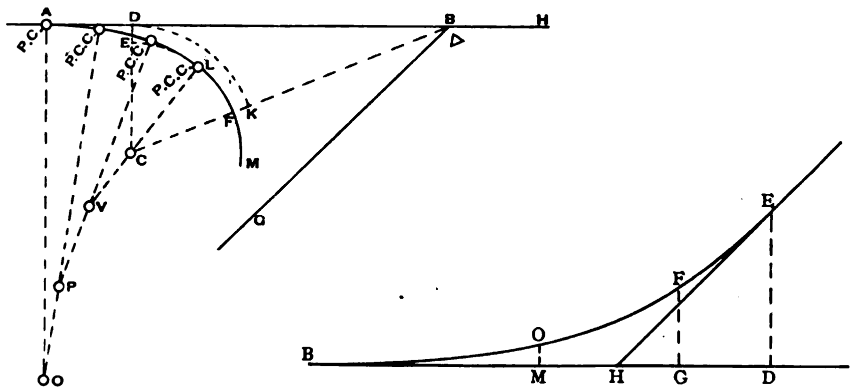

Fig. 65.—Tapering Curve. **Fig. 63.**

co-ordinates from the tangent considered as one of the axes, are equally simple.

Laying out the cubic parabola by tape-line measurements is simple work and it may be quite accurately done. Suppose (Fig. 63) it is desired to lay off a curve to the left of the line BD to some point opposite D. The distance BD is then the y_e of the formula. Suppose that at some point opposite D it is desired to develop a curvature of radius R. We then have the equation $y^3=6Cx=6Ry_ex$; or $x=\dfrac{y^3}{6Ry_e}$. The point E opposite D will then be distant

$$DE=x_e=\frac{(y_e)^3}{6Ry_e}=\frac{(BD)^3}{6R(BD)}=\frac{(BD)^2}{6R}$$

Any other point on the curve, as F, opposite G, will then be distant from BD, $GF=x_f=\dfrac{(y_f)^3}{6Ry_e}=\dfrac{(BG)^3}{6R(BD)}$. Or it may be found by proportion, thus:

$$GF:ED=(BG)^3:\ (BD)^3;\ \text{therefore}\ GF=ED\frac{(BG)^3}{(BD)^3}.$$

---

*The general expression is, of course, $y^3=6\ R_y y x$. As we are dealing with a parabola which joins a circular curve, R_e and R are equivalent and the equation, which otherwise would be expressed $y^3=6\ R_e\ y_e\ x$, is perhaps most convenient in the above form.

If $BM=\frac{1}{2}BD$ then $OM=ED\frac{(BD)^3\div 8}{(BD)^3}=\frac{ED}{8}$; and so any point on the curve between B and E may be found by computing direct from the formula; that is, by substituting in the place of y the distance from B to the foot of the perpendicular dropped from the point on the curve to the line BD; or its distance from BD will be such portion of ED as the cube of the distance from B to the foot of its perpendicular is to the cube of BD.

Having the curve laid out to E, it may be desirable to get its direction at that point; that is the direction of the tangent to the curve at that point, from which to lay off a circular curve by deflection angles, perhaps. From the calculus, the tangent of the angle which the direction of a curve makes with the tangent (BD) at any point $=\frac{dy}{dx}$. In this case it would be $\frac{dx}{dy},=\frac{3y^2}{6C}=\frac{(y_e)^2}{2C}=\frac{(BD)^2}{2R(BD)}=\frac{BD}{2R}$; that is, the tangent of the angle $EHD=\frac{BD}{2R}$, and the angle $HED=90$ deg. minus the angle whose tang. is $\frac{BD}{2R}$. Setting up at E, then, sighting the instrument on D, and turning off toward H the angle HED, puts the line of sight on tangent to the curve at E. But the point H may be determined by direct measurement.

Tang. $EHD=\frac{(y_e)^2}{2C}=\frac{(BD)^2}{2C}=\frac{ED}{HD}=\frac{(y_e)^3\div 6C}{HD}=\frac{(BD)^3\div 6C}{HD}$. Therefore $HD=\frac{2C}{(BD)^2}\times\frac{(BD)^3}{6C}=\frac{BD}{3}$. Measuring off HD, back from $D,=\frac{1}{3}BD$, gives the point H as a backsight to get on tangent at E.

Suppose it is desired to join two tangents by a circular curve having this parabolic curve at each of its ends. Let, in Fig 64, JK be one of the two tangents. Locate, at first on paper (or make calculations for whatever circular curve is desired for the main part of the curve) the point M, this being the tangent point of such curve. Decide what length (BD) is desired for the easement curve, and measure it off along JK equally each side of M, so that $BM=\frac{1}{2}BD$. The distance (DE) to the point where the parabola joins the circular curve will be, as before, $(BD)^2\div 6R$, where $R=$ the radius of the circular curve. M being midway between B and D, the distance (MO) to the parabola will be $\frac{1}{8}$ ED. Run through $M'R$ the tangent $M'K'$, RD being equal to $MM'=2MO$. Run in the circular curve $M'N'$ between the two new tangents. This curve can be met at E by a para-

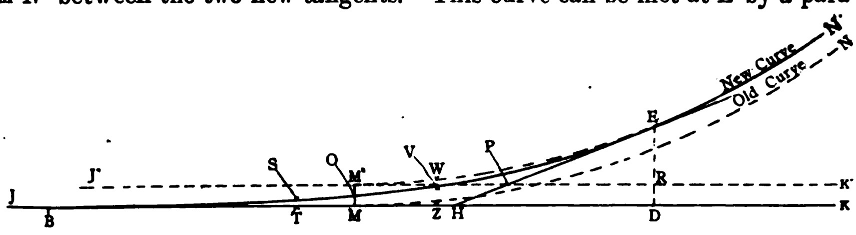

Fig. 64.

bolic transition curve which passes through B and O: for, from similarity of triangles, $PR=\frac{3}{4}HD$, because $RD=MM'=2MO=2\times\frac{1}{8}ED=\frac{1}{4}ED$; and $ER=\frac{3}{4}ED$. Therefore $PR=\frac{3}{4}HD=\frac{3}{4}\times\frac{1}{3}BD=\frac{1}{4}BD=\frac{1}{2}MD=\frac{1}{2}M'R$; and (very approximately) $M'P=PE$, as two tangents drawn from a point to a circular curve properly should be. This proves that, within the accuracy to which we are working, the tangent line $M'P$, from which the circular curve was run, is properly offset a distance $MM'=2MO$ from the tangent JK, from which line the parabola is run. Other points on the parabola between B and E may be located as described for Fig. 63. For instance, a point S will be from JK a distance $ST=x_s=\dfrac{(y_s)^3}{(y_e)^3}x_e=\dfrac{(BT)^3}{(BD)^3}ED$

Should any point, V, which it is desired to locate, be inaccessible to a measurement from JK, it may be located from the circular curve $M'N'$ by a measurement $WV=x_e\dfrac{(y_e-y_v)^3}{(y_e)^3}=ED\dfrac{(BD-BZ)^3}{(BD)^3}$; or it may be used as a check upon the other method. The distance of the point V from the old circular curve MN would, of course, be the difference between MM' and WV.

The parabola at the other end of the curve is laid out in the same way. To put a parabola on the end of an old curve, the old curve is first thrown in a distance $MM'=\frac{1}{4}$ of the distance calculated for ED according to the formula; the old curve is then relocated. Of course, the circular curve can be run from E, and need not be located back as far as M' except as a check.

The necessary formulas are now, for convenience, grouped together:

(1) $y^3=Ax=6Cx$; or $x=\dfrac{y^3}{A}=\dfrac{y^3}{6C}$

(2) $C=Ry_e$, or radius of circular curve $\times$ BD.

(3) $BM=MD=\frac{1}{2}BD$.

(4) $ED=x_e=\dfrac{(y_e)^3}{6C}=\dfrac{(BD)^3}{6C}=\dfrac{(BD)^3}{6R(BD)}=\dfrac{(BD)^2}{6R}$

(5) $MM'=2MO=\frac{1}{4}ED=\frac{1}{3}ER=\frac{1}{8}$ tangential offset of circular curve in a distance$=\frac{1}{2}$ the length of the easement curve.

(6) $x=\dfrac{y^3}{(y_e)^3}\times x_e=\dfrac{y^3}{(BD)^3}\times$ED.

(7) $WV=x_e\dfrac{(y_e-y_v)^3}{(y_e)^3}=ED\dfrac{(BD-BZ)^3}{(BD)^3}$

(8) $HD=\frac{1}{3}BD=\frac{2}{3}MD$.

(9) Tang. $EHD=\dfrac{y^2}{2C}=\dfrac{(y_e)^2}{2C}=\dfrac{(BD)^2}{2R(BD)}=\dfrac{BD}{2R}$

(10) Min. radius$=0.56744\sqrt{A}=1.46815\times y$ at p.m.r.

(11) y at p. m. r.$=0.38650\sqrt{A}$.

(12) R_y (Radius at any point y) $=\dfrac{y^3}{6yx}=\dfrac{y^2}{6x}=\dfrac{(y_e)^3}{6yx_e}=R\dfrac{y_e}{y}$

It now remains to show the application of these formulas to a practical example. Suppose it is desired to ease off a 6 deg. curve which has

5 ins. of elevation. As a precaution, the maximum length of useful curve to which the formulas will apply with exactness is $.38 \times R$ of 6 deg.$=.38 \times 955.4=363$ ft.; but as 200 ft. is sufficient length in which to run cut 5 ins. of elevation, we are far within the limit of accuracy. y_e is then equal to 200 ft., and our equation becomes $y^3=Ax=6Ry_ex=6\times 955.4\times 200\times x=1{,}146{,}480x$; or $x=\dfrac{y^3}{1{,}146{,}480}$. Simply to show another check, we find that the minimum radius of this parabola$=.56744\sqrt{A}=.56744\sqrt{1{,}146{,}480}=607.6$; which comes at $y=.38650\sqrt{A}=413.8$. We thus use less than half the available curve, and hence the application of the formulas to this curve is practically precision.

The distance x_e or ED will be $\dfrac{(y_e)^3}{6C}=\dfrac{200^3}{1{,}146{,}480}=6.98$ ft; and the offset MM' of the circular curve from the tangent$=\dfrac{6.98}{4}=1.745$ ft. Computing independently of the formula the departure of the circular curve from the tangent BD, after being set over 1.745 ft., is found to be 6.98 ft. at 100 ft. from M. This measurement agrees exactly with that for the point E at which the parabola should meet the circular curve, and thus shows that within the limits stated the reliability of the formula cannot be questioned. From (5) it is also apparent that ED is equal to $^4/_3$ of the tangential offset of the circular curve at a distance from the P. C. equal to half the length of the easement curve.

For circular curves sharper than 11 deg. a parabolic curve as long as 200 ft. cannot be accurately computed by these formulas, the limit of accuracy being restricted to a length of about $.38R$, as before stated. Formulas might be given which would accurately apply to the cubic parabola throughout its full length to the p. m. r.; but inasmuch as, for the most part easement curves are used with circular curves of less than 11 deg., it is considered that within this limit formulas so simple and accurate as the foregoing are more desirable to use than those necessarily more complicated. The formulas for computing deflection angles for laying out the cubic parabola with the instrument are not as simple, and it is therefore more usually the case that the curve is laid out by offset measurements from the tangent, as above worked out.

52. Tapering Curves.—Another method of easing curves that is largely in practice is the use of a series of compound curves of gradually changing curvature, the chords of which are equal and comparatively short, usually from 30 to 50 ft. The engineering departments of some roads have arranged tables of deflection angles for the use of their surveyors, so that these compound curves can be run out by the ordinary method of deflection angles, at one setting of the instrument at the P. C., instead of setting up anew at each P. C. C. located. A number of curves varying at different rates from 30 min. per 30 ft. (or whatever chord length), up to perhaps 2 deg. 30 min. per 30 ft., are used in different instances. For instance, in easing off a 2-deg. curve: beginning at P. C., it might be run out by starting with 30 ft. of a 30-min. curve, followed by 1-deg. and $1\frac{1}{2}$-deg. curves successively, each of 30-ft. chords, after which the 2° curve would be run in. A 15° curve might be eased off by five compound curves varying by 2° 30′ successively, until the full 15° is reached. Tables changing by 30 min., 1°, 1° 30′, 2° and 2° 30′ per chord length would apply to almost any curve in a manner to suit different men's ideas of the proper rate of easement. Formulas for length of tangent, and whatever modifications of simple circular curve formulas are necessary for properly locating the curves, are simple and easily worked out. These curves are usually called "tapering" curves. Although, in the process of running them out, the points established are points of compound curvature, the track need not be lined as so many compound curves but can be made to vary in curvature gradually by simply using the P. C. C.'s as points of a gradually varying curve, instead of points of distinct change of curvature. In this form, if the chords be short, the curve resembles closely the cubic parabola, and the elevation can be put in more satisfactorily, perhaps, since the full curvature is in this way attained by a gradually varying rate instead of by stages, as it were.

In Fig. 65 (not drawn to scale) is shown a circular curve, *LM*, eased off by three curves of different radii. Considering the case a general one, a number of formulas applicable to any curve, with any number of compoundings, will be derived. Let *A B* and *B G* be two tangents. Then the angle *H B G* will be the intersection or Δ angle, and it is required to know what measurements are necessary for laying out between these tangents a circular curve with tapering ends and how these measurements are derived. If *C* be the center of the main or middle portion of the curve, then a simple curve drawn between the two tangents about this center would be *D K*, it being, for the present purpose, necessary to show only half of it. The angle *D C B* is $\frac{1}{2}\Delta$, and the tangent distance *D B* is (*C D* or *C K*) $\times$ tang $\frac{1}{2}\Delta$. Suppose, however, that the curve *L M*, the center of which is *C*, is the main or middle portion and is eased off by any number of compounded circular curves having equal chord lengths. The tangent distance of the compound curve is *A B*, which for convenience we will divide into two portions, *A D* and *D B*. Let the distance *A D* be called "t"; the distance *C D*, "*S*"; and the distance *E D*=*F K*, "*s*." *O P*, *P V* and *V C* are the differences of the successive radii. *A D*=*t*, is then equal to the sum of the products of *O P*, *P V*, etc. by the sines of the angles which these lines, *O P*, *P V*, etc., respectively, make with the line *O A*, the radius of the first curve. In other words the distance *t*, for any central or main curve which may be used, is found by adding together the products of the successive differences of the radii of the curves leading up to the central curve, by the corresponding sines of the total curvature at the end of each of these successive curves. In like manner the distance *C D*,=*S*, for any central curve, may be found by subtracting from *O A* (the radius of the first curve) the sum of the products of the successive differences of radii by the corresponding cosines of the angles of total curvature at the ends of the successive curves.

The distance *ED*,=*s*, is equal to *S* minus the radius of the main curve =*S*—*R*.

The distance from the middle of the main curve to the intersection

$$\text{point}=FB=(S\times\text{ex. sec. }\tfrac{1}{2}\Delta)+s=\frac{S}{\text{Cos.}\frac{1}{2}\Delta}\text{ minus radius of main curve}$$

$$=\frac{S}{\text{Cos.}\frac{1}{2}\Delta}-R$$

The distance from P. C. to intersection point=$AB=DB+t=S\times$ tang. $\frac{1}{2}\Delta+t$.

The central angle of each portion of the compound curve is found by the solution of an isosceles triangle, two sides of which are equal to the radius of the curve; and whatever chord length is taken forms the third side.

The deflection angles from the tangent *AB* to each P. C. C., or from tangent at any one of the P. C. C.'s to any other P. C. C., are found by solving triangles wherein two sides and the included angle will be found given in each instance.

Table IX gives to the nearest half minute the deflection angles from the P. C., or from any P. C. C., to any point of change of curvature, for any central curve from 2 to 10 deg. The portions of the compound curve change 1 deg. each 40 ft. The distances *"S," "t,"* and *"s"* are given, also the total curvature to any point, and the long chord distance from the P. C. to the P. C. C. of the main curve. There is also included a list of ordinates for laying off the points of the curve by linear measurement alone.

In running out the curves by transit it is best, after fixing the P. C., to establish the P. C. C. of the main curve, using the tabular long chord distance and deflection angle or a direct measurement by the ordinate distances given. In this way a check is had on the work of the successive

deflections and short chord measurements. Should the main curve be of such degree that it comes between those given in the table—say a 5° 30′ curve—run in the tapering curve to P. C. C. 5°, putting in this point by the method just described. Then run in 20 ft. more of a 5° curve to P. C. C. 5°30′. In any case, for the last compounding of the tapering curve, take a length of chord which would divide the tabular chord in the same ratio as does the main curve divide up the angular distance between the two adjacent tabular curves. For instance, if the main curve were 5° 20′, use a chord ⅓ the tabular length, or 13⅓ ft.; for a 5° 45′ curve use a chord ¾ the tabular length, or 30 ft. Then correct the values of *S* and *t* as follows: multiply respectively the sine and cosine values of the total curvature up to the main curve, by the difference of radii of main curve and the last branch of the compound curve; add the sine product to *t* and subtract the cosine product from *S*, such values of *t* and *S* being taken from the table for the last branch of the compound curve.

Mr. Wm. Hood, chief engineer of the Southern Pacific road, many years ago worked out formulas and a series of tables applying to tapering curves, which are used on that road. His list includes tables for the following curves: one changing 30 min. each 30 ft., applicable to curves up to 10 deg.; one changing 1 deg. each 30 ft., applicable to curves up to 10 deg.; one changing 2 deg. 30 min. each 30 ft., applicable to curves up to 20 deg.; one changing 2 deg. 30 min. each 15 ft., applicable to curves up to 20 deg.; and one changing 15 min. each 30 ft., applicable to curves up to 5 deg.

The Torrey Easement Curve.—A similar system of transition curves is also in use on the Michigan Central R. R., where it was introduced by the late Mr. Augustus Torrey, chief engineer. Transitions from tangent to curve or from lighter curve to sharper curve are made by curves of regularly increasing degree, constructed upon a series of chords of equal length and compounded at the end of each chord. That end of an equal chord which joins an equal chord of less curvature is designated as the "small end" and that which joins an equal chord of greater curvature, the "large end." His list includes ten curves of the following tabulated description:

Length of equal Chords.	Variation per Chord.	Applicable to Curves up to
100 ft.	1 deg.	6 deg.
100 "	30 min.	4 "
50 "	1 deg.	12 "
50 "	30 min.	6 "
50 "	15 "	3 "
25 "	2 deg.	20 "
25 "	1 deg. 30 min.	15 "
25 "	1 "	12 "
25 "	30 min.	6 "
25 "	15 "	3 "

The data contained in the tables applying to these curves comprise the following linear and angular measurements: offset from the tangent through the small end of any chord to the large end of any chord; projection upon the tangent through the small end of any chord, of the line joining that point of tangency with the large end of any chord; prolongation to the tangent through the small end of any chord, of the radius drawn through the large end of any chord; length of long chord joining the small end of any chord with the large end of any chord; angle between the tangent through the small end of any chord and the tangent through the large end of any chord; distance on the tangent through the small end of any chord, from that point of tangency to an intersection with the radius prolonged through the large end of any chord; deflection angle from the tangent through the small end of any chord, from that point of tangency to the large end of any chord, and vice versa from the tangent through the large end of any chord, from that point of tangency to the small end of any chord. There are, in addition, tables giving data showing changes in line which follow upon the use of the various transitions given in the above mentioned ten tables. Problems involving the calculations for tangent lengths, central curve, easement of simple curve already built and easement of transition from one curve to a lesser one in the same direction are taken up and formulas deduced therefor. These problems are treated in a manner somewhat different from the foregoing treatment of tapering curves, since the formulas derived have reference to the intersection points on the two tangents to the curve, of the radii produced through the ends of the central or circular portion of the curve, instead of the points of intersection (D, Fig. 65) of radii drawn from the center of the circular portion of the curve perpendicularly to the two tangents. The solution of these problems, together with the tables referred to, and diagrams illustrating their use, have been embodied in a neat book of pocket size entitled "Switch Layouts and Curve Easements." The book, also, as the name implies, includes the solution of a number of switch problems.

53. Searles' Spiral.—The "Searles Spiral" is a multiform compound curve, the same in principle as the tapering curves just described, but susceptible of a much wider range of application and a much finer adjustment. A single spiral for any curve consists in chords of equal length subtending arcs of circles varying in degree by an amount which is practically a common difference (equal to the degree of curvature of the first arc), up to the degree of the main or central portion of the curve. The list includes different spirals with chords varying in length by 1 foot, all the way from 10 to 50 feet,—that length of chord to be chosen which for any curve seems to best suit the requirements. The rate of variation in curvature between any two adjacent arcs is always the same for any curve, notwithstanding that for different spirals the chord lengths are not the same. The real difference, then, between any two spirals is not in form but in the room taken up by them, or in the relative scale on which they are laid out. Its points as laid down form, for all practical purposes, the locus of a cubic parabola, the essential difference between the two not amounting to anything.

"The Railroad Spiral," a book of pocket size, contains a table of deflection angles for a curve of 20 points or less, and other tables giving deflections for a setting of the instrument at any point of the twenty; the central angle of the spiral, up to any point, is also given. The variation in curvature between any two adjacent chords being practically the same, the deflection angles remain the same for similar points in all spirals of any chord length, providing all the chords are made of equal length. The location of these spirals with the transit is thus reduced to the simplicity of running out simple circular curves. There are also tables corresponding to all chords varying, by 1 ft., between 10 ft. and 50 ft. These tables give the degree of curve for the arc subtended by any chord, in any spiral not longer than 400 ft., thus enabling a spiral suitable for any curve to be picked out of the tables. The choice of a spiral is had by choosing one such that the last chord of the spiral, and one more, subtends an arc equal in curvature to the main curve, or very nearly so. There is generally a large number answering the requirements, so that, by choosing from tables of different chord lengths, a spiral of almost any desired length, also, may be found. These tables further contain values of ordinates for points on the spiral, so that they may be laid off by tape-line measurements from assumed axes.

In my estimation "The Railroad Spiral" is the most easily adapted and the most practical printed matter to be had on transition curves, and it is published in a form convenient for immediate application to the uses of the field. In form the "spiral" is, for railroad use, just as good as any of the curves thought to be nearer the ideal but more complicated to calculate and apply. So far as practical results are concerned there is no sensible difference between any of the curves mentioned in this chapter. but there are considerable differences in methods of application, and the fact that with this curve the same deflection angles are always used, for any spiral, very much simplifies the field work and makes it undoubtedly the easiest to lay out. An investigation by the track committee of the American Railway Engineering and Maintenance of Way Association, in 1901, covering 83 of the principal railroads of the country, showed that 71 of those roads were using some form of transition curve. The form of tran-

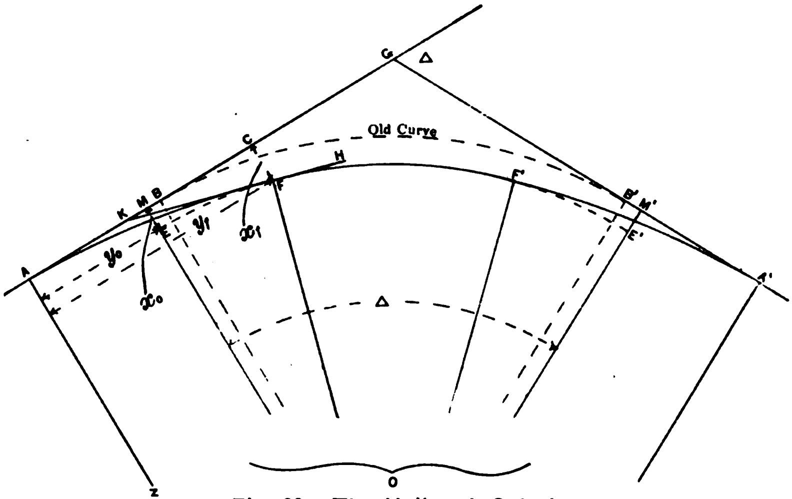

Fig. 66.—The Holbrook Spiral.

sition found to be in most extensive use was the Searles spiral, with the Holbrook spiral next in order of preference, these two being mentioned more frequently than all other forms of transition curves combined.

54. The Holbrook Spiral.—The theoretically true easement curve is the Holbrook spiral, worked out by Mr. Elliot Holbrook and first published in 1880. (At that time Mr. Holbrook was an engineer with the Pennsylvania Lines West. In 1900 he became chief engineer of the Kansas City Southern Ry.). As it leaves the tangent the radius decreases, or degree of curve increases, with the distance; that is, the degree of curve at any point is directly proportional to its distance measured along the spiral from the P. S. or point of spiral. Supposing R to be the radius of curvature at any point of the spiral, and L the distance of the point from the tangent point or P. S., measured along the spiral, then the definition of the Holbrook spiral is expressed by $RL=A$, where A represents some constant quantity. To illustrate this, suppose it is desired to use a spiral whose degree of curvature, beginning at the P. S., increases at the rate of 1 min. per foot or 1 deg. per 60 ft.; then, that the equation remain true it must apply to any point on the spiral which one may choose to take. If it be taken at the first foot, R would be the radius of a 1-min.curve,which is 343,774.68 ft., and $L=1$. Then $A=RL=343{,}774.68$; and it is the same for any other point, because R decreases just in proportion as L increases. Hence to find the radius at any point, distant L from the P. S., we use the formula $R=\dfrac{343{,}774.68}{L}$. This is for a spiral increasing 1 min. per foot; but if it increased at any other rate, A would have some different value, which could be found (nearly enough) by dividing 343,774.68 by the rate of change of curvature in minutes per foot. To find the length of spiral required to reach a circular curve of any certain degree, divide the degree of curve in minutes by the rate of change in minutes per foot—a very simple calculation.

Without taking up their demonstration, formulas for solving the simple problem of running in a spiral at each end of a simple circular curve, the intersection angle or Δ being given, will here be presented.

Referring to Fig, 66, let AG and GA' be tangents.

Δ =intersection angle.

BB'=simple circular curve.

B=P. C.; B'=P. T.

AF and $A'F'$=spirals.

FF'=circular arc in new position.

Δ_1=angle which tangent to spiral at any point $(x\ y)$ makes with the tangent line GKA; Δ_1 at $F=GKH=\Delta_t$. It is also the central angle of the spiral at any point.

D=deflection from any chosen point y_1 on tangent to any point (x, y) on spiral.

D'=deflection from a point on tangent GA, 200 ft. from A, to any point (x, y) on spiral.

$MOM'=\Delta$.

E and E' are points where the circular curve in new position becomes parallel to tangents GA and GA'.

Let GA be the axis of Y and AZ the axis of X, taking A for the origin; x and y will then be the co-ordinates of any point on the spiral.

The point E is denoted by the special co-ordinates x_0, y_0.

The following general formulas are now given:

(1). $RL=A$.

(2). $\Delta_1=\dfrac{\frac{1}{2}L}{R}=\dfrac{L}{2R}=\dfrac{L^2}{2RL}=\dfrac{L^2}{2A}$. In minutes (2) becomes (3).

(3). $\Delta_1=\dfrac{3437.7468\,L^2}{2A}$

(4). $y=L-\dfrac{12L^5}{4A^2 1.2.3.4.5}+\dfrac{1680L^9}{16A^4 1.2.3.4.5.6.7.8.9}-\text{etc.}=L-\dfrac{L^5}{40A^2}$, nearly enough.

(5) $x=\dfrac{2L^3}{2A1.2.3}-\dfrac{120L^7}{8A^3 1.2.3.4.5.6.7}+\text{etc.}=\dfrac{L^3}{6A}$, nearly enough.

(6). $x_0=x_t-R_t$ vers. sin Δ_t.

(7). $y_0=y_t-R_t$ *sin* Δ_t.

(8). Tang. $D=\dfrac{x}{y-y_1}$. When deflection is turned off from P. S., $y_1=0$ and (8) becomes (9).

(9). Tang. $D=\dfrac{x}{y}$

D' is calculated for $y_1=200$ ft.

T=length of tangent GA

T_1=length of tangent GB, or tangent of circular curve of same radius (R_t) as the middle part of the curve (FF')

(10). $T_1=R_t\times$tang. $\frac{1}{2}\Delta$. We then have (11).

(11). $T=T_1+BM+MA=GM+y_0=(R_t+x_0)$ tang. $\frac{1}{2}\Delta+y_0$.

We now have all the measurements necessary to lay off the curve. Beginning at the P. S. we can turn off computed deflection angles for different points on the spiral or we can measure them off from the axes of co-ordinates from A as an origin, by computing x and y for such points. It is well to establish E (x_0, y_0) by measurement; and also F, which equals

x_t, y_t, for a length of curve equal to the degree of the central circular curve divided by the rate of change of curvature. When the spiral is so long or so obstructed that it cannot be run from one setting of the instrument at A, set up at a point 200 ft. along the tangent toward G, and turn off the deflections D'.

Table X gives values of the elements of a spiral varying 1 deg. per 40 ft. or $1\frac{1}{2}$ min. per foot. Points are taken for every 10 ft. on the spiral and the table is given as an example. By substituting in the foregoing formulas, convenient tables are easily worked out for any rate of change. The sum of the deflections for the circular arc should be $\frac{1}{2}\Delta - \Delta_t$ and

the length of the circular arc is then $\dfrac{\frac{1}{2}\Delta - \Delta_t}{\frac{1}{2}\text{ deg. of circular curve}} \times 100$ ft.

For spirals having central angles up to about 12 deg. (which corresponds to spirals of 300 to 380 ft. length where the rate of increase of curvature is 1 deg. per 40 to 60 ft.) the foregoing formulas give results which are practically exact, in fact so nearly exact that the discrepancies are not measurable with the transit. Beyond this, that is with spirals longer than would be used in good practice, there is room for hair splitting. The Holbrook spiral, developed by different methods, is the curve used in several field books, including "The Transition Curve," by C. L. Crandall, and "The Railway Transition Spiral," by A. N. Talbot.

Of General Application.—In order to change an old circular curve to one of the same degree but having spirals or transition curves of any form at the ends, the old track must, as has been shown, be thrown in all the way around the curve. The old track may be kept in place at the central portion of the curve, and nearly so all the way around, by increasing slightly the degree of the circular or central portion of the curve. In order to change a circular curve for one having transitions at its ends, in a man-

ner not to change the length of the shifted track (so as to avoid cutting rails), the central or circular portion of the curve must be thrown outward at its middle and inward at its ends, thereby increasing the degree of curve; this method leaves the new curve as nearly as may be on the old ground. The central portion of the old curve may remain undisturbed by compounding at its ends, thereby increasing the degree of curve at those points. The treatment of these special problems, as well as numerous ones arising in the application of transition curves between the branches of compound curves, in different ways, will not be taken up. These problems the reader will find worked out in any of the text books heretofore mentioned.

The prevailing method of running out the elevation on transition curves has already been stated in defining the principal purpose of these curves. The track at the beginning of the easement, or at the tangent point, is made level transversely, and the elevation for the circular or main portion of the curve is developed with the easement, full elevation being used at the end of the easement or beginning of the main curve. In a few instances there are exceptions to this practice. On the St. Louis & San Francisco R. R. the form of easement is a tapering curve of 25-ft. chords and the development of the elevation begins on tangent a chord length in advance of the point of easement. The purpose of this arrangement is to give the elevation required for the first chord of the easement, at the tangent point, so as to be able to obtain the full elevation for each chord of the easement as it is reached by a train approaching from the tangent. Similar practice is in vogue on the Michigan Central R. R., where, also, the form of easement is a tapering curve. With the cubic parabola or any of the spirals it is plain that no question of the necessity of any such provision arises. In the largest practice the transition curves of the same road are of variable lengths, according to the degree of the main curve or

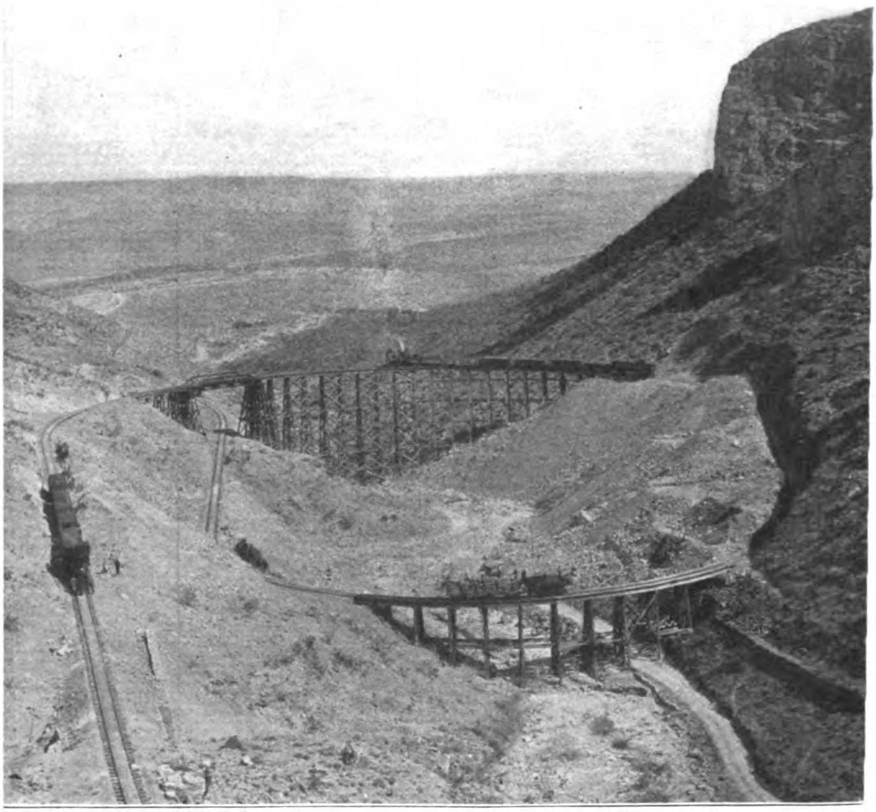
the elevation of the same, but in a few instances all the transition curves of a road are of standard or constant length, as was stated to be the case with the run-off of simple circular curves on several roads.

On some roads where transition curves are used it is not the practice to apply them to curvature that is easier than 1 or 2 deg., while on others it is the rule to ease all curves of whatever degree, even down to ½ deg., such being the practice with the Vandalia Line and the Michigan Central R. R. On the latter road each roadmaster and section foreman is supplied with a record of each curve under his charge, in the accompanying tabulated form.



Some Curves on the Morenci Southern Ry., in Arizona.

The Morenci Southern Ry., in Arizona, reaches Morenci through a narrow canyon, the natural grade of which is 6 per cent, and there are no side branches. The ascent of the railway on its maximum grade of 3½ per cent is accomplished by means of five complete loops, three tunnels and many very sharp horseshoe curves, locally known as "merry-go-rounds." On four of the loops the track crosses over itself on trestle, and in the other case the loop is made in a tunnel, on a sharp curve. The above view shows the fourth loop from and below Morenci, being only one mile distant, in an air line. The gage of the track is 3 ft., and there are some high trestles on 38-deg. curves.

CHAPTER VI.

SWITCHING ARRANGEMENTS AND APPLIANCES.

55. Turnouts.—A turnout, as the name implies, is an arrangement by which a car may pass from one track to another. The principal parts of a turnout are a switch and a frog, with a connecting piece of track called the *lead.* The rails connecting the switch with the frog, in both main track and turnout, are called *lead rails,* or the *main lead* and the *turnout lead.* A switch is a device for shifting the route at the entrance of a turnout. A frog is a union of two rails which cross each other, in such a manner that a wheel rolling along either rail will have an unobstructed flangeway while passing the other rail. The principle of the turnout is to cross the adjacent rails of the two tracks at the frog and to extend them beyond, so as to bring all four rails of both tracks near together to a point called the *point of switch* or *toe,* where the rails usually stand 5 or 6 ins. apart between gage lines. Then by means of two rails, each having one end free to move, a car may be switched from one track to the other. These two rails constitute the *switch,* and are usually called the *switch rails* or *moving rails.* It is usual to call the whole arrangement from switch to frog, "the switch," but the proper term to use is *turnout.*

In the *stub switch* the two rails of each track are cut squarely off at the toe and the switch rails are thrown so as to meet the fixed ends of the lead rails of either track squarely end to end. If the ends of the rails are cut off at a bevel, so as to lap by slightly when thrown, the switch is called a *lap switch.* The *point* or *split switch* is made up of a rail from each track, both rails being tapered a long way back and connected together, so as to throw alongside the through rail of either track. In this switch one rail of each track is cut off squarely at the heel and the other rail is left continuous; that is, one main-track rail is continuous, and one rail of the side-track is continuous with the main-track rail, being bent at the point of switch so as to turn from main track into the side-track. The fixed end of the switch is called the *heel,* the movable end to *toe.* In a stub switch, the heel is the end of the switch farthest from the frog; in a split switch, the end nearest the frog. The toe of the split switch is the point of switch. The distance from toe to heel in either case is called the *length of switch.* The distance over which the free end of the switch is moved is called the *throw* of the switch. In stub switches the throw must obviously be the same as the distance between the gage lines of the fixed rails in main track and turnout at the toe; but in point switches it need be only enough to give room for moving the point rail out of the way of the wheel flanges; four inches is sufficient. The turnout, between the switch and frog, is usually made a simple circular curve.

There is another switch used to some extent, known as the *Wharton switch.* With this switch both main track rails are unbroken and continuous. The switch rails consist of one point or grooved rail, which works against the main-track rail on the side opposite the frog, and another rail to which it is cross connected, working against the outside of the main-track rail on the frog side. This movable rail on the frog side has a sloped top which runs up higher than the main rail against which it is thrown and lifts the wheel so that its flange passes above and across it to the turnout lead rail. Stub and split switches are the ones in most general use.

56. Stub Switches.—Formerly the stub switch was the one the most used. It is durable, serviceable, and there is nothing in its make-up that is particularly delicate, but owing to certain objectionable features it has gone out of use for main-line service on nearly all of the heavy-traffic roads. Among these objectionable features or points of weakness are the frequent settlement of the headblock, due to the heavy pounding of the wheels at the open space which must be left at the toe; and the "tight switch," due to expansion and creeping of rails in hot weather. Quoting from a committee report to the New England Roadmasters' Association in 1890, "the stub switch, with its open joint in winter and tight joint in summer, with a loose headblock to be tamped every few days," is well to the point. The derailment of trains which trail (approach from the direction of the frog) an open or misplaced stub switch, is, however, the dangerous and, therefore, the most objectionable, feature. Although the point switch was in use at an early day, still the preference for the stub switch was for many years so strong that it was in some cases equipped with a rerailing device to prevent wheels from leaving the track when trailing the switch wrongly set. One arrangement of this kind was the Tyler switch, used to some extent at one time. It consisted of a short guard rail bolted to the gage

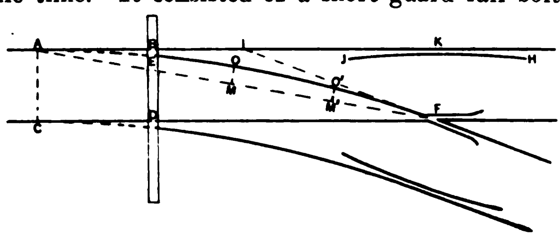


Fig. 67.—Diagram of Stub-Switch Turnout.

side of each moving rail and flared to cover the end of the stub rail, with an inclined plane bolted to the outside of the rail. With this arrangement wheels trailing the switch wrongly set would be caught on one side of the track by the guard rail and on the other side by the inclined plane and guided to place on the moving rails.

Measurements for Stub-Switch Turnouts.—A stub switch on straight track is shown by diagram in Fig. 67. $A B$ and $C D$ constitute the switch or moving rails; $B E$ is the throw; A or C is the heel; B or D is the toe or point of switch; AB is the length of switch; F is the point of frog. The distance from D to F is called the *lead;* from C to F, the *total lead.* The whole turnout from A to F is usually made a simple circular curve, as already stated, and in that case the point A is easily found by producing the line of the turnout rail of the frog straight ahead until it intersects the opposite rail at I. $I A$ must be equal to $I F$, because the two tangents from the same point to any simple circular curve must be equal. The formulas for the various measurements of a stub-switch turnout are simple and are given below. A geometrical demonstration of the same, prepared by the writer, was published in the Railway and Engineering Review for Dec. 31, 1897.

The distance CF—that is, the distance from heel of switch to frog point, or the "total lead"—is twice the frog number times the track gage, or $2\,n\,g$.

The radius of the center line of the turnout (r) is equal to twice the square of the frog number times the gage, or the total lead times the frog number. The formula is therefore $r=2n^2g$. The radius of the outer rail of the turnout curve is then $2n^2g+\frac{1}{2}g$.

The length of switch (AB) or the distance from heel to toe, in feet, is twice the frog number times the square root of the product of the throw and the gage, both expressed in feet [$2n\sqrt{(gt)}$]; or it is equal to the square root of twice the product of the radius and the throw in feet, or $\sqrt{(2\ r\ t)}$.

The length of the chord AF of the outer rail of the turnout is $g\sqrt{(4n^2+1)}$.

These formulas are easily understood and used by any person acquainted with common arithmetic. As an example, let us compute the distances from heel to point and the length of switch rail for a turnout with No. 8 frog and a switch with 5-in. throw. The distance heel to point$=2\ n\ g$ $=2\times8\times4.708=75.328$ ft. Length of switch in feet$=2n\sqrt{(g\ t)}=2\times8$ $\sqrt{(4.708\times{}^5/_{12})}=22.4$ ft.

If the toe of the frog or the beginning of the straight portion of the frog leg is taken as the end of the lead curve, the "total lead" for the stub-switch turnout then becomes $2n(g-k\ \sin\ F)+k\ \cos\ F$; and the radius, $2n^2(g-k\ \sin\ F)$; where k represents the length of the straight portion of the leg in advance of the point of frog, and F the frog angle.

Some trackmen line the outer lead rail quite well by the eye, but it can be located to the exact curve with but very little trouble by stretching a string from heel to frog point and laying off the middle ordinate equal to $\frac{1}{4}$ the track gage, and the quarter ordinates $\frac{3}{4}$ of this, or ${}^3/_{16}$ of the track gage. To be exact, the middle ordinate of the center line of the turnout is $\frac{1}{4}g$, and that of the outside rail slightly more; but the difference is not as great as ${}^1/_{16}$ in. in any case. In practice, however, in any turnout from straight track, regardless of frog number, the middle ordinate MO (Fig. 67) may be taken at $\frac{1}{4}g$, or $14\frac{1}{8}$ ins., and the quarter ordinate $M'O'$ at ${}^3/_{16}g$, $=10\frac{5}{8}$ ins. The middle ordinate of a chord drawn from E to F, that is from toe to frog point, is always 7 ins., and the quarter ordinate, $7\times\frac{3}{4}=$ $5\frac{1}{4}$ ins., for any length of lead or any frog number, where the main track is straight. Some use the middle ordinate of this chord in preference to the one from heel to point. Still another method of lining the lead curve is to lay the outer rail by offsets from the main-line rail to which it is tangent. The offset at the middle point (O) is $\frac{1}{4}$ of the gage ($\frac{1}{4}g$), at the quarter point it is ${}^1/_{16}g$ and at the third quarter (O') it is ${}^9/_{16}g$.

Originally the standard throw for stub switches was 5 ins., but for the heavier rails with wider heads which have come into service a larger throw is necessary in order to provide a flangeway of sufficient width. Where the width of the rail head exceeds $2\frac{1}{4}$ ins. the throw should be at least $5\frac{1}{2}$ ins. Table XI (see index) gives the necessary measurements for stub-switch turnouts with frogs of different angles, including the length of switch, for both a 5-in. and $5\frac{1}{2}$-in. throw. In connection with stub switch measurements notice should be taken of the fact that the length of switch corresponding to a throw of 5 ins. and a No. 11 frog, or frog of higher number, exceeds 30 ft.; and for a throw of $5\frac{1}{2}$ or 6 ins. the length of switch reaches 30 ft. with a frog of smaller number. For this reason it is not practicable to have the full length of free switch rail with frogs of the higher numbers (say No. 9 and above) unless rails longer than 30 ft. are used. In practice, not to exceed 25 or 26 ft. of a 30-ft. rail, or the length of switch corresponding to a No. 9 frog, would be left free. Hence the curvature of the switch must sometimes be made sharper than that of the lead.

In laying a turnout from curved track the lead distances may be taken the same as for straight track, for ordinary frog numbers, without noticeable error. If the turnout be *with* the curve (that is, from the inside of the curve), its degree, corresponding to a given frog number, will be increased, over that for straight track, approximately by the degree of curve of main track. If the turnout be *against* the curve its degree, corresponding to a given frog number, will be decreased, from that for straight track, approximately by the degree of curve of main track; and when the curvature of the main track becomes equal to that which the turnout would have in straight track, for a frog of given number, then the turnout becomes straight. In order to find the number of the frog required for a straight turnout from the outside of a curve of given degree, we may consider the straight track as the main line and the curved track the turnout, and then find the frog required for a lead curve from straight track equal in degree to that of the curvature given. In that case the radius and gage are given to find the frog number. From a previous formula we have $r=2n^2g$; from which $n=\sqrt{(r\div 2g)}$.

In lining the lead rails of turnouts from curves the middle and quarter ordinates of the outer rail are different from those used for leads from straight track. In Table XI there is a column giving the rate of change in the ordinate per degree of curvature of main track. When the turnout is from the outside of the curve the ordinate should be decreased at this rate, and when it is from the inside of the curve the ordinate should be increased at the same rate. This rate of change is found by dividing the ordinate for straight track by the degree of turnout curve for straight track which corresponds to the number of the frog used.

The length of switch in turnouts from curves is also practically the same as in turnouts from straight track. The length of switch, however, need not always be laid down to exact measurement, since it can be determined easily by trial, by throwing it first to main track and then to switch, backwards and forwards, as the rails are being spiked at the heel. Owing to the fact that some rails are stiffer than others, the switch will sometimes curve better if not made exactly the computed length, being lengthened or shortened by spiking less or more ties, respectively, as it seems to curve best to meet the fixed ends of the lead rails.

In turnouts from the inside of curved track the curvature of the turnout runs up pretty fast as the curvature of main track increases, and unless frogs of the higher numbers are introduced the limit is soon reached. Although freight cars and some switching engines may be successfully operated around curves as high as 60 deg. or more, the limit for ordinary locomotives, where guard rails are not used, is about 16 or 17 deg. So frogs of higher number than would ordinarily be used on straight track may come into use in turnouts from the inside of curves, but in turnouts from the outside of curves the reverse is true; that is, frogs of the lower numbers are brought into service.

57. Laying Stub-Switch Turnouts.—As a rule but few turnouts are put in when track is first built, and hence the work of laying turnouts usually involves tearing up the old track. A matter of importance in laying a turnout is to do it with a minimum cutting of rails. Where the track is laid with square joints and the frog is of such angle and length that it can go in, either behind two 30-ft. rails and make the proper lead distance, or else with one 30-ft. rail and a piece, so as to take up just 60 ft. and make the proper lead distance, a stub switch turnout can be put in by cutting only one main rail—that to make room for the frog. By the latter arrangement one rail additional must be cut for the turnout between switch and frog, while with the former it need not. The deviation of a few feet either way from the exact lead distance can be made without materially impairing the lead curve; still it is just as easy to make a frog of one angle as another, and it is of no consequence if the frog number be fractional. In standard practice the exact distances may be had as well as not, and by standardizing there is a saving of expense, as then fewer frogs need be carried in stock. This matter can easily be provided for by a little calculation. Suppose, for instance, that the frog is made a standard length of 10 ft. and that its point is 6 ft. from its heel and 4 ft. from its toe. Let the throw be 5 ins. Then if the frog be put in behind two 30-ft. rails, from the headblock, the lead distance will be 64 ft. and the frog angle corresponding to this lead, 5° 55′; the number is 9.67. If a frog of the same length from point to heel and toe was put in within the 60 ft., the lead distance would be 54 ft. and the frog angle required would be 7° 01′; the frog number corresponding is 8.16. Thus by making the frog of standard length each way from its point, a standard lead distance by something less or more than 60 ft., as the case may be, can be used by making the frog angle to suit this lead. One or both of the frogs calculated in this manner might be chosen as standard, both being about equally convenient for laying; say No. 8.16 where the shorter lead would answer, and No. 9.67 where the longer lead would be desired. The former gives a turnout curve of 9° 8½′, the latter 6° 30½′. To purposely make frog numbers integral, simply for the sake of it, is of no particular convenience. On the Chicago & Northwestern Ry. the scheme for avoiding the cutting of closure rails (the standard frog numbers with one exception being integral) is to vary the lengths of the frog legs to fit in with closure rails of standard length—24 ft., 28 ft. or 30 ft.—as explained in connection with the work of laying point switches (§ 69).

After the location for the headblock has been determined upon and the place to be occupied by the frog has been noted, the first thing to be done is to put in the switch ties, if such are to be used. If there is time between trains, the main-track rail on the frog side had better be taken up for 60 feet and the rail on the other side blocked up, in order that the old ties may be taken out without so much digging. In this way the ties may be changed in half the time required to dig between each two and take them out in the usual manner; besides, at least one rail on that side must be taken up anyway, to let in the frog. If there is not time between trains, one or two ties may be removed at a time, as opportunity offers, and replaced with switch ties, but such rails as must be taken up when the frog goes in should not be full spiked; on straight line, it is well enough to simply tack down part of the spikes, not driving them all the way down. Care should be taken not to dig into the beds of the old ties any more than will be sufficient to let in the switch ties snugly, as thereby much tamping can be avoided. If short ties (8-ft. ties) are to be used in the turnout, the first thing to do is to lay a guard rail opposite the place where the frog is to go in; and in any case the guard rail can be and should be laid before the frog is placed. If the rails on hand for laying the turnout are not suitable for use in main track, then the main-track rails must be taken up and cut. In any event, frog, guard rail and long switch ties, when used, go in first, and after these the headblock.

By using blocks of the same thickness as the headshoes, or slightly less, the headblock may be put in without the headshoes (splicing all joints in the rails) and be so left for any length of time, in case the work is interrupted at this point; but lead rails should not be spiked down until after the switch ties have been tamped to surface, the main track between switch and frog put in line and headshoes in place. When short ties instead of switch ties are used in the turnout, the track between headblock and frog should be put to surface, if not already so, before the short ties are laid.

The remainder of the work may be done in such order of arrangement as seems most convenient. Lead rails may be bolted together and to the frog, and lie in the track secured by tacking a spike on a tie near the toe of the switch, so that the loose end may not be swung around by any means and get in the way of the flanges of passing car wheels. Switch rods may be placed on the moving rails and the rails may then be partially spiked down again, if there is not time between trains to connect them to the stand and secure it. When this is done braces should be put down temporarily to keep the rail ends in place on the headshoes. Angle bars or fish plates placed endwise against the web of the rail and spiked to the headblock, through the bolt holes, and at the end, serve well for this purpose. The switch rods are driven on from the headblock end of the moving rails, blocking up the rails a tie or two back from the headblock and starting all the rods on together, if they are nearly enough of the same gage (as they should be) to allow it. The moving rails are then blocked up at their ends and the rods driven to place. There is no need of taking splices from both ends of the moving rails in order to get the rods on, or of pulling more spikes than to make free the proper length of switch rail. Switch rods should, as a general thing, be equally spaced; but after throwing the moving rails and trying a few times it is sometimes found that they can be changed to give the rails a better curvature than where all the rods are equally spaced; besides, the spacing of the ties will not always admit of even spacing of rods. Moving rails of stub switches should always be the full length of 30 feet, so as to avoid having a joint near the heel. If there is a piece of rail to go in on that side of the headblock it should be put in back of the moving rails. With the frog and guard rail in, switch rods on, and moving rails connected to the stand, in its place, the main-track part of the work is done.

Where track is laid broken jointed, more cuts must generally be made than where the joints are even. If the frog is No. 6, 7 or 10 it is generally better to locate the headblock underneath a joint on the side opposite the frog. With a frog of any other number it is usually better to locate the headblock under a joint on the frog side of the track, as by so doing, some cuts, to avoid putting in short pieces, will be saved. Where the headblock is located under a joint there will frequently be sufficient expansion space in the joints each way to close up some and allow room for the necessary opening between the rails at the headblock; if not, then a piece must be cut off, If hack saws are used, any length of piece can be taken off, but it is difficult to notch and break off a piece shorter than 3 ins. with hammer and track chisel. Whatever length of piece is cut off, there should not be left a clear space of more than ½ in. at the headblock, but the excess opening should be distributed among the joints each way. Where a rail must be taken out to be cut, so as to give more opening at the headblock, the moving rail should not be cut unless the end is battered. It is easier to take out one of the rails behind the moving rail. Ends of moving rails on headblocks should be directly opposite each other; that is, squarely across the track from each other; and no lip should be permitted to exist. Half fish plates are sometimes bolted to the ends of stub switch rails, to strengthen the web and prevent the end of the rail from being battered down. This practice was quite common when iron rails were used.

In setting a switch stand the connection with the head or neck rod should be made before the stand is secured to the headblock, and the moving rails should be in the main-track position, without lip. If the stand is then made fast and there is no lost motion, and the throw is right, there will be no lip when the switch is thrown to the turnout.

Lip is the lateral projection of a rail end at a joint; it is most bothersome and dangerous at the headblocks of stub switches. It may be caused between switch and lead rails by improper setting of the switch stand or of the headshoes; by improper throw; by wearing of parts in the stand or of the bolts in connecting joints; or by the switch rail becoming loose through wear in the head rod connection therewith. The remedy for the first cause is, of course, to reset the stand or headshoes. Oftentimes proper care is not exercised to make the gage at the stub ends of the lead rails in main track or turnout correspond with the gage between the ends of the switch rails. The best way to prevent improper throw—that is, a throw not corresponding to the movement required by the distance between the lead rail ends in the headshoes—is to inspect all switch stands and headshoes before sending them from the storeroom. Herein lies the value of having everything standard. Lost motion must be taken up. Sheet tin cut from old tomato cans comes handy to wrap around bolts or to put in bearings to take up lost motion, when bolts of larger size or new parts are not on hand. Rails loose in switch rods can be keyed.

Lead rails should be curved before they are laid; otherwise it is difficult to prevent them from twisting the headshoes around when attempting to spring a curve into them. Both legs or ends of frog rails are usually cut off at the same length, and as the turnout lead is 2 or 3 ins. longer than the main-track lead, where a frog is put behind two 30-ft. rails there will be an opening of corresponding length in the turnout lead. To avoid leaving the rails open at this point or cutting rails to close the space it is usual to fill the opening with a short piece of rail which trackmen call a "dutchman." The ends of all cut rails meeting at a splice should be drilled, so that all splices in both main track and turnout may be full bolted. By putting the cut ends of the rails into the headshoes the drilling of some holes may be avoided. To resist creeping as much as possible the splices between frog and switch and at all joints in the vicinity should be slot-spiked, and to permit this the switch ties must, of course, be spaced accordingly.

When laying a turnout it is well to bring to the site an assortment of spare pieces of rails if the same happen to be conveniently at hand. When such is done it is often the case that combinations of pieces can be selected which will save cutting rails. It is well for section foremen to keep a list giving the exact length of each spare piece of rail on the section, and the location of it. By a piece of rail is meant, of course, any piece shorter than the standard rail length. Every time a cut can be avoided there is a saving of time and usually some waste of material is avoided.

There are so many little details connected with the work of laying a turnout, and circumstances may vary so much, that it is not possible to describe the work except in a general way. Much must be left to the judgment of the foreman in charge. Shortly after a road has been built, when there are many turnouts to go in, and when many of the foremen are new and inexperienced, it is economy to select one or two foremen who are experts at laying turnouts, and give them crews of their own, to put in all the turnouts to standard requirements. In order to make fair headway, where trains must be dodged, the work must be crowded a little, at times; but unless men have had some experience they cannot do this. One or two crews engaged in laying turnouts soon become skillful at the work, whereas, if they are laid on each section by its own crew the men just begin to learn how when they get through, and that at the expense of the company, both in the cost and quality of the work. It is well to make up the extra crew or crews engaged at this work by taking a man or two from each section, for a few sections each way from where the work is being done. When not bothered much by trains, a good foreman and six fair trackmen can put in either a stub or a split switch turnout in one day of ten hours, including the removal of old track ties and putting in switch ties. The remainder of what is said concerning the work of putting in the different parts of a turnout is included under discussions of the several parts of a turnout as they are separately taken up.

58. Frogs.—A frog, of any of the kinds in general use, is made of four pieces of rail properly shaped and held together by some device or arrangement of minor parts. Figure 68 shows the principal parts of a rigid frog and the conventional names for the same. The pieces of rail *A B* and *C D* are called the *wings* or *wing rails.* The ends *B* and *D* are flared 3½ to 4 ins., in a length of 10 to 15 ins., to serve as a guard for the wheel flanges. The portion *H K L* is the *tongue,* it being usually about ½ in. thick or wide at the end *H,* and sometimes chamfered off about $^1/_{16}$ in. at the corners. The imaginary point *P,* where the gage lines of the frog intersect, is the *point of frog* or simply *the point;* the blunt end *H* is the *point of tongue* and not the point of frog; it is also quite commonly called the *half-inch point.* The

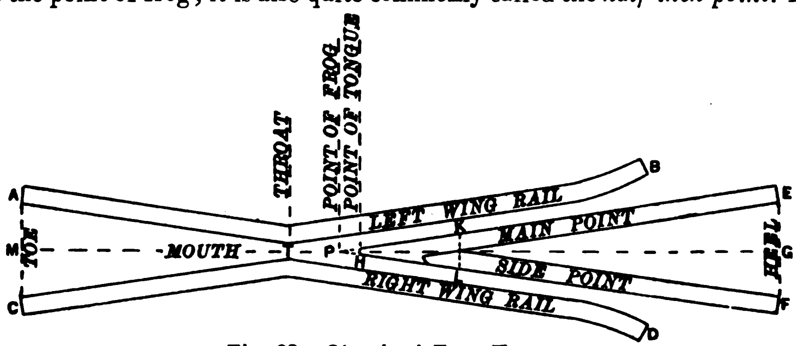

Fig. 68.—Standard Frog Terms.

ends *A* and *C* are called the *toe* of the frog; the ends *E* and *F,* the *heel.* The open portion *T,* where the wings are nearest, is called the *throat,* and sometimes the *knee.* The space between the toe and the throat is called the *mouth.* The spaces between the wings and the pieces *H E* and *L F* are the *channels* or *flangeways. H E* and *L F* are made straight and are called the *point* pieces; *H E* is the *main point* or *long point* and *L F* the *side point* or *short point. H E* is supposed to be used for the main track, and hence frogs made in this way are known conventionally as right-hand or left-hand, according as the side point piece is on the right or left side as one faces the point. The side point, however, is usually supported by the rail flange of the main point and used as a main-track or side-track rail indifferently, so that with rigid frogs it is not usual to make a distinction between rights and lefts. Some prefer to use the side point for main track, for the reason that if it is weaker than the main point it will receive severe treatment from the false flanges of badly worn tires, if placed on the turnout side.

In the process of the manufacture of the frog the point pieces should be planed down cold and not heated and forged. A dovetail joint between main and side point pieces is preferable to a straight joint without notching. The point pieces should be securely riveted together, through the webs, with not smaller than ⅞-in. rivets. In order to avoid drawing the temper of the metal the wing rails should also be worked cold, or heated no higher than is really necessary when they are bent. The bending should be to the arc of a small circle and not to a sharply defined angle. The throat is necessarily a trifle wider than the channels converging thereat, even if it is assumed that the wings are bent to an angle; this for the simple reason that the measurement of the throat is not made perpendicularly to the direction of either channel. As the wings are bent to an arc the throat must needs be somewhat wider still, and therefore appreciably wider than the channels. As it is sometimes necessary to find the point of frog it is a good idea, if the construction of the frog will admit, to indicate this point by a punch mark or by a cross cut with a cold chisel, on the filling or plate.

The angle of the frog is the angle $K\ P\ L$ or $E\ P\ F$. The *frog number* is the rate at which the rails forming the frog diverge in proportion to its length; it might also be correctly called the proportion of the frog. It may be found by dividing the distance from point of frog to heel by the spread at the heel, between gage lines ($P\ G \div E\ F$); or by dividing the length of the frog, over all, by the sum of the distances between gage lines at heel and toe, or on both ends—that is, $M\ G \div (E\ F + A\ C)$. Example: if a frog is 9 ft. long and the gage sides of the rails are 7 ins. apart at the toe and 5 ins. apart at the heel, then the frog number $= (9 \times 12) \div (7+5) = 9$. It is more usual to denote a frog by its number than by its angle, and the angle is usually made such that the proportion or number is an integral number, although there is no particular reason why it should necessarily be so.

A convenient way of ascertaining the frog number when no measuring instrument is at hand is to cut a stick the length of $E\ F$ and apply it to the distance $P\ G$. This distance expressed in lengths of the stick is, of course, the frog number. The number of a frog is 57.3 deg. or 3438 min. divided by the frog angle; or, conversely, the angle of a frog is 3440 min. divided by the frog number. Trigonometrically expressed, the number is half the cotangent of half the frog angle, or $n = \frac{1}{2} \cot \frac{1}{2} F$.

The established rule for finding frog numbers is as above stated. Nevertheless, some of the manufacturers consider the frog number to be the ratio between any distance on gage line and the spread at that point, as $P\ E \div E\ F$ (Fig. 68) or $P\ A \div A\ C$. This makes the frog number $\dfrac{1}{2 \text{ Sin } \frac{1}{2} F}$ (or practically $\dfrac{1}{\text{Sin } F}$ for frogs of ordinary angle). The difference between this value and $\frac{1}{2} \cot \frac{1}{2} F$ is so small that it is not worth taking into account.

Number 9 and No. 10 frogs are the ones in largest use in main track. In yards Nos. 7 and 8 are most frequently used, with No. 7 perhaps in the lead.

Rigid Frogs.—Frogs are of two kinds—rigid or stiff-rail frogs and spring-rail frogs. In a rigid frog all the parts composing it are supposed to be rigidly connected. The parts of both rigid and spring-rail frogs are joined together in three different ways: (1) by placing filler blocks between the pieces of rails and holding them together with bolts passing through the webs; (2) by riveting the flanges of the pieces of rails to a plate; and (3) by clamps or by clamps and wedges. Figure 69 shows a bolted frog; Figure 70, a riveted frog; and Fig. 71, a clamped frog, all being common types. Of the three ways the bolted frog gives the best satisfaction, if it is properly made. The base of the main point piece at and near its end should be planed to take a bearing on the flanges of the wing rails, as shown sectionally in Figs. 69 and 71. The base of the side point should, in the same manner, be planed to rest upon the flange of the main point piece, but unless the frog bolts are kept tight the support from these parts cannot be maintained satisfactorily, for the bearing is rapidly worn away after the parts get loose. Without some means of support independent of the frog bolts it cannot be expected to hold the tongue to place under load. In forming the point pieces the full web support should be carried to the extreme end of the piece. In order to do this it is necessary to bend the end of the piece sufficiently to bring the web over to meet the line of the planing. An example of such bending is shown by the broken lines illustrating the webs of the point pieces in Fig. 74. Additional support for the tongue should be obtained by shaping the channel filling to a snug fit under the head projections. The end of the tongue is sometimes made as thin as $\frac{3}{8}$ in., but seldom thinner. The end of the tongue, above the filling, is sometimes cut off to a sloping edge (Fig. 69) instead of a vertical one.

The bolted frog usually has 7 bolts. They should be 1 or $1\frac{1}{8}$ ins. in diam., according to the size of the rail, and the holes should be drilled perpendicularly to the axis of the frog; that is, perpendicular to the line *MG*, Fig. 68. The specifications of some roads require that the bolts of rigid frogs shall be set perpendicular to the main-line rail, but such increases

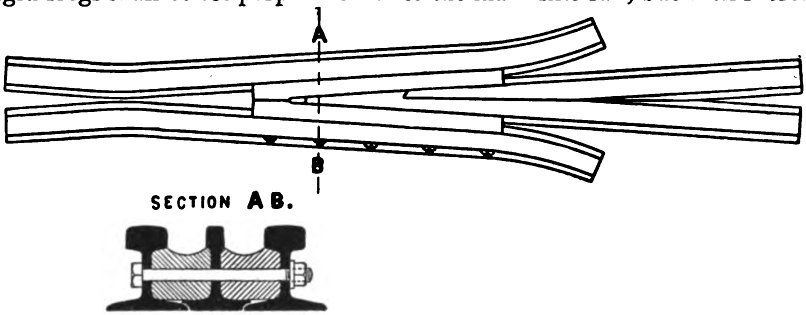

Fig. 69.—Rigid Bolted and Filled Frog.

their angularity with the turnout rail. The drillings for the bolts of spring-rail frogs are made perpendicular to the main-track rail or gage line.

Formerly the channel filling of frogs was made of cast iron, but wrought iron or rolled steel is preferable, and these are now the standard materials for this purpose. Cast filler blocks are sometimes made in one solid forked-like piece which straddles the tongue and fills both channels. The Elliot Frog & Switch Co. accomplishes the same end with wrought iron and steel filling by welding together the two pieces ahead of the point. Another method of forming solid filling, in practice to some extent, is to cast-weld it in place after the rail pieces of the frog are bolted together or otherwise assembled. The filler blocks should be machined to fit snugly between the rail pieces and they should extend from the flare of the wing rails to 6 or 8 ins. ahead of the point. Cast beveled washers are used to provide an even bearing for the bolt heads and nuts. The throat of a bolted frog should, for strength, be filled and bolted. Usually a 6-in. filler is placed at this point, but in Fig. 72 is shown a frog which has been used by the Lake Shore & Michigan Southern Ry. having a throat

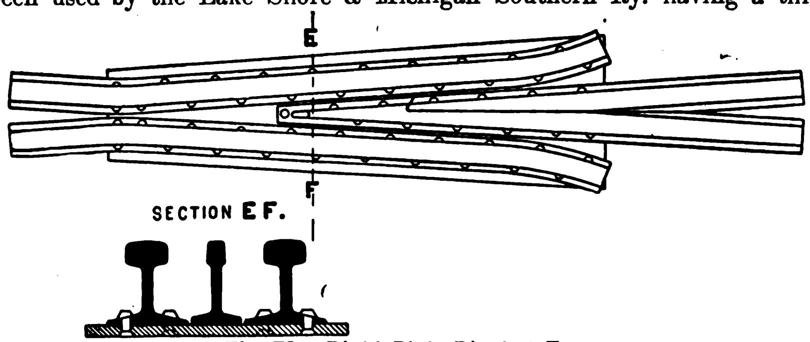

Fig. 70.—Rigid Plate-Riveted Frog.

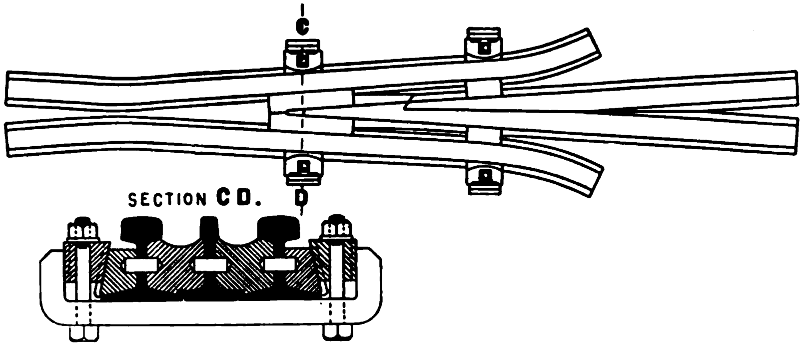

Fig. 71.—Rigid Clamped Frog.

filling block extending a sufficient distance into the mouth to serve the purpose of a foot guard. Blocks are also placed at the flare of the wing rails for the same purpose, the whole arrangement contributing very much to increase the rigidity of the frog.

The pieces of rail in a plate frog are secured to the plate by two rows of rivets, staggered, and sometimes countersunk on the under side. The plate used on different roads varies in thickness from $\frac{5}{8}$ in. to 1 in., $\frac{3}{4}$ in. being quite common. The plate should be at least 5 ft. long, and no wider than to allow for proper security in riveting, so as to discommode tamping as little as possible; for this purpose the plate may be cut with the long edges parallel with the wing rails (see Fig. 70) rather than rectangular. The rivets should be about $\frac{3}{4}$ in. in diam. Frogs constructed on tie plates, and other frogs which have tie plates riveted to them, are in use to some extent to prevent cutting into the ties. Either arrangement, however, can hardly be considered an improvement, for the separate tie plates when substituted for the ordinary large plate do not make so rigid a frog; and so far as the purpose of a tie plate is concerned, it is just as well, and perhaps better, not to attach the plates to the frog, since they may then be shifted

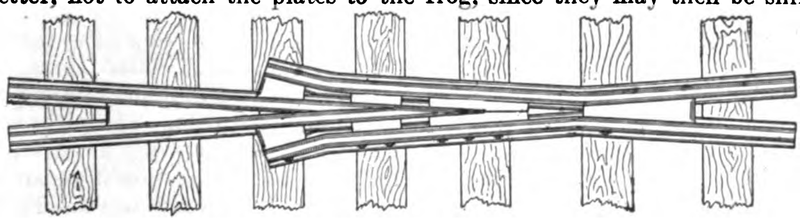

Fig. 72.—Frog with Mouth and Heel Filling, L. S. & M. S. Ry.

to suit the positions of the ties; otherwise the ties, if already laid, as in renewing a frog in an old turnout, might have to be shifted to suit the positions of the plates. As in other frogs, the point rails of plate frogs should be riveted together.

The pieces of rail in a clamped frog, also known as a yoked frog, are held in two ways: (1) by wedges which are driven against the web of the rail and held in the clamp by keys, or else by wedges which are held and adjusted by bolts (the better method) which draw them to a close fit, as in Fig. 71; and (2) by solid clamps or yokes which engage the frog rail pieces directly, by a close fit around the rail flange and against the web, the clamps being held to place by adjustable side rods that pass through the clamps and are made fast to the wing rails. One well known example of this type is the Strom frog, Fig. 73. The side or stay rods in this case hook around the ends of the wing rails. As the clamps wear loose they are driven on further and held against slipping back by following up with spring cotters on the rods. The fillings and wing rails are held against slipping by countersinking the heads of rivets into the fillings. No bolts pass through either the rails or filling pieces. Another frog of this type is the Ramapo yoked frog, Fig. 74. The yokes or clamps are adjustable by means of stay bolts extending parallel with the wing rails. The Weir clamped rigid frog has two steel clamps 4 ins. wide by 1⅛ ins. thick, and is tightened by means of two steel wedges. The filling blocks at each clamp (Fig. 75) are secured by a long through pin. But few claim to obtain satisfactory service from the clamped frog. The clamps work loose in spite of the utmost care to keep the wedges screwed or driven on tightly. In laying the frog the switch ties must be spaced to dodge the clamps or else they must be notched to let the clamps into the tie. It is not, therefore, a convenient frog to use where switch ties are already in or where another style of frog has been taken up, as some respacing of the ties is usually necessary. Clamped frogs have too many parts, are nearly always

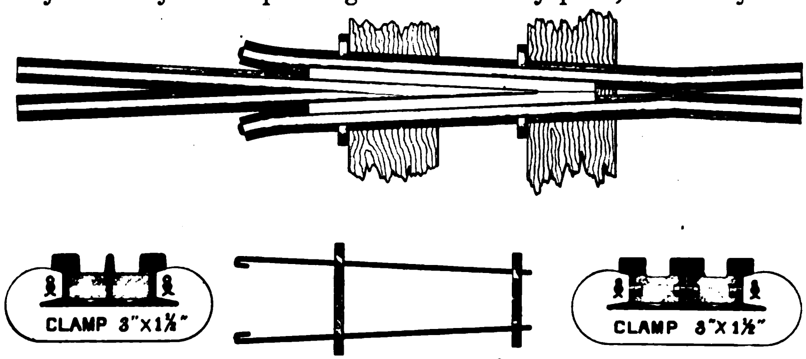

Fig. 73.—Strom Clamped Frog.

loose, and on general principles, really possess the least merit of any of the three forms. As expressed by vote in the annual convention of the Roadmasters' Association of America, in 1897, 29 preferred the bolted and filled frog, 9 the plate frog and 7 the clamped frog. A clamped frog is stiffened and improved by placing a clamp and filling block at the throat.

By combining the principal features of plate and bolted frogs, all weak points of both are overcome and a very stiff and durable frog is produced. An ordinary bolted frog is riveted to a steel plate. The plate will keep the tongue up to place and the bolts will keep the wings from working loose and shearing the rivets. This style of frog is now extensively used on roads where rigid frogs are preferred. As made for the Pittsburg & Western and Baltimore & Ohio roads, the wing rails are not riveted to the plate , but are held by the bolts only. The rivets which hold the frog to the plate are passed through the filling, as shown in Fig. 76. This arrangement permits the removal and renewing of the wing rails without cutting the rivets. One feature in the maintenance of plate frogs not to be overlooked is the fact that the plate does not wear out with the frog, but may be used over and over.

There is another device not answering exactly to the description of any one of the three foregoing types, known as the "U-plate" frog. It is made principally for use with rails not exceeding 60 lbs. per yard. The wing rails are bolted to the point pieces by means of heavy steel U-bars,

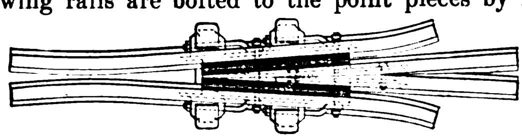

Fig. 74.—Ramapo Yoked Frog.

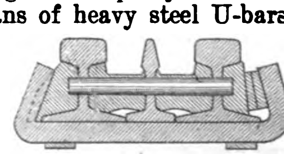

Fig. 75.—Weir Frog Clamp.

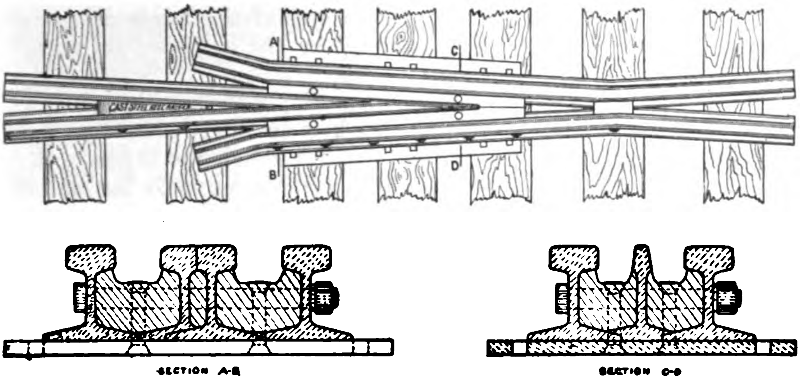

Fig. 76.—Combination Bolted-Plate Frog.

which are riveted to the point pieces each side; a U-bar is also placed in the throat. The arrangement is shown as Fig. 77. An advantage claimed is that a deeper channel is secured than could be had with ordinary filling blocks.

Rigid frogs of large angle are sometimes made with short pieces of double-headed wing or "easer rail" near to and opposite the tongue, so as to furnish a broader bearing surface for the wheel tread, and thus render cutting less severe. This double head is made by planing away the flange from one side of a short piece of rail and then bolting the piece to the wing rail. The space for a short distance between the two point pieces in rear of the tongue forms a place for the outside flange of badly worn wheel treads to spread the point pieces when running in the direction trailing the frog. To prevent this trouble the space is filled with a "heel block" or "heel raiser," as shown in Fig. 76. It usually consists of a short piece of rail planed to fit between the point pieces, so as to afford

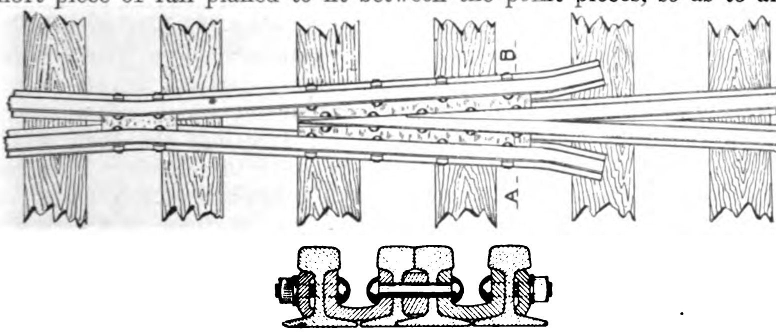

Fig. 77.—"U-Plate" Frog.

a bearing for the outer flange of guttered tires and carry it over without spreading apart the point pieces. The broad end of this piece of filler rail is sloped down so that an outside flange can mount it gradually. In some instances the short piece of rail planed down for the heel block is inverted, and in others a cast steel block extending far enough back to serve as a foot guard is used. In any case the "raiser" or "lifter" piece should extend back as far as the point where the combined width of block and rail head covers the reach of the engine tires. Heel blocks should be securely bolted through and through with the point pieces, as, being wedge shaped, the striking of "double flanges" tends to drive the block ahead and spread the point pieces apart. In some instances where trouble of this kind has occurred trackmen have taken the block out and thrown it away. The need of such a device is suggested by the fact that where it is not in service the inner top edges of the heads of the point pieces will usually be found chamfered off by the climbing action of the wheels.

Spring-Rail Frogs.—In an ordinary spring-rail frog the wing which takes the bearing of wheels on main track is movable, and, except when it is spread by the flange of a wheel passing through the turnout, it rests against the point pieces. With such a frog there is normally but one channel. As successive wheels pass between *D* and *H* (Fig. 78) the movable wing, or "spring rail," as it is called, is pushed aside by the flanges and returned to normal postion by the spring. As to the position of the spring which holds the movable wing against the point rails there are divers arrangements. A very common device is that shown in Fig. 78, consisting of a bolt *A-B* across the mouth of the frog, with a boxed spiral spring at either end. The objection to this arrangement is that the bolt or spring

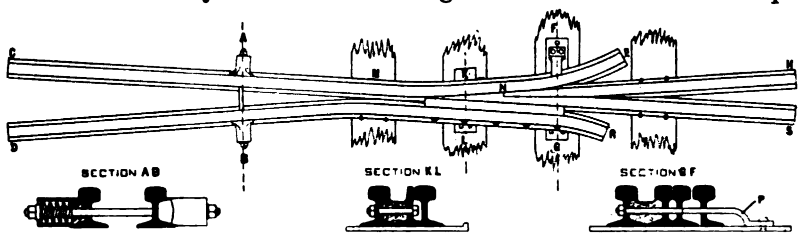

Fig. 78.—Ordinary Bolted Spring-Rail Frog.

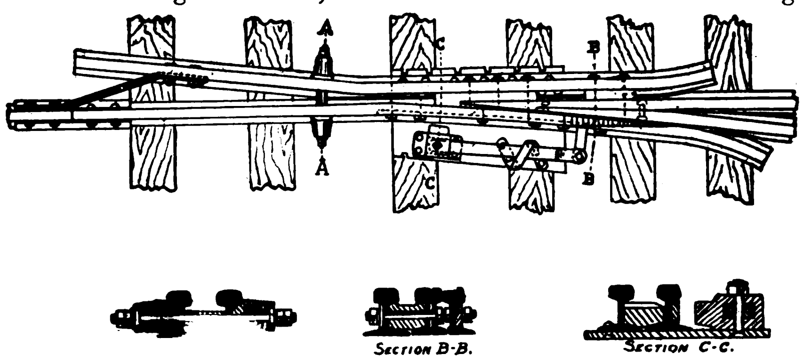
is exposed at both sides of the rail to the chance of being cut by a derailed wheel. A safer arrangement in this respect is had by placing the springs in the position shown in Fig. 83, with the spring bolt through the tongue (Section *C-D*), but it stands open to the objection that only a slight creeping of the rail will cause the bolt to bind and render one or both springs inoperative or unable to return the spring rail to its normal position. In the mouth of the frog the spread of the rails gives the bolt more latitude of movement in a case of creeping, and it is not so liable to bind. Another arrangement which is considered safer against derailed wheels than the one first mentioned is that of using a boxed spring which acts against the movable wing somewhere between point of frog and the heel, with no bolt through the frog. Figures 85 and 86 show this device. It is found most frequently, but not exclusively, with hinge-rail spring frogs. One style of Weir frog has both arrangements—that is, there is a spring bolt across the mouth of the frog and a boxed or housed spring at the heel bend of the movable wing. Any rigid frog can be used with a switch turning either to the right or left, whereas the same spring-rail frog can be used only with switches turning in one direction; hence frogs of this type must be made rights or lefts, as there is demand for them. A frog or



g Devices for Spring-Rail Frogs.

switch is right or left according as it will turn a car to the right or left when entering the turnout.

The spring-rail frog is much more durable than the rigid frog, as it presents a continuous-bearing main-track rail, and does not therefore allow the wheel to drop in the channel after trailing the point and cut into the wing rail at the outer edge of the tread. Its life is generally conceded to be at least three times that of a rigid frog. Spring-rail frogs of various designs have to a large extent taken the place of rigid frogs for main-line service and are now very generally standard. For the successful operation of spring-rail frogs three devices are recognized as particularly essential; namely, an anti-creeping device, a holding-down device and a reinforcement for the spring rail. In the frog of ordinary type the spring rail *C E* (Fig. 78) is secured to the main-track rail only by a splice at the joint *C*. A connection between the splice and turnout leg at this end of the frog is sometimes made by bolting a heavy bar or strap between the two, as shown in Fig. 79. The bolt holes of this strap match with

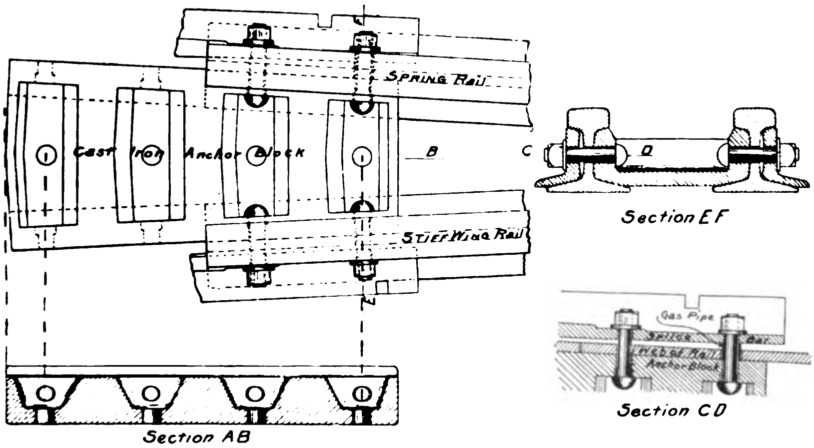


Fig. 80.—Cast Iron Anchor Block for Spring-Rail Frogs.

those in the splice, so that it is held by the heads of the ordinary track bolts. This connection holds the joint at the toe against being worked loose or spread by the action of the spring rail and allows of no creeping of that rail relatively to the fixed parts, which, if permitted to occur, would lock or bind some of the parts of the frog and restrain the freedom of action of the spring rail. Thus, for instance, creeping might cause the holding-down arms to bind so hard in their housings that the springs would not be able to bring the movable rail back against the point piece after being opened by passing wheels. There is also a danger element in unrestrained creeping, in that the binding action on the spring rail may be so intense that it will not spread for the wheels of empty freight cars trailing out of the turnout. In such cases cars have been known to climb the rail at the flare and go off the track.

Another anti-creeping arrangement is a cast iron anchor block bolted in between and through the two joints at the toe and spiked to the tie underneath. It is shown in Figs. 80 and 83. Another anti-creeping device is had by attaching the spring rail to one end of a parallel arm or link arrangement which is anchored to the frog plate, as shown in Fig. 81. One pattern of Weir spring frog designed for use in turnouts with Wharton switches has two links attached to the spring wing, one extending from its pivot toward the heel, as in Fig. 81, and the other extending from its pivot toward the toe, or in the opposite direction from that of the other. Owing to the unbroken rail at a Wharton switch the tendency of the main-track lead rail to creep in the facing direction is greater than is the case with a point switch, and the purpose of the double link arrangement is to afford a stronger resisting device and, also, by pivoting each link to stand at a small angle with the spring wing (that is, out of parallel with it), to always force the spring wing against the point pieces, no matter in what direction creeping takes place. In Fig. 82 is shown an anti-creeping device consisting of a link carried between two strong lugs in the mouth of the frog, one projecting from the spring rail and the other from the turnout leg.

In order to hold down the free end of the spring rail while wheels are passing a low joint at the toe, or prevent it from being raised by dirt or snow, or from being torn up by dragging brake gear, several devices are in use. That shown in Figs. 78 and 83 is common. It consists of a flat bar bolted to a base plate and passing through a slot in the web of the spring rail, beyond which it is attached to a bolt or is shouldered and drawn out into a bolt which passes through the rigid rails. Another device consists of a lug or plunger bolted to the web of the spring rail, and working into a holding-down cuff or guide box secured to the base plate, as shown in Figs. 81 and 82. This cuff permits some longitudinal play of the spring rail but no appreciable vertical play. Another form

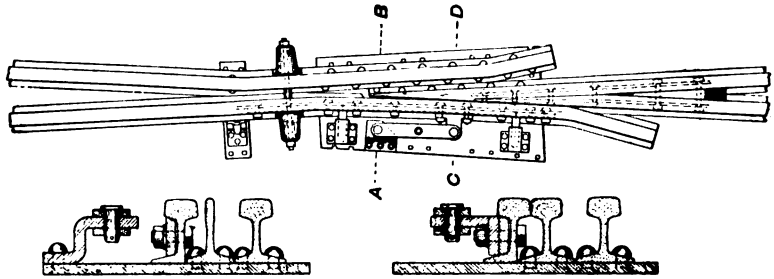

Fig. 81.—Link Anti-Creeping Device for Spring-Rail Frog.

of holding-down device consists of a narrow, flat plate riveted to the base of the spring rail and extended under the rigid rails; and still another consists of a heavy "monkey tail" strap bolted to the web of the spring rail at the end and twisted downward to extend under the rigid rails. This form of holding-down device for a plate frog is bolted to the web of the spring rail at the side, somewhere near the end, and is then bent around the edge of the plate to pass underneath. Figure 79 shows a combined holding-down and anti-creeping device which explains itself. The anti-creeping attachment to the splice at the toe is obviously not used with this frog, being shown in this figure only for the purpose of illustration. When two holding-down devices are used they are ordinarily placed opposite the point and heel respectively; when only one, it is placed near the heel. The spring rail is prevented from being opened too far by stops or rail braces secured to the base plate or by arranging the holding-down devices to answer as stops; these limit its movement to the width of the proper channel or flangeway. They ought to be placed opposite throat, point, and heel of wing rail and be so adjusted that they act together, all opposing any abnormal movement of the spring rail at the same time. Where tie plates are riveted to the base of the frog the ends of the same are sometimes split and a strip of metal half as wide as the plate is bent up at the proper distance from the spring rail to form a stop, as in Fig. 82 A. In some instances where enough stops have not been provided in the construction of the frog, ordinary rail braces have been used.

The flange of the spring rail, opposite the point pieces, must necessarily be cut away, so as to allow its head to rest against the head of the point piece. This trimming of the flange weakens the spring rail, and, for a long time a valid objection to the use of the spring-rail frog was that when the spring rail broke there was nothing to hold the broken piece in place, whereas in a bolted or plate-riveted rigid frog the broken piece is held fast. To guard against the probability of such danger all spring rail frogs of modern pattern have the spring rail reinforced by a heavy wrought iron strap or equivalent device bolted or riveted to the web. This strap is usually ¾ in. thick and is placed on the outside of the rail, but an additional strap about ⅜ in. thick is sometimes secured to the inside, thus reinforcing both sides of the web. The spring rail of the standard frog of the Chicago & Western Indiana R. R. is reinforced with a piece

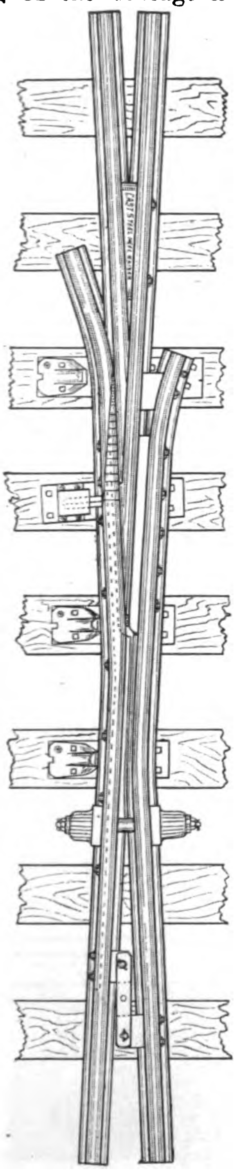

Fig. 82.—Frog with Link Anti-Creeping Attachment in the Mouth.

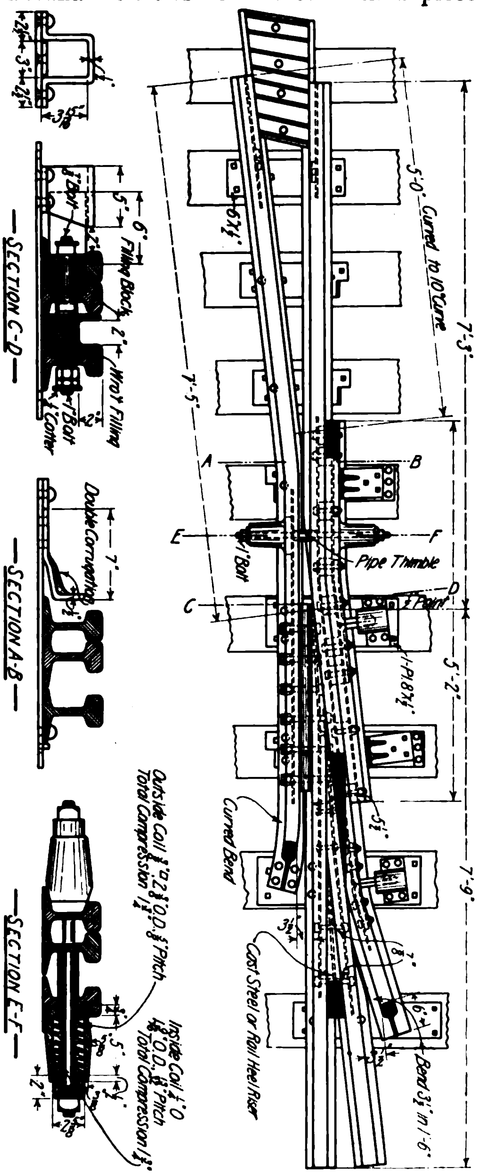

Fig. 82 A.—Standard Spring-Rail Frog, Chicago & Western Indiana R. R.

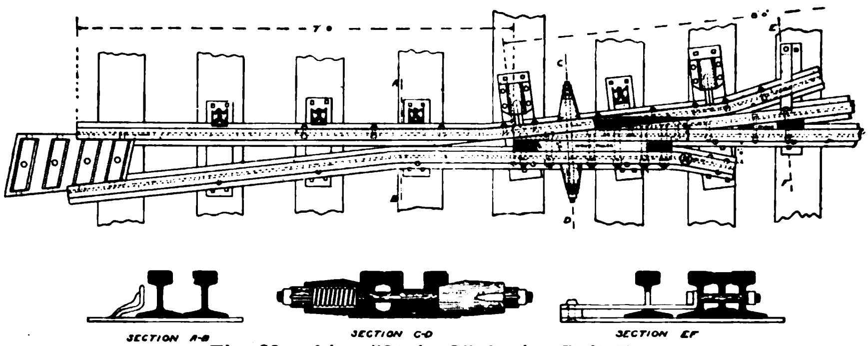

Fig. 83.—Ajax "Style G" Spring-Rail Frog.

of rail 5 ft. 2 ins. long planed to shape and bolted on with the heads touching and a filling piece between the webs. The middle of the reinforcing rail comes about opposite the point of frog. To prevent dragging parts from catching, the heel of the spring rail is cut off at a slope of 40 deg. with the horizontal.

The spring rail does not usually rest against the tongue (Figs. 79 and 81), but is flared out over a length of about 8 ins., so as to allow the wheel flange to pass the point, when entering the turnout, without crowding the spring rail over (at least to its full extent). This arrangement is calculated to relieve the guard rail opposite the frog of some strain. The loose end of the spring rail should be flared out gradually, so as to avoid sharp blows when it is set over by trailing wheels and prevent sharp wheel flanges from cutting into or mounting it. The usual flare, measured when the spring rail is closed against the point piece, is $3\frac{1}{2}$ to 4 ins., and the length of flare, 17 to 20 ins.; with the rigid wing the flare and length of flare are usually the same as in rigid frogs. The flare for this end guard should not begin until more of the side point piece than any wheel tread can cover has been lapped by the closely-fitting portion of the spring rail. Ordinarily this specification requires that the spring rail shall extend farther toward the heel than the fixed one, and it very much reduces the risk that the spring rail will be caught and opened by the outer edge of the tread of deeply worn wheels trailing the frog on main track. Nevertheless it does not alleviate the punishment of the spring rail by the cutting action of worn wheel treads. To provide against trouble of this kind it is necessary to channel or groove the head of the spring rail (*B-B,* Fig. 79) parallel to the main-

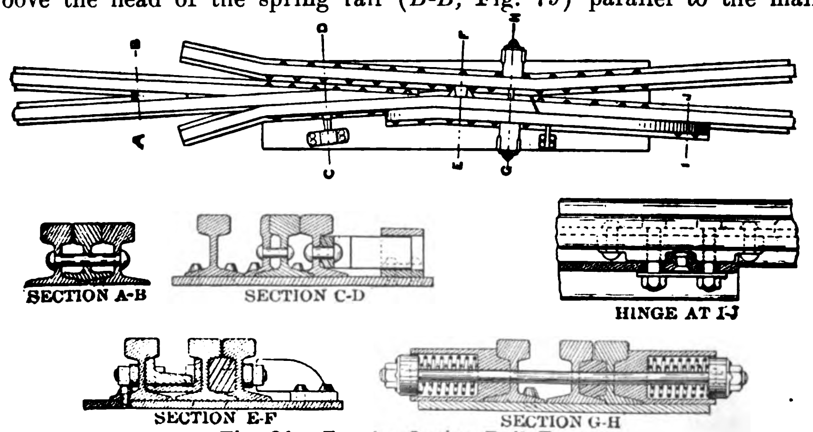

Fig. 84.—Eureka Spring-Rail Frog.

track gage line, and to such a width as will cover the reach of the outer flange of any badly worn tread. Another arrangement is where the spring rail is made to fall or drop away gradually ¼ or ⅜ in., say from the point *N*, Fig. 78. This inclination is accomplished by reducing the thickness of the plate under that part the proper amount, thus placing the endangered portion of the rail out of reach. An arrangement in vogue with the New York Central & Hudson River R. R. is to plane down the head of the spring rail on a slope from the point where the guttered tire reaches over the point piece to the free end of the spring rail, where the

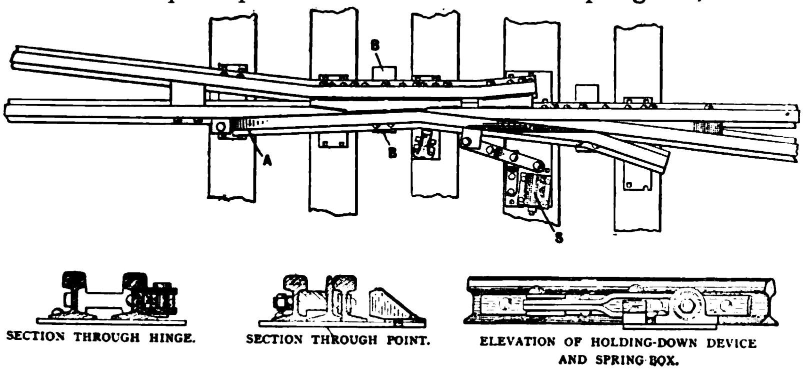

Fig. 85.—Frog with Hinged Spring Rail.

head retains about half its regular depth. The foregoing four features of design, namely the anti-creeping device, the holding-down attachment, the reinforcement of the spring rail and the grooving of the spring rail for worn wheels, should all receive careful attention in the selection of spring-rail frogs.

To avoid the necessity for special devices to prevent disturbance to the spring rail by creeping of the track, and to render the spring rail less dangerous in case of breakage, several designs of frogs have been brought out wherein a short spring rail is hinged either to a rigid leg or to the base plate opposite the mouth, or to the side point rail at the heel, thus removing it from the line of stress. All four ends of the frog are fixed, as in a rigid frog. In the Eureka frog (Fig. 84) the spring rail makes a miter joint with a fixed leg in the throat and is bolted to a piece of reinforcement rail which breaks this joint and is hinged at *I-J*, thus affording a double running rail. In the Weir frog of this type (Fig. 85) the spring rail is outside the gage line of the main running rail and is bent so as to

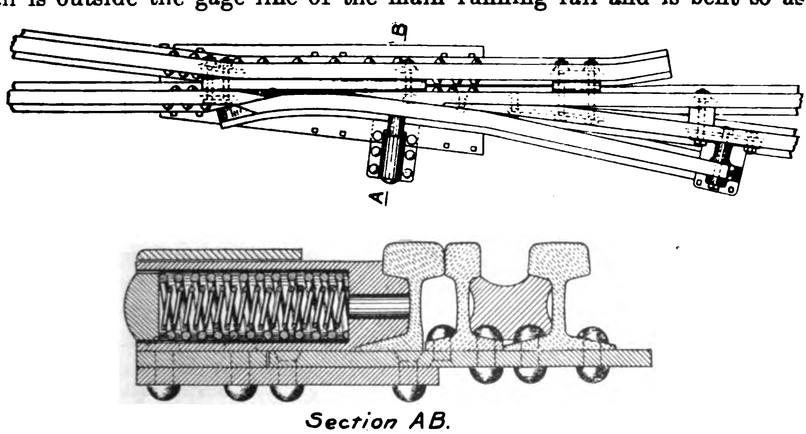

Fig. 86.—Vaughan Spring-Rail Frog.

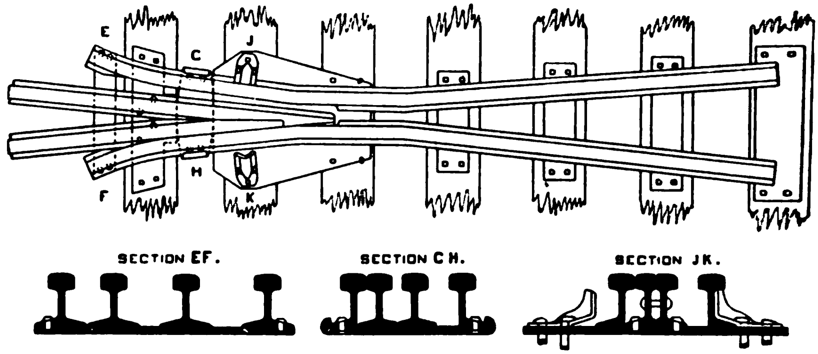

Fig. 87.—Wood Sliding-Rail Frog, Pennsylvania R. R.

project somewhat within the opening between the point piece and a rigid piece in the main running rail. It is hinged at *A*, and held up to the point piece by a spring *S*, acting reversely to the usual direction on the shorter arm of a pivoted lever, which effects a reduction in the compression of the spring. One of the holding-down devices is shown at *B* and consists simply in a plate riveted to the base of the spring rail and projecting under the rigid portion of the frog. There is a similar device at the flare of the spring rail. In another style of Weir frog the holding-down plate is of similar design and works through a guide riveted to the under side of the main point piece. The filling between throat and point is of steel and arranged to hold up and guide the wheel flange, even though the spring rail was broken or entirely removed. The Vaughan frog, shown in Fig. 86, is quite similar to that just described. The spring rail is hinged at the heel, however, instead of at the mouth, and is not bent so sharply

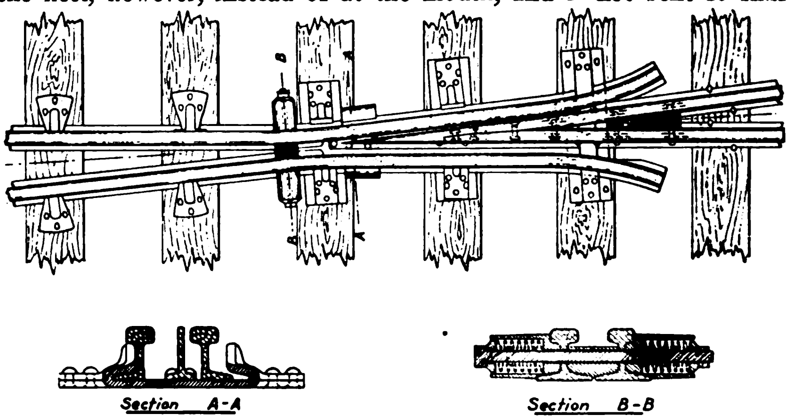

Fig. 88.—Vaughan Sliding Spring-Rail Frog.

opposite the point of tongue. The filling block is arranged to carry the wheels, in case of accident to the spring rail, as in the other case, and it has a rib fitting under the head of the spring rail.

Promiscuous Designs.—A good deal of attention has been devoted to frogs of special design for yards, or for the junction of two tracks both of which carry heavy traffic, the object in view being a continuous-bearing rail for trains moving over the frog on either track—main or turnout. The Wood frog, shown in Fig. 87, is one of the oldest of this type. The point pieces are made rigid or fast to the plate. The wing rails are rigidly attached to each other, but not to the plate, so that either wing rail may rest against the point rails, according as it is moved to position by the crowding of the last wheel flange which passed against the opposite wing rail. There is no spring and, the wing rails being held rigidly together by base clamps at *C-H* and *E-F*, the point rails thus act as a stop for them. This frog is intended for use in yards, where speed is slow and the turn-out side of the frog is more frequently used than is the case with most frogs on main line. It was designed by Mr. Joseph Wood, an engineer of the Pennsylvania R. R., and has been used for many years on the United Railroads of New Jersey division of that road. The design is open to the objection that the automatic setting of the wing rails, when not in place for a wheel approaching in the facing direction, takes place with the weight of the wheel on one of the wings. The movement of the wings under load must therefore be attended with much friction. Moreover, should a bolt, a nut, or any piece of iron drop from a passing train into one of the channels of the frog, the wings would be rendered immovable and serious consequences might follow, to both the frog and the train. To accomplish the same purpose, namely, to produce a frog with double spring rails which do not open and close at the passage of every wheel or truck over the frog, there is a design known as the Vaughan sliding spring-rail frog (Fig. 88), in which the two movable wings, instead of being rigidly attached to each other, are spring connected in the usual manner. These spring rails are separated by a spacing block on the spring bolt a sufficient

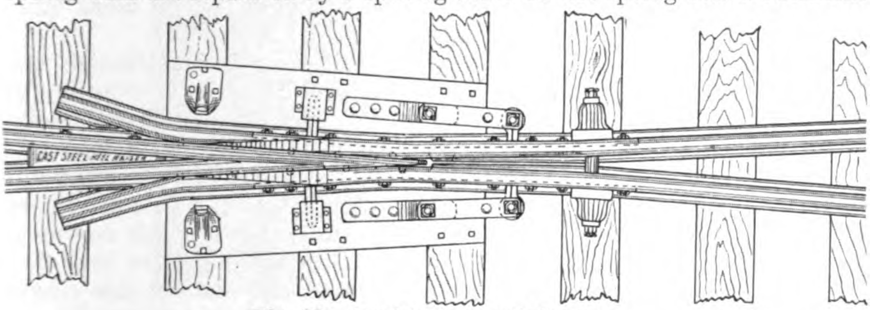

Fig. 89.—Double Spring-Rail Frog.

distance to maintain an open flangeway in the track in use, the flangeway in the unused side remaining closed. In case wheels passing over the frog in the facing direction run through the closed flangeway, the closed wing is forced open, compressing the spring, as in the ordinary action of spring-rail frogs, the movement of the other wing rail follows, as soon as it is released from load, and the frog then remains set for that route. When the frog is set by trailing wheels both wing rails are moved to place simultaneously, without bringing the spring into action. Both wings are backed by proper stops, and should one of them be blocked by any object falling between it and the tongue, the other wing, being retained only by springs, is allowed to move; hence the objectionable feature consequent upon attaching both sliding wing rails rigidly together is removed. The Douglass double spring-rail frog is a plate frog of substantially the same construction operating in the same manner.

Of double spring-rail frogs which open and close at every passage of a wheel or truck there are a few examples in service. The frog shown as Fig. 89 is of substantial construction, with heavy link anti-creeping attachments on both wings, and either wing acts independently of the other. The Eureka double spring-rail frog operates on the same principle, being of the same design as that illustrated by Fig. 84, except that the movable wing rail is duplicated on the other side of the point. A double spring-rail frog (Fig. 90) in use on the Michigan Central R. R., designed by Mr. O. F. Jordan, formerly roadmaster with that road, has wing rails rigidly secured at both ends. At the toe the wings are spliced to the lead rails in the ordinary manner, while at the other end of the frog they extend 2½ ft. past the heel of the point pieces and are securely bolted to the fixed main and turnout rails through filler blocks 8 ins. long. The flare at these blocks is the usual 4 ins., and the wing rails, which are 19 ft. long, are bent to rest normally against the point pieces by the action of their own spring. Ordinarily the elasticity of the rails themselves is sufficient to hold them to place, but to provide against accident they are reinforced at the mouth by a spring bolt. The pressure of the wheel flanges opens the wing and the width of flangeway is limited by stops

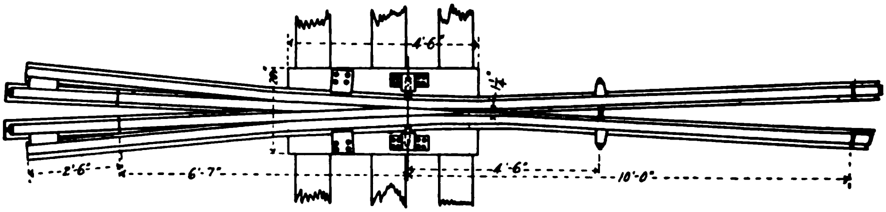

Fig. 90—Jordan Double Spring-Rail Frog, Michigan Central R. R.

secured to the base plate to which the point pieces are riveted. Vertical movement of the wing rails is restricted by hold-downs of the usual form. This frog is used only in yard tracks.

None of the foregoing double spring-rail frogs is in extensive use. They are rather expensive for general yard service, and the propriety of placing at the end of double track, or at the junction of two main tracks, where high speed is made, any frog with movable parts to be automatically set by the train is certainly questionable. As a matter of fact spring-rail frogs of any description are used but little in yards. In such places the speed is necessarily slow and the spring rail is not so much needed as it is in main line, and then there is also the forcible objection that they cannot be blocked as effectually as rigid frogs, and are for this reason a greater source of danger to brakemen in getting their feet caught. It is also proper to remark that spring-rail frogs are not considered as safe in the outside rail of curves as are rigid frogs, for the reason that the yielding wing throws all the duty of guiding the wheels between toe and point upon the guard rail; with a rigid frog this duty is imposed only while the wheels are passing between throat and point.

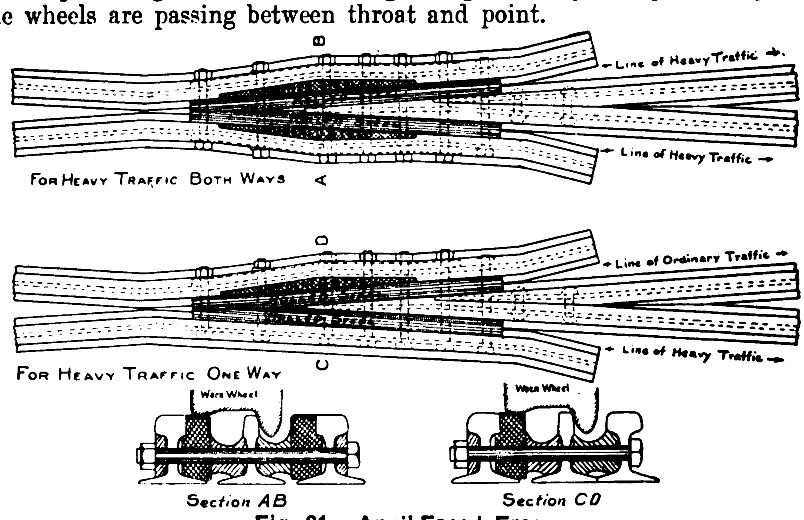

Fig. 91.—Anvil-Faced Frog.

For service under heavy traffic there is a rigid frog with hardened steel parts to take the bearing opposite the point, where the wear is usually most rapid. This frog, known as the "Anvil-Faced" frog, is in use on a number of roads, the Pennsylvania, the Southern and the Lake Shore and Michigan Southern, among others, and is illustrated by Fig. 91. The upper engraving shows the design for heavy traffic over both tracks, while the lower design is intended for heavy traffic on only one track through the frog. The frog is constructed in the ordinary manner, the space for the hardened portion being provided for by bending the wing rail around it. A frog with wearing parts of manganese steel is described in §214.

On some of the English railways trial has been made of frogs with hot-pressed flangeways. In the Tyler & Ellis frog (made by the Tyler & Ellis Mfg. Co. Ltd., at Peterboro, Northamptonshire, England) the main rail through the frog is continuous, the flangeway for the turnout being formed by heating the rail and pressing it into the head by hydraulic machinery. The metal displaced is not cut away, being forced downward to strengthen the web. Some of these frogs used on the Great Northern Ry. (England) are reported officially to have given fairly satisfactory results. They are in use on some of the railways of South

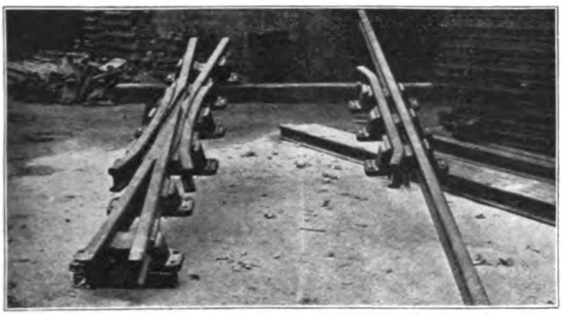

Fig. 91 A.—Split Twin-Rail Frog, Midland Ry.

America, and they have been tried experimentally on the Pennsylvania R. R., in West Philadelphia. Another method of manufacturing frogs, designed by the well-known railway engineer, Mr. Price Williams, in co-operation with Mr. E. P. Martin, equally well known as an iron and steel manufacturer, is worked by the Railway Switch & Crossing Co., Ltd., 15 Victoria St., Westminster, London, England. The frogs are known as "split twin-rail crossings," the four legs being formed by splitting up the ends of a rail rolled double the usual width, by sawing, and opening out the two halves of the same to form the frog angle. Figure 91 A shows an ordinary frog made by this method of rail-splitting. After opening out the split ends of the rail, grooves are planed out for the flangeways, and wing rails bent to proper shape are then clamped on. The four legs of the frog and the tongue are therefore one solid piece, and there can be no "ducking" of the point under traffic. As will be noticed, both the frog and guard rail shown are assembled by means of cast chairs, with tightening wedges driven against the web of the rail. Double-pointed crossing frogs are made by the same process (See Railway and Engineering Review, Feb. 23, 1901). The Midland Ry. (England) is one of the roads on which these frogs are in service.

Some Features of Frog Design.—The usual practice in making frogs has been to cut off the legs, at toe and heel, evenly. This arrangement brings the two splices at each end of the frog directly opposite, and unless the point pieces in frogs of small angle are of unusual length there is not room enough inside the rail ends for two angle bars, to splice the joints, so that fish plates must be used or else the bottom leg of one of the angle bars must be cut away. The same kind of interference occurs at the toe of short rigid frogs. This trouble may be avoided by making one point piece and one wing rail each longer than its mate by the length of a splice bar, as in Fig. 92. I have seen this plan carried out in practice, with good results in more ways than that just stated. To further discuss the advantages of the arrangement it need only be said that the principle of breaking joints is of universal application in engineering practice. Nothing lies in the way of standardizing frogs designed on this plan. If the angle of the frog was computed with the idea of laying the frog in one of two ways relatively to two 30-ft. rails in main track, as heretofore discussed, a piece of rail of fixed length, less than 30 ft. (or whatever standard rail length) by the amount one wing rail is longer than the other, should go with the frog to be put in main track or turnout, according as the frog is to be used as left or right. Since spring-rail frogs can be used but one way, the rigid or turnout leg should always be cut off enough longer (about 2 ins.) than the main or movable leg to make up for the increased length of the turnout lead over the main-track lead, thus making it

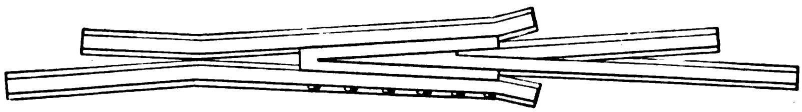

Fig. 92.—Frog with Unequal Legs.

possible to square the joints at the headblock or heel of switch without extra cutting or by using a short piece of rail ("dutchman"). The frogs shown as Figs. 82A and 83 are made in this manner, and the practice is now standard with a number of roads. With spring-rail frogs, also, the turnout side should be curved to fit the lead corresponding to the number or angle, thus avoiding the necessity for a short stretch of straight track in the turnout at the frog. If the leg of the frog is long enough that portion can be sprung to the curve, but it might just as well be curved when the frog is made. An example of this practice of curving the fixed wing of a spring-rail frog is shown in Fig. 82A.

A good deal might be said on the question of the proper length of frogs, particularly rigid frogs. As the wear of rigid frogs under heavy traffic is rapid, it is an old and familiar text that it is a waste of material to make the legs longer than is required to obtain the necessary spread for splicing; hence 9 or 10 ft. has been the customary length of rigid frogs. It should be understood, however, that the length of the frog has much to do with the conditions of wear. When the wing of a frog not longer than 10 ft. gets loose there is then in the track a pretty short piece of rail to flop up at the passage of every wheel over the toe. A frog made of long pieces is not so soon loosened under the jar of the traffic as is one made of short pieces. Rigid frogs should be at least 12 ft. long and a length of 15 ft. is much better. The Chicago, Rock Island & Pacific Ry. uses in main track rigid frogs of plate-riveted pattern 15 ft. long. The Chicago & Northwestern Ry. has standard rigid frogs 17 ft. and 20 ft. 1 in. long (Fig. 157A). The worn parts of a 15-ft. rigid frog will still make a 10-ft. frog for use in yards or side-tracks. The most frequent length of spring-rail frogs, up to No. 10, is 15 ft. The length of spring-rail frogs of higher number is usually greater. With the Pennsylvania R. R. the standard toe-to-heel lengths corresponding to No. 10, No. 11 and No. 13 frogs are 15 ft., 18 ft. and 20 ft., respectively.

The standard width of channel for frogs is $1\frac{3}{4}$ ins. If proper attention be paid to the gage of the track and of the guard rail, this width allows plenty of room for wheel flanges. One object in restricting the width of channel or flangeway to the actual requirements is to so constrain the wheel that its tread reaches as far as possible over the wing on the opposite side of the tongue, thereby increasing the bearing surface. As between channels $1\frac{3}{4}$ ins. wide and $1\frac{7}{8}$ ins. wide, on a No. 9 frog, say, the wheel tread is constrained to follow the wing rail in the former case $1\frac{1}{8}$ ins. farther than might occur in the latter case, and the bearing for some little distance is $\frac{1}{8}$ in. wider. Increase in width of channel or flangeway increases the length and width of the open spaces behind the gage lines, between the point of tongue and the throat, on both sides of rigid frogs and on the turnout side of spring-rail frogs. A recognition of this principle is shown in one of the designs of the Elliot company, known as the "Main Line" frog, in which the flangeway for the turnout is considerably narrower than the one for main track, thus affording all possible bearing for the wheel tread in the vicinity of the point. To refer again to the matter of flaring the guard ends of the wing rails, it may be said that the method of making the flare by beveling off the side of the rail head is rather too abrupt, and not as satisfactory as that of bending the end of the rail to make the flare.

Frogs should be designed and constructed to standard specifications, so that like parts of frogs of the same number and pattern will be interchangeable. Before specifications are finally adopted, however, they should be put to the test of making a frog and be submitted for the criticism of the frog maker. In this way slight modifications may sometimes be suggested which will improve the design. It is well to have a care about being too rigorous with the minor and unimportant details. A case in point comes to mind where the engineers of a certain road had spent a good deal of time preparing an elaborate set of specifications, which covered all such minute details as the exact location of every bolt and rivet, and other folderols, and before testing their correctness they were printed in pamphlet form. When the manufacturer came to make the frogs he found bolts which interfered with others and with hold-downs, and the workmen found other incongruities. It is not always important that bolts and rivets should come in just such and such places, but it is important that all frogs of the same designation should be made alike. To this intent the specifications may point out the dimensions wanted and should require a certain uniformity of parts and interchangeability. Of course it is necessary that the drilling of the main bolt holes in different frogs should correspond. Details not concerned in these requirements may then be left to the frog maker. In a general way the same principles of design apply to the specifications for split switches. Table XII is submitted as an

15	12'-0"	9'-8"	8'-0"	13'-0"	16'-2"	20'-0"	8

example of the dimension features of a set of specifications for the spring-rail frogs of a certain large railway system. These specifications cover frogs made from 60-lb., 70-lb., 85-lb. and 100-lb. rails.

The advantage of interchangeable parts is that spare pieces may be kept on hand for the repair of broken ones or ordered to replace worn parts. Thus, the point pieces of a rigid frog will outlast the first set of wings, and to get all the available wear out of these frogs the worn wings may be exchanged for new ones, or the worn wing of a frog in a turnout to the right may be exchanged for the unworn wing of a frog in a turnout to the left. With bolted and clamped frogs such exchanges may be made in the track, but plate-riveted frogs require to be sent to the shop. In the former case it is usual to have a spare frog on hand to put down in the place of one of them between which an exchange of wings is made, but where such is not the case and wings are to be exchanged at a distance, the switch may be spiked at some favorable interval between trains and a short piece of rail spliced in temporarily to take the place of the frog while the transfer is being made. When repairing frogs by changing the wings it is sometimes necessary to shim up the worn point. Interchangeable wings for crossing frogs are referred to in connection with the subject of crossings.

As frogs must undergo unusual service the material used in making them should be first class; nevertheless they are frequently made from rails of second quality. Rails not quite up to standard size in width or depth of head or in total hight of section should obviously not be selected for frog material; likewise rails with such defects in head, web or base as might affect the strength.

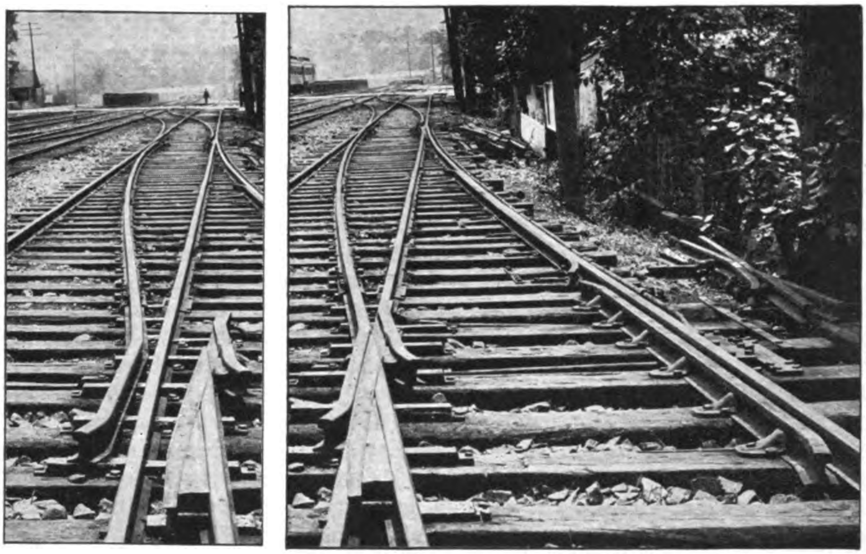
Laying Frogs.—With 1¾-in. flangeways through the frog there will be no trouble from wheel flanges striking the wing rails, providing the frog is laid to exact gage. Some trackmen are always apprehensive of spiking a frog to gage, even on straight track, but there is no necessity for fear in this regard; indeed if there be any cause for anxiety it should be rather for not laying the frog to gage. The nearer the frog is spiked to gage, the less severe will be the blows of the wheel flanges on the wings. If the wing is struck heavily by wheel flanges the spikes holding the frog are usually spread, and accordingly some will brace the frog wings with rail braces; but this it not the proper thing to do. When the wings are being severely used it indicates that the frog is out of gage, and the proper remedy is simply to put it in gage. On this point there are some inconsistencies of practice. The rules of some American railroads require that the gage of both tracks within the limits of the turnout (point of switch to heel of frog) shall be ¼ or ½ in. wider than standard, and that outside of these limits the gage shall be narrowed to standard in a distance of 30 ft. in each direction. In tracks where there are several switches in succession or close together, as in the ladder of a yard, the widening of the gage is maintained throughout, or past all of the switches and frogs. On the other hand, it is extensively the practice on English and European roads to lay frogs and switches and the track intervening ¼ in. tight for gage, the idea being to prevent lateral play of the wheels and steady the motion of the trains past the turnouts.

The way to lay a frog is to first splice it to the main-track rails at toe and heel, spike the heel to gage for main track, and then do the same at the toe; then spike it to gage at a point about 6 ins. back of the point of tongue and drive the remaining spikes straight down without using the gage. A clamped or bolted frog spiked only at the heel and toe can usually be sprung a little at the point, in case it is not exactly straight;

or, if the frog is long enough, it may be sprung to an easy curve, if desired; but with a plate frog or any short frog made of rails of heavy section this cannot be done. In laying a plate frog it is not necessary to adz down the switch ties to make room for the plate, but let the plate rest on the tops of the ties; then when spiking the turnout rail opposite the frog, spring the ties up to it. A frog when first put in is all the better for being the thickness of the frog-plate high. In laying frogs care should be taken to leave the proper allowance for expansion at the joints at each end of the frog and for several joints in the adjoining rails. The angle bars should then be slot spiked at all these joints, so as to hold, as well as may be, against creeping. As the frog forms part of two tracks it should be in line with the turnout lead and the side-track rail beyond the frog, as well as with the main-track rail, but where the rails creep badly it is difficult to maintain this condition at all times; hence the necessity for frequent readjustment. The ties under the spring rail, particularly, should be evenly surfaced, so that the rail will be evenly supported and slide evenly on its plates.

The question of widening the gage on curves, already discussed, has to do also with frogs. A frog on the inside of a curve gets the worse for widening the gage, and there is no remedy, for the wheel flanges will continually be pounding the inside wing rail and breaking the frog bolts or loosening rivets or some other parts. The cause is clear. A reference to the M. C. B. standard frog and wheel gage (Fig. 96) will show that when standard-gage wheels are running on standard-gage curve and the flange of the outer wheel is crowding the rail, the back of flange of the inner wheel will reach over just 1¾ ins. from the gage side of its rail; hence it cannot strike hard against the inside wing rail of any frog spiked to gage, unless the flange of the outer wheel be badly worn. If, however, the gage of the track at this point be widened, one of several things must happen: either by the amount the gage is widened, by just so much must the channel of the frog be made wider than standard; or by just so much must both wheels be jogged over by the wing rail; or by just so much must the frog be jogged over under the wheels, unless the wing is loosened or the bolts broken; or else the sudden jar against the inside wheel must spring the car axle. The last named effect must at least subject the axle to much strain. It would certainly be interesting to know just what proportion of broken car axles is due either to improper gage at such points in the track or to improper gaging of the wheels. Of course, it is not usual to find a frog on the inside of a heavy curve; but suppose the gage is widened ½ in. and there is a frog on the inside of the curve. Then, unless the channel of the frog be widened to 2¼ ins., the front pair of wheels of every car truck passing that frog will get a jog sidewise, which in turn must jolt the car. Neither are conditions much more favorable to frogs on the outside of curves. Bolts in bolted frogs will be broken notwithstanding the widening of the opposite guard rail flangeway, because the rear wheels in each truck will seek the inner side of the curve, and if the gage at the frog be widened, such wheels will run that amount nearer the inside rail of the curve and strike against the wing rail of the frog. Such effects must certainly be telling upon rolling stock, and the time will come, no doubt, when more railway men will be brought to a realization of the fact that standard-gage track means standard-gage curve. The evil effects of widening the gage of track on curves have long been seen. Indeed, in years past it has been the practice of some roads to tighten the gage ¼ in. at frogs on the inside of curves, so as to provide against blows to the wing rail by wheels with worn flanges.

Effect of Guttered Tires.—The life of frogs of any type depends to no inconsiderable extent upon the vigilance of the mechanical department in maintaining the locomotive tires in good condition. The manner in which damage may occur from deeply worn wheel treads has already been pointed out in connection with features of frog design intended to provide against the same. No frog is well designed without a heel raiser, and in spring-rail frogs the grooving of the movable wing is an essential, but the question then arises as to how deeply this wear of the tires may be permitted to go before these devices will fail to give the desired protection. The heel raiser protects the frog against spreading of the point pieces by the false flanges of guttered tires, but it does not protect it against heavy blows from the same or prevent the wearing down of the side point. Abnormal wear to the wings of rigid frogs caused by badly worn tires cannot be prevented. For such reasons it is usual to set a limit upon the allowable depth of rut in locomotive tires; and this limit is quite liable to be



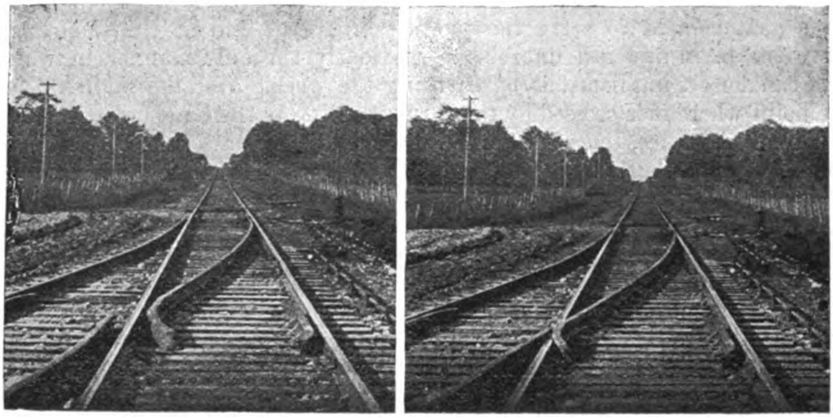
Set for Main Line. Set for Siding.

Fig. 93.—The Price Frog.

a compromise of the views of the track and motive-power departments, for the trouble and expense of frequently taking locomotives into the shops and turning down the tires is considerable. In 1891 the New England Roadmasters' Association recommended $^3/_{16}$ in., and in 1895 the Roadmasters' Association of America recommended $\frac{1}{4}$ in., as this limit. As to standard rules on this matter various railways seem to stand about evenly divided for $\frac{1}{4}$ in. and $\frac{3}{8}$ in. as the limit, but unless the roadmasters are watchful even the higher limit is liable to be exceeded in service. Some railways place the limit at $\frac{3}{8}$ in. for freight engines and at $^5/_{16}$ in. for passenger engines, but both are too high. The limit for passenger engines should not exceed $^3/_{16}$ in., and for freight engines the limit should not exceed $\frac{1}{4}$ in. in road service and $^5/_{16}$ in. in yard service. Tire-dressing brake shoes are helpful in maintaining tires in good condition. It is the business of roadmasters to report engine tires found worn deeper than the limit in force, and for the purpose of testing the depth of rut a pocket templet is convenient. The effect of hollow-worn tires on the stock rail of split switches, just in rear of the point where the planing of the point rail runs out, is about the same as on frogs and is again referred to.

Continuous-Rail Frogs.—Many attempts have been made to devise some arrangement to serve the purpose of a frog and at the same time leave the main-line rail unbroken. Obviously the only manner in which this can be accomplished is by carrying the wheels over the main rail at the point where it is crossed by the turnout rail. As there are a few frogs of this kind in service, some account of the same is proper. The Price frog, designed by Mr. C. B. Price, formerly division superintendent of the Allegheny Valley Ry., has been used on that road and on the Pennsylvania R. R. As will be seen by the engraving at the left in Fig. 93, the main rail is unbroken and continuous, but the turnout rail is in two parts, and is connected to, and operated by, the switch stand, so that when the switch is set for a siding movement the two parts of the frog are brought up against the main-line rail and locked in that position, as shown by the engraving at the right. The construction of the frog is such that it forms, in effect, a continuous rail for the passage of the wheels, and at the same time raises them up high enough to permit the flanges to pass over the top of the main-line rail. For siding movements the device fits over the main-line rail in a manner similar to the closing of the movable wing against the point rail in spring-rail frogs. It will be noticed that the frog has "safety wings" or inclined planes which fit over the main-line rail for some distance. This arrangement serves a double purpose: by thus lengthening out the movable wing on the turnout side the frog is given a desirable degree of stability, and there is secured a provision for the safety of a train on main-track which might find the switch wrong and the frog resting upon the main rail, in which event it would pass over the safety wings in the same manner that it would pass through an ordinary spring rail frog, and that without injury to either train or frog. There is also provided a means to prevent the frog being thrown prematurely, for switchmen would be liable to set the switch for the main line, after the last pair of wheels had cleared the switch, when entering the siding, thus removing the frog from the main line and causing a derailment. A device for overcoming this difficulty is a spring guard rail mounted to form an inside "protector bar" or spring rail, which normally fits up against the gage side of the lead rail, between the switch and ordinary guard rail, as is shown in the figure. The flanges of the wheels of a train in passing into the siding crowd back this bar and cause a hooked lug which is connected to it to engage with a notch or lug on the operating rod and thus prevent its movement until all of the wheels have passed safely beyond the frog.

The MacPherson Frog, designed by Mr. Duncan MacPherson, division engineer with the Canadian Pacific Ry., is one of the standard devices of that road, and is in service on quite a large number of other roads. Figure 94 shows the frog in both the open and closed positions. It consists of two parts, which are well clear of the main track rails when the switch is not set for the turnout, thus avoiding wear. One piece of the frog consists of a point rail, which is thrown up to the main rail at the proper angle for the frog, and the other piece consists of a rail curved or flared at the end to make a proper junction with the point rail, across the top of the main rail. These parts are high enough to overlap the main rail and carry the wheel flanges well clear of that rail. The frog is connected with the switch by pipe line and bell crank, both frog and switch being interlocked and thrown by the same movement of the switch stand, so that the frog is always set right for the position of the switch. A wrong setting of the frog cannot endanger trains on main line. Should a train on main line trail the frog when it is set for the turnout, the

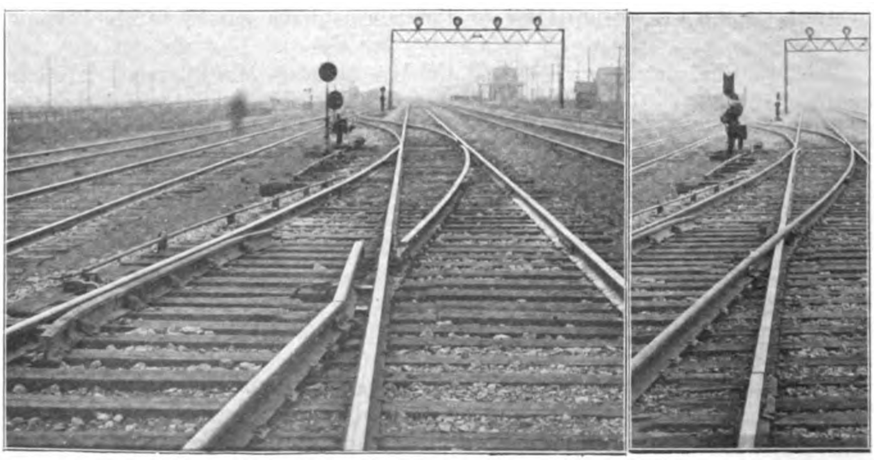


Set for Main Line. Set for Siding.

Fig. 94.—MacPherson Frog, Canadian Pacific Ry.

wheel flange would catch the flaring end of the frog rail and force it aside, while the outer portion of the wheel tread would force aside the point piece on the opposite side of the main rail. This frog may be used with any type of switch, either split or stub, by interlocking the movements of the two. On the roads where it is in service it is in some cases used with the ordinary split switch, and in other cases with the Mac Pherson switch, which is constructed on the Wharton principle and is described further along.

The Coughlin "swing-rail" frog, in use on the Western Maryland, Lehigh Valley and other roads, consists essentially of a piece of rail about 6 ft. long, which, when set for the siding, is swung diagonally across the main rail, in line with the fixed leads of the turnout. It is pivoted at one end and, when thrown for the siding, the other end rests in a seat at the fixed end of the turnout lead rail, with which it makes a miter joint. The hinge of the swing rail and the seat referred to are supported by a base plate, which extends under and supports also the main-track rail, but is not rigidly attached thereto. The swing rail is made from a piece of 100-lb. rail, with the base and web cut away from that portion which



Set for Main Line. Set for Siding.

Fig. 95.—Coughlin Swing-Rail Frog.

passes over the main line rail. The fixed ends of the turnout lead rails are elevated to conform to the swing rail, which carries the wheels 1¾ ins. above main rail, and is guided to the proper hight to slide across the main rail, by raising plates. Frog and switch are connected by a pipe line through a bell-crank, and both are moved by the same stand, which may be placed either at the switch or opposite the frog. In the operation of a specially designed switch stand of the cam class, intended for use in connection with these frogs, the first half throw of the lever sets the switch and the second half or completion of the throw operates the frog and locks the switch. In throwing the stand back to its position for main line, the reverse movement takes place, the frog being operated at the first half of the return stroke, and then the switch. When thrown to the siding the swing rail is locked in position against side or vertical movement by wheels on the turnout, but a tripping bar is provided which permits the swing rail to be pushed aside should a train on main track trail the frog while it is set for the siding. When set for the main track the swing rail is moved to a position parallel with the main-line rail, clearing by an ample flangeway, so that no guard rail is needed. It would seem proper, however, to use a guard rail in the turnout, opposite the frog. To prevent the frog from being thrown while a car is between

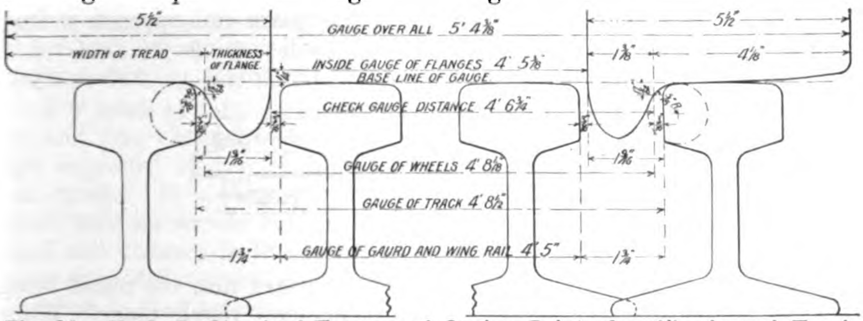


Fig. 96.—M. C. B. Standard Terms and Gaging Points for Wheels and Track.

it and the switch a detector bar is used. This device and its operation are described under § 82 of this chapter, on the "Machine Operation of Switches." See § 221 for the Coughlin-Sanford switch point lock.

Both the MacPherson and Coughlin frogs may be and are used without guard rails in the main track, and in connection with a Wharton switch they thus preserve the continuity of the rails and an unobstructed track throughout the length of the turnout—apparently a very safe arrangement for high-speed trains. They are not intended for use in yards or at turnouts where a great deal of switching is done. The prevailing disposition toward these devices seems to be to first try them at outlying turnouts in main line, that are used only occasionally, but where the speed on main line is rapid.

59. Guard Rails.—The purpose of the ordinary guard rail in turnouts is to so constrain the wheel flange that the flange of the wheel on the other end of the axle is kept clear of the point of frog. In order that this condition may obtain, the frog should be laid to exact gage and the wheels should be set according to measurements which conform to standard track gage. Unless both of these conditions be fulfilled wheels will not pass smoothly by the frog. Figure 96 shows a pair of wheels of standard shape, gaged according to the Master Car Builders' standard (4 ft. 8½ ins.), on track of standard gage. The gaging point of the wheels is on the flange fillet (the curve by which the flange meets the tread) $^{17}/_{64}$ in. out from the tread. This point on the fillet is the supposed normal limiting point of contact between the wheel and the rail. It will be seen that the width of flangeway, or space between guard rail and running rail, is $1\frac{3}{4}$ ins. This width of flangeway allows a play of $^3/_{16}$ in. between the back of wheel flange and guard rail, and the same amount of play between the back of flange and frog wing. When this play between back of flange and guard rail is taken up by the motion of a wheel the flange fillet of the mating wheel may then just reach the frog tongue, but the flange is held away, so that it cannot impinge upon the point when it comes facing; that is, when it approaches the frog from the direction of the switch. For wheels trailing a frog no guard rail is needed.

If the flangeway of the guard rail on track of standard gage be made wider than $1\frac{3}{4}$ ins. the wheel flanges will impinge on the point of tongue. If the gage at the frog be wider than 4 ft. $8\frac{1}{2}$ ins., as on a curve, the flangeway should be increased by just the amount the gage is widened, or the flanges will strike a heavy blow on the wing of the frog. In other words, the service side of the guard rail head, opposite the frog tongue, should be 4 ft. $6\frac{3}{4}$ ins. (4 ft. $8\frac{1}{2}$ ins.—$1\frac{3}{4}$ ins.) from the gage line of the frog, regardless of the gage of the track. As a rule which applies in all cases, then, the guard rail should be spaced not from the rail adjacent but from the gage line of the frog or the rail on the opposite side of the track. This rule is often overlooked when laying the guard rail opposite a frog, in the turnout. From the fear that flanges will impinge on the end of the tongue many trackmen make the gage at the frog $\frac{1}{4}$ in. wide without

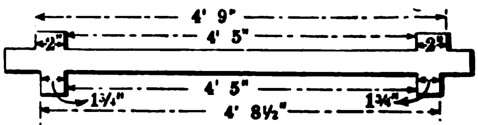

Fig. 97.—Guard Rail Gages.

making due allowance in the flangeway of the guard rail, the result being that the turnout wing of the frog must undergo rough usage. While there is no necessity for increasing the gage of the turnout at the frog, and while so doing makes an unsightly jog in the rail, still, whatever be the gage of the track, the guard rail should always be spaced the same distance from the gage side of the frog, as above stated. This distance, 4 ft. $6\frac{3}{4}$ ins., might properly be called the *guard rail distance.*

Wheels are supposed to be gaged according to the M. C. B. standard, or 4 ft. $6\frac{3}{4}$ ins. from the back of flange on one wheel to the gage line of the flange on the other. This measurement, called the *check gage distance,* is the same as the guard rail distance, and when such is observed, both guard and wing rail blows and point impingements are avoided. The standard distance between wheels is 4 ft. $5\frac{3}{8}$ ins., back to back of flanges, and to provide for variation in thickness of flanges a deviation is allowed between the limits of 4 ft. $5\frac{1}{4}$ ins. and 4 ft. $5\frac{1}{2}$ ins., which permits a maximum flange thickness of $1^7/_{16}$ ins., and a minimum thickness of $1^5/_{16}$ ins. (for new wheels). A standard distance back to back of flanges, is not, however, a consistent gage for mounting wheels in all cases, because if the flanges are not of standard thickness such a gage permits a comparatively wide range of measurements between gage lines of the flanges; that is, in the *gage of wheels.* For wheel flanges not of standard thickness there is only one logical basis of measurement, and this is from the back of one flange to the gage line on the flange fillet of the other. This measurement and the guard rail distance must be the same; otherwise the proper relationship of the wheels to the track at switches cannot be maintained.

Although the thickness of flange does affect the back-to-back measurement of wheels set to proper gage no harm results so long as this distance is not less than 4 ft. 5 ins.

Some complication appears to arise over the proper gaging of wheels with worn flanges; for although the ideal condition obtains with new wheels gaged in the manner just pointed out, both guard and wing rail blows follow upon appreciable flange wear, since the check gage distance then becomes less than the guard rail distance and the wheels have more lateral motion or play across the track. This trouble can be remedied by pressing the wheels farther apart an amount equal to the wear of one flange. This change restores the wheels to the standard check gage distance, and as long as this gage is not exceeded there can be no impingement on the point of tongue. It should be stated that the desired results from this treatment of worn wheels cannot be had unless the flanges be of equal thickness; but two wheels differing in thickness of flange to any appreciable extent should not be used on the same axle, since with such the check gage distance cannot be made to measure the same both ways over the pair. The M. C. B. rules permit a variation in thickness not to exceed $^1/_{16}$ in. With this precaution it must be plainly evident that a rigid adherence to the 4 ft. 6$\frac{3}{4}$-in. measurement between back and gage lines of flanges is the solution of the worn or irregular wheel flange difficulty. The M. C. B. rules require that wheels with flanges worn to a thickness of $1^1/_{16}$ ins. or less shall not be remounted.

For track of 4 ft. 9 ins. gage the standard width of guard rail flangeway and frog channel is 2 ins. Figure 97 shows the standard guard rail gage suggested by the M. C. B. Assn. for both standard-gage and 4 ft. 9-in. tracks. It is seen that the same distance of 4 ft. 5 ins. is maintained between service sides of guard and wing rails in either case. The guard rail distance in this case is 4 ft. 7 ins., thus exceeding the standard check gage distance by $\frac{1}{4}$ in. and permitting minimum guard and wing rail blows to that extent, from wheels of standard gage; if a frog of standard channel width (1$\frac{3}{4}$ ins.) be used the wing rail blow is increased to $\frac{1}{2}$ in. It is thus seen that on 4 ft. 9-in. track with 2-in flangeways ideal conditions for wheels set to standard gage are impossible.

It may be well enough to here call attention to the fact that the gaging point of wheels, although officially defined, has no fixed position, so far as may be determined from conditions of contact with the rail. The point or line on the wheel to which the gage is referred is that which is supposed to coincide with a plane which stands perpendicular to the track on the gage line of the rail, when the flange is crowding the rail to the limit of lateral movement. On a new wheel this point is supposed to be on the flange fillet, and it may or may not come in contact with the rail, even when the flange is crowding the rail to the limit. This supposed gaging point is not easily identified, even on new wheels, and on worn wheels it cannot be distinctly located. The limit of the lateral motion of a wheel relatively to the rail depends upon the shape of the top corner of the rail head and the condition of the wheel flange fillet respecting wear. The line of contact between flange and rail is not precisely determinable even with new wheels and rails, and it may change with wear of either wheel or rail. By means of models or observations of experiments with actual wheels and rails the gaging point can be located approximately for any assumed contour of wheel and rail. For the M. C. B. standards it was located for new wheels and a rail with a top corner radius of $\frac{1}{4}$ in. For the above reasons the technical thickness of wheel flange cannot be exactly determined. The only fixed point on the wheel from which definite gage measurements can be taken is the back of the flange, and no comparison of the wheel gage with that of guard rails, frog points and frog wing rails is reliable unless the back of the wheel flange is made the basis of measurement.

So far as danger of impinging on the frog tongue is concerned, there is no necessity for maintaining the guard rail distance except at the point directly opposite the point of tongue. In fact such an arrangement is in practice on some roads, including the Great Northern Ry. The guard rail is bent sharply at the middle with a jim-crow and the bend is placed opposite the point of tongue at the proper guard rail distance. For several reasons, however, it is considered better practice to lay the guard rail parallel with the gage line of the frog for some little distance, at least 3 or 4 ft. In the first place, the wear on the straight piece of guard rail is not so rapid as it is on the small amount of restraining surface presented by a sharp bend. There is an element of safety in maintaining the guard rail at the proper guarding distance (4 ft. 6¾ ins.) for some distance in rear of the point directly opposite to the point of tongue. Sometimes a loose or widely-gaged wheel or a wheel on a bent axle will ride the point, and if there is a foot or two of straight guard rail at the proper gage distance the wheel is likely to be brought back again. With spring frogs the length of guard rail set to proper guard rail distance should at least cover the movable wing in advance of the point. This arrangement relieves the spring rail from side pressure, particularly if the frog is on the outside of a curve (where a spring-rail frog ought not to be), and it reduces the risk of derailment in case the spring rail should break or some other accident happen to the frog.

The flare at the ends of guard rails is usually 4 to 6 ins. from the running rail, and it should be made gradually, say in a distance of 4 to 6 ft., so as to draw the wheels to the guard point without jar or shock. The easier or more gradual the flare the better is the guard rail able to withstand the side blows from badly gaged wheels or wheels with badly worn flanges which have not been regaged. If the rail is of proper length it can be sprung to make the flare without curving, but if it is short it should be curved. The practice of heating the rail and bending or curving the ends within the short distance of a foot or two is a bad one and produces a poor guard rail, which is the cause of unpleasant riding. There can be no doubt but that car axles are often severely strained, if not broken, by the sudden jogging of the wheels against short guard rails, or against those which are curved or bent at the ends too suddenly. In order to strengthen the guard rail against overturning it is quite extensively the practice to flare the ends 8 to 12 ins.; in which case tilting or overturning cannot take place except by a square lift at the center of the rail. For the same purpose it has been the practice with a few roads to turn the ends of the guard rail at right angles, toward the center of the track, for a length of 18 ins. or so. In the instance of one road whereon this principle has been adopted the head and web are cut from the squarely bent ends and three holes are punched through the base which remains, for spiking these ends to the ties. No spikes are then driven in the flangeway to hold down the straight portion of the guard rail, which is 7 ft. in length, the total length of the guard rail before bending being 12 ft. On the Michigan Central R. R. the flare of each end of the guard rail is made in two distinct bends, one 2½ ft. from center to give the flangeway a gradual taper and the other 5½ ft. from center and 2 ft. from the end of the rail, to bend in a short portion to a clearance of 8 ins. from the running rail, for stability against "rolling" or tilting.

Guard rails should be at least 18 ft. long and are all the better if longer. A guard rail as short as 8 or 10 ft. in length, without reinforcing devices, is easily torn out by derailed wheels, if it does not get loose from ordinary service. A long guard rail can be firmly held in place by the spikes alone, and it affords plenty of rail to make a gradual flare. Guard rails placed on the inside of curves should be a full rail's length. They can be flared for a gradual approach to the necessary guarding point, and if the portion parallel to the running rail be restricted to a short length at the middle the unusual length will not increase the liability of the wheel flanges to bind in the flangeway. Where a turnout is laid only temporarily, and there happen to be no pieces of rail of convenient length for guard rails, it is well to use a whole rail in preference to cutting it. The guard rail should be placed centrally opposite the frog point or nearly so (as the ties at the ends of the guard rail will determine), not only for sake of appearance but because the wheel should be guarded as gradually while trailing the frog as when moving facing to it; for while there is no need of guarding a wheel trailing a frog, still the guard is there and the wheel flanges must meet it just the same as when they come facing. It is quite commonly the practice to lay the guard rail with its center in advance of the frog point. The standard practice of the Philadelphia & Reading Ry. is to lay guard rails opposite frogs to bring the middle point 2 ft. 8 ins. in advance of the frog point.

The top of the guard rail should not stand higher than that of the running rail, as if it does it comes in the way of, and is liable to receive heavy side blows from, the inside false flange of blind drivers, the tires of which are wider than those of the flanged drivers and are usually placed closer back to back. Neither should the top of the guard rail be much lower than that of the running rail, as if it is some of the effectiveness of the rail as a guard is lost. On a certain road where it was attempted to use 75-lb. guard rails with 100-lb. running rails, without raising the former off the ties, it frequently happened that the wheel flanges would climb the flared ends of the guard rail and cause derailment. On the Burlington & Missouri River R. R. the guard rail is set to bring its top $\frac{1}{8}$ in. lower than that of the running rail, in order to escape interference with worn blind drivers, as just explained.

Old flange-worn rails from the outer side of curves make good guard rails, as they are already curved and serve the purpose just as well as a new rail. Old iron rails have been much used for guard rails but are now becoming scarce and are of too small section to match with the new rails laid in these days unless chairs or raising blocks are used to bring the top of the guard rail to proper hight. Figure 99 shows the form of cast chair and brace in service on the Southern Pacific road, designed to allow the use of a 50-lb. guard rail with a 75-lb. or 76-lb. running rail. The casting is ribbed, as indicated by the broken line, and is set upon a special Servis tie plate 12 ins. long and 5 ins. wide, with two spike holes punched to come at the edge of the chair. Three of these chairs are used on the standard guard rail (10 ft. long), one being placed at the middle and one near each end, where the bend is made for the flare, the length of the straight portion of the guard rail being 7 ft. 4 ins. By means of a bolt and a pipe filler or spacing sleeve the two rails are securely braced together.

The ends of a guard rail cut off squarely, as they usually are, form ugly obstructions to snow plows and flangers and to parts of brake rigging which may be hanging loose or dragging, and oftentimes such parts are torn loose at guard rails and cause derailment. Moreover, trainmen are occasionally injured by stubbing against them and falling, even though the ends of the guard rail are blocked; for foot guards usually pass under the head of the rail. It is therefore a good plan to have the ends of guard rails sloped down to the rail base, something like the end of the piece shown in Fig. 98. By heating the end and cutting out a triangular portion of the web the head is bent to slope down to the base and a hole is punched through the end for a spike. Guard rails made in this way will not catch and hold anything which may be dragged against them, and they are therefore not so liable to be torn out. Pieces of rail of lengths suitable for guard rails may be sent to the shops to be so shaped and then stored until needed. Short pieces of rail 2 or 3 ft. long which cannot be utilized in making frogs, and which usually go to the scrap pile, may be utilized in this way by splicing on to the ends of guard rails already laid, using old fish plates for splices. On some roads the ends of

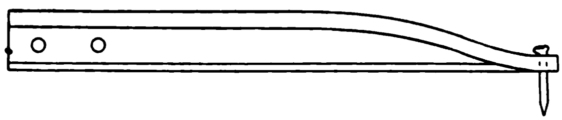

Fig. 98.—Sloped End Piece for Guard Rail.

the guard rails are sawed off to a slope. This is a much better arrangement than the squarely cut ends, but the sharp under corners at the end of rail head still have some tendency to catch things dragged against it.

Before laying a guard rail which rests upon the ties metal must be taken from the edge of the flange which comes next the running rail or notches must be cut out of the same, to afford spiking space in the flangeway. Unless the flanges of the two rails interfere with bringing the heads to a proper flangeway it is better to notch out for the spikes than to plane or chip off the edge of the flange along the whole length of the straight portion. The best way to take off a strip of the flange or to cut out places for the spikes is to turn the guard rail on its head, notch out with the track chisel, in outline, on the base, the strip or portions to be cut away and then break them out with the hammer, slanting the stroke inward toward the rail web. Some go to needless pains in work of this kind, by laying a piece of rail for an anvil and cutting full depth to remove the necessary metal. As either steel or iron rails will break to a notching it saves much time and effort to merely notch the metal and break it off. In fact the metal is sometimes broken off without notching with a chisel, but the work is irregular and no time is gained.

The way to lay a guard rail is to place it in position and spike the portion opposite the frog point first. A sharp pick is an excellent tool to use in case the rail must be sprung to place while spiking it. After the middle portion is secure for the whole distance over which it is to be laid parallel to the running rail, spring out the ends, if they are not already curved, and secure them in the proper position, after which spike down the remaining portion of the rail, both sides, throughout, double-spiking the ends and the middle portion, if the rail is to be held by spikes

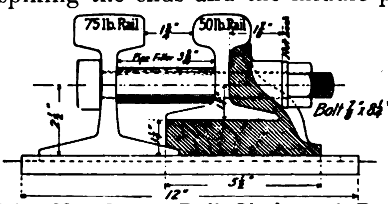

Fig. 99.—Guard Rail Chair and Brace. S. P. Co.

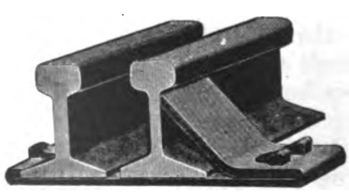

Fig. 100.—Edwards Guard Rail Brace.

Fig. 100 A.—Graham Guard Rail Brace, Southern Ry.

only. In some cases guard rails are secured by spikes alone; and if the rail is of good length it may remain quite firmly in place while the ties are new; but there is considerable leverage tending to overturn it inward to the track, and it is now extensively the practice to fortify guard rails with some form of brace.

Guard Rail Braces and Clamps.—There are many ways of bracing or giving additional security to guard rails. A common practice has been to tightly fit one or more pieces of 3-in hardwood plank endwise between the webs of the guard rail and frog wing, spiking the plank to the top of a tie. This method, however, is open to the objection that the planking is in danger of being torn out at any time by dragging brake rigging. The Graham guard rail brace is a metallic device applied in the same way. It consists of a pressed steel strut of inverted U-section, flanged for spiking to the ties, and reaching from guard rail to frog wing (Fig. 100A). The ends conform to the shape of the side of the rail web and head, like a rail brace. It is used on the Southern Ry. and other roads.

Ordinary rail braces are commonly used for the purpose, spaced symmetrically each side the middle of the rail. Four braces—one at each end of the straight portion and one at each end of the rail—answer very well. A very secure way is to drill holes through the webs of the guard and running rails and through these to bolt the guard rail fast to the running rail, using 1-in. bolts. Spools or spacing blocks should be used with the bolts, so as to permit the nuts to be turned on tightly without tilting the guard rail or narrowing the flangeway. Heavy washers for the outside, made by cutting up old fish plates, are sometimes used. A heavy clamp, similar in design to a frog clamp, placed opposite the frog point, and sometimes at the ends of the straight part of the guard rail, is used to

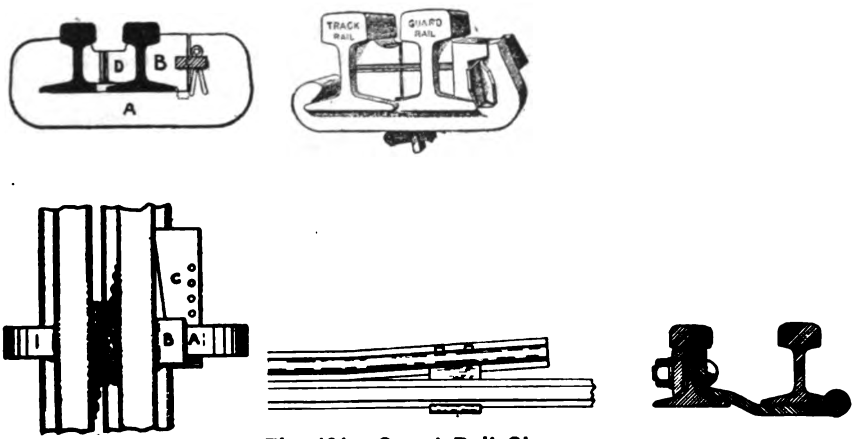

Fig. 101.—Guard Rail Clamps.

some extent. At the left in Fig. 101 there is shown the Wharton adjustable guard rail clamp. It consists of a heavy forging A, a cast filler D, a cast wedge block B and a steel wedge C, with cotter pin. The cast filler D is composed of two similar triangular-shaped pieces with rounded saw-tooth projections, which, as they are moved by each other, give variations in the opening of the flangeway to suit any desired adjustment. The device shown in the upper right side of the figure is the Pennsylvania Standard guard rail clamp made of iron 4 ins. wide and 1¼ to 1½ ins. thick, according to the size of the rail. The metal spacing blocks are secured by a vertical flat key bolt and split key driven under the clamp, and the clamp is tightened and secured by driving the horizontal soft steel wedge and spreading open the split end. The device shown in the lower right side of the figure is in use on the Chicago & Western Indiana, the Chicago, Rock Island & Pacific and other roads. It is a steel plate clamp 10 ins. wide and ½ in. thick, bent up at the inner end to bolt to the web of the guard rail and formed into a clasp at the outer end, which

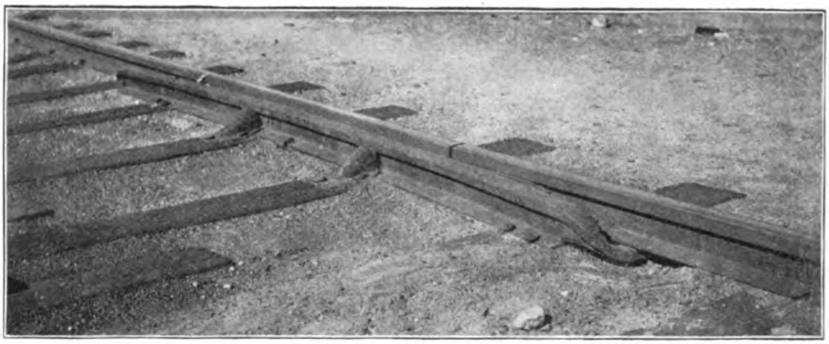

Fig. 102.—Standard Guard Rail, Maine Central R. R.

is passed under the running rail and hooked over the edge of the flange. It is applied to the flared end of the guard rail, as shown in the plan view, and the adjustment is by means of a series of holes in the end of the guard rail, the clamp being moved to bolt on nearer to or farther from the end as a narrower or wider flangeway is desired. The Edwards guard rail brace (Fig. 100) is made all in one piece, to fit under the head of the guard rail on the off side and to hook around the outside edge of the flange of the running rail.

The standard guard rail of the Maine Central R. R. has ends bent to form clamps, as shown in Fig. 102. The guard rail is 10 ft. long, bent at the middle and flared to a clearance of 4 ins. at the ends. At each end of the rail the base and web are cut out to leave a projecting piece of the head 12 or 15 ins. long, and this head is turned down like a ram's horn, passed underneath the running rail and clinched over the base on the other side. In some cases, however, the head and web are cut away and the flange (instead of the head) of the guard rail is bent under and around to embrace the outer flange of the running rail. The arrangement holds the guard rail securely against canting or being torn out by derailed wheels or dragging parts.

The method of securing the guard rail to the running rail, in any manner, is opposed by some trackmen on the ground that the position of the guard rail is thus dependent upon the stability of the rail to which it is attached, whereas it should be maintained in position with reference to the frog regardless of the position of the rail opposite. If the guard rail is laid at the proper distance from the frog, however, the objection is not serious, because the running rail, by itself alone, is ordinarily secure enough for a guard rail, and if the guard rail is well spiked (as it should be) there is but small probability that the two will be moved out of gage. Of course the true principle would be to unite guard rail and frog instead of guard rail and running rail, and those inclined to the position stated claim that if anything in the nature of a guard rail clamp is worth having at all it should be such as will secure the guard rail to the frog; in other words preserve the proper gage of guard and wing rails. As a suggestion on this idea I am indebted to Mr. D. M. Taylor for the sketch of a proposed device shown as Fig. 103. It consists of a round bar threaded into a steel casting bolted to the guard rail, at one end, and flattened at the other end or so shaped as to be most conveniently fastened to the frog. The steel casting (*A*) might be similar, in shape and method of attachment, to some switch lugs now in use, but quite heavy. If the gage bar

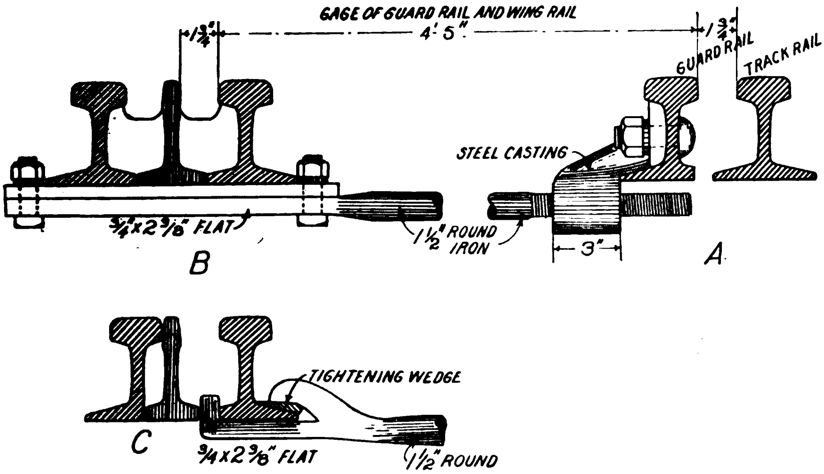

Fig. 103.—Proposed Device for Holding Guard Rail to Gage.

was to be attached to a plate frog the simplest method would perhaps be to use bolts as shown at *B*, and as the service stress on the bar would be that of compression, there might be a shoulder on the bar to abut against the frog plate. If it is to be attached to a spring frog without plate the end of the bar might be forged into some such shape as is shown at *C*, admitting of easy removal by simply knocking out the tightening wedge which holds the bar to its place in a manner similar to that sometimes used with clamped frogs. The device would certainly be practicable, and would not probably cost any more than some of the guard rail clamps now in use. Further on the matter of guard rail clamps, it may be stated that one objection to the use of a non-adjustable filling block between main and guard rail, bolted through and through, is that it does not permit the guard rail to be reset and moved in to a proper flangeway when the service side becomes unduly worn.

An interesting departure in guard rail design has been in satisfactory service for several years on the Duluth & Iron Range R. R., in the shape of an angle bar guard. This device was first designed for use with 100-lb. rails and spring-rail frogs, but has since been adopted for use with spring-rail frogs in 80-lb. track. The design shown in Fig. 104 is for 100-lb. track, the rail being 5¾ ins. high, 5¾ ins. wide on base, with a head 2¾ ins. wide. The guard rail is 20 ft. long and made of a 6x6x ¾-in. steel angle fitted in the factory and shipped with the frog. All the details and measurements are given on the engraving. It will be noticed that there are seven cast spacing blocks, in three sets, with bolts for securing the guard angle firmly to the running rail. The guard

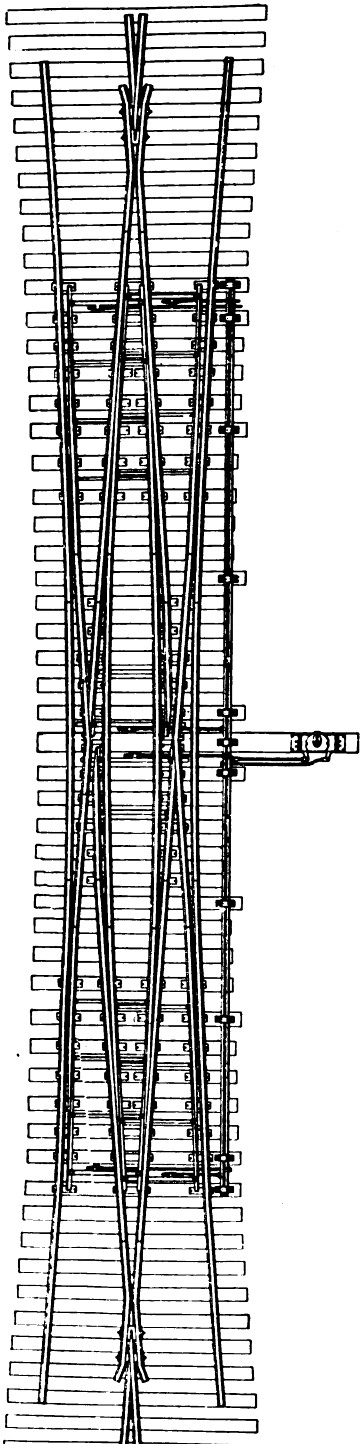

Fig. 104 A.—Elliot Rocker-Shaft Connection for Operating Movable-Point Frog and Slip Switch.

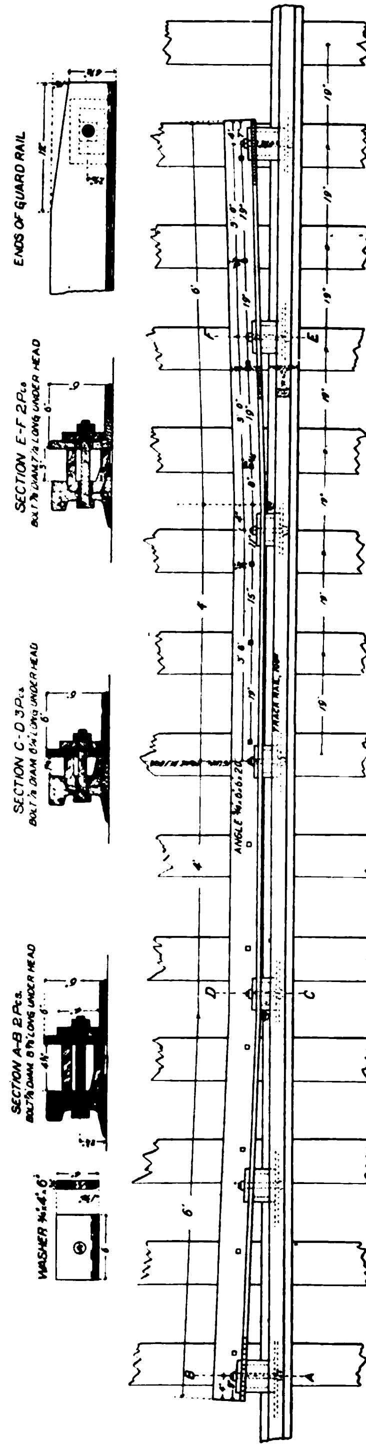

104.—Angle-Bar Guard Rail, Duluth & Iron Range R. R.

angle is further secured by spiking it to the ties through punched holes, spaced to correspond to the standard tie spacing. The ends of the guard angle are sloped down 1½ ins., in 12 ins., as shown, to make it less obstructive to loose parts of rolling stock. The angle bar in place weighs about the same as a 100-lb. T-rail of corresponding length used for the same purpose. A commendable feature of the design is the length of the guard rail, and another is the large portion of the length which is given to make the flare—six feet on each end, leaving 8 ft. of the guard rail straight or set to a 1¾-in. flangeway. On some of the railways of Germany guard rails of similar design are in service, the difference being that a bulb angle is used instead of a plain angle bar. This bulb angle is a specially rolled shape, the bulb projecting from the outside of the vertical leg of the angle instead of from the inside, as in the regular commercial shape; that is, the bulb is on the service side of the guard angle.

For various causes guard rails sometimes need to be taken up and reset. Among these causes are the spreading, canting or rolling of the guard rail, from wheel pressure; wearing away of the service side of the head; the wearing down of the running rail or the cutting of the ties under this rail, which leaves the guard rail too high for the worn tires of blind drivers. Deeply guttered blind tires are severe on guard rails and frog wings in any case, because they are usually 1 to 1½ ins. wider than the flanged tires and set in closer back to back, so that the inner false flange which runs into the flangeway of the guard rail must either climb out again when it meets the flared end or crowd against the guard rail with tremendous force. The coning of blind tires on the inside and outside of the tread helps matters for guard rails and frog wings when the tires become worn.

Another cause of the loosening or the spreading of guard rails arises in winter, when the flangeway gets closely packed with snow. It will thaw and then freeze and expand, but owing to the shape of the cavity the expanding material cannot easily force itself out, and consequently there is exerted a powerful force tending to spread the two rails apart. This trouble may be avoided by blocking the guard rail its whole length. For blocking the flangeway along the straight portion of a guard rail the channel filling of worn-out frogs comes handy, and is sometimes used. Being of the proper width and shape all that is necessary is to drill holes in the guard and main rails corresponding to some of those in the filling blocks, and then bolt the guard and main rails together like the wing rail and point pieces of a frog.

60. Switch Rods.—A switch rod, sometimes called a "bridle rod" or "tie bar," is an iron bar having slots or connections near or at its ends to fit the flanges or webs of the two switch rails, to hold them to gage. A stub switch rod is usually made from 1⅝-in. or 1½-in. round iron. If it is designed to gripe the rail flange it should be a forging rather than a rod with cleat attachments for this purpose. It ought to fit snugly the two rails at exactly standard gage distance apart. The rod placed next the headblock is usually extended a few inches beyond the slot on one end and flattened and drilled, to join with a connecting rod to the switch stand; it is sometimes called the "eye bar," "neck rod," or "head rod." This rod should fit the rail flange so closely that it must be driven on in order to get it to place. The bolt joining it to the connecting rod should fit both it and the connecting rod snugly. This rod should be placed as near the headshoe as it can be worked, so as to make the throw of the ends of the moving rails correspond as nearly as possible to the throw of the connecting rod or the switch stand. It should also be placed squarely with the two rails; that is, perpendicular to each switch rail when set for the main track. It can be kept from slewing around by a guard attached to the headblock, or by driving two stakes beside it into the ballast. With the stub switches of the Grand Trunk Ry. the head rod is a flat bar about 4 ins. wide and 1 in. thick, supporting the moving rails and sliding on a flat headshoe to which the stub ends of the lead rails are secured by riveted lugs.

A loose rod may be made to fit snugly by driving a key between the edge of the rail flange and the end of the slot, and then clinching the key. If the rails do not then come to gage and there is not room in the slots to permit them to be adjusted the necessary amount, the adjustment can be facilitated by trimming from the edge of the rail flange and keying it over that much. For this purpose switch rods should be so slotted that the part of the slot for the rail web is wider than the thickness of the

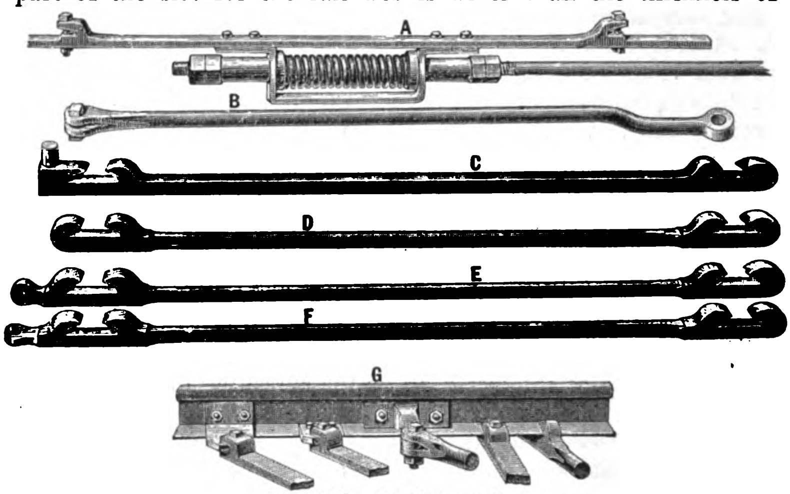

Fig. 105.—Switch Rods.

web by at least ½ in., thus making it possible to key and adjust the rail flange. If the rods are not all pretty nearly of the same gage this adjustment should always be made, so as to put the two rails to the same gage throughout. Different sizes of wire nails and telegraph wire make excellent keys for this purpose.

In order to protect the rods from getting bent in derailments, which will occur more or less in switching at stub switches, a sawed tie should be placed each side of each rod, leaving a space of about 2½ ins. between the ties for the rod; but unusually wide spaces should not be left between the other ties with the idea that bunching two together in a place will make up for the unequal distribution. It is at all events a good plan to have ties closely spaced under moving rails, in order to hold up the wheels in case of derailment. Ties placed in this manner also keep the rods to place. In case rods become badly bent one should not attempt to straighten them cold; but build a fire and heat them, before straightening. Ballast should not be dressed between the ties to reach the rods, and before winter sets in particular attention should be given to the matter to see that the ballast is everywhere clear of the rods, and that little trenches are dug, if necessary, to drain the spaces about the rods. The necessity of such precaution is to prevent the rods from freezing fast.

Figure 105 shows an assortment of switch rods. The rod *D* is the ordinary stub switch rod or "back rod," and the right-hand connection on

G shows the way it gripes the rail flange. Rods *C, E,* and *F* are different forms of head rods, *E* being for use with a ground switch stand and *F* with a revolving switch stand. Rod *B* is a connecting rod made to join with the head rod *F*. The four connections shown to the left hand on *G* are some ways of attaching rods to point switch rails; other figures in this chapter show still other methods. The rod *A* has the well known Lorenz spring or safety connection for point switch rails, referred to further on.

61. Headshoes.—Headshoes or "headchairs" are made either of cast iron, wrought iron or steel plate. A cast shoe, if thick enough, will give good service. A wrought or steel plate shoe is made by riveting properly shaped lugs or stops to a heavy plate. They will not break in two, as cast shoes do sometimes when engines or cars get off the track, but when poorly made the parts get loose. A cast shoe should be at least $1\frac{1}{2}$ ins. thick underneath the rails, and for heavy traffic the thickness should be 2 ins. It should be cored to fit snugly the section of the rail used with it. The metal should, of course, be tough and of good quality. A large proportion of the headshoes in use are badly designed in one particular: there is at the

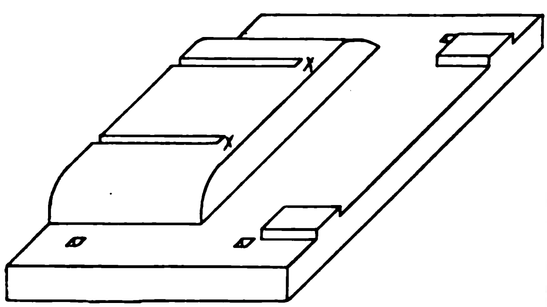

Fig. 106.—Cast Iron Headshoe.

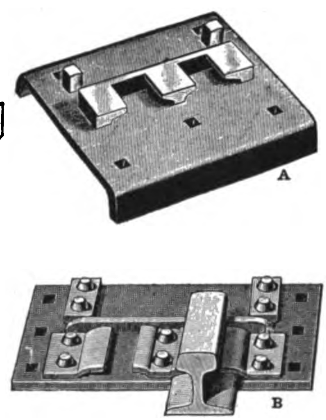

Fig. 107.—Steel Plate Headshoes.

back of seat of the stub or lead rail—that is, between the lead rail and the moving rail—a backing or ridge on the cross bar ("X," Fig. 106) $\frac{3}{4}$ to 1 in. thick, thus requiring the joint to be unnecessarily wide. There is no necessity for a thickness of metal at the back of seat of more than $\frac{1}{8}$ in. If it is not more than that the joint can be reduced to $\frac{3}{8}$ or $\frac{1}{4}$ in., and thus the heavy pounding due to a wide joint can be avoided. To prevent this thin wall of metal or backing from breaking out by the creeping of the rail, the corners of the slot for the rail flange should be cast solid, thus requiring the corners of the flange of the stub rail to be clipped off in order to fit the space. This arrangement provides plenty of metal as an abutment for the end of the rail. A headshoe with a thick wall back of the seat can be made to answer, however, by cutting out with a hack saw a piece from the flange and web at the end of the lead rail or moving rail, so as to allow the head of the rail to project over the backing or ridge, and in this way reduce the opening at the joint. The Ramapo headshoe (*B*, Fig. 120) is well designed in this respect.

In Fig. 107 are shown two forms of steel plate headshoe. The Buda rivetless headshoe *A* is the standard form on the Union Pacific road and *B* is the Elliot headshoe. The former is of $\frac{5}{8}$-in. rolled steel plate, with dependent flanges to fit over the sides of the headblock, to hold the headshoes square with the block. The lugs for holding the rails in their seats are held to the plate by bosses of rectangular section which extend through the plate and are countersunk on the under side thereof. There is a design of headshoe which relieves the connecting rod of the duty of holding the moving rails to position. For this purpose there is a rib or lug between the main and side-track positions on the seat for the ends of the moving rails, so that in either position of the switch the ends of the moving rails rest as it were in a rut. In order to throw the moving rails from one position to the other it is necessary to lift them out of these ruts or over the intervening lugs, and this is done by means of a foot lever which holds the rails above and clear of the lugs while they are being thrown. This device is in use on the Chicago & Western Indiana R. R.

The spike holes through a headshoe should be square and no larger than will nicely let a spike through. The headblock should be made smooth and even, where the shoe rests upon it. The two shoes should be cast from the same pattern and should be spiked to place at standard-gage distance apart respecting like points in each. The proper way to lay them, however, is to first fit them to the lead rails and then to spike them down with the gage resting upon the stub ends of the lead rails. Headshoes should be set squarely across the track; that is to say, squarely with the rails for main line. If a headshoe is set skewing it gives trouble when moving rails are expanded by heat and shoved tightly against the back of the sliding seat. Where the headshoe is set squarely with the rails for main line the switch may be thrown, even though the rails are shoved up tightly, by the assistance of a hammer or coal pick, with some oil. If the shoe is so skewed that there is less room for the moving rail when thrown for the turnout, the rail cannot be driven over; if, however, the shoe is skewed the other way, the switch rail, after being driven or thrown to the turnout, will expand so that it cannot be driven back to main line again.

62. Switch Stands.—An early form of switch stand, commonly known as the "harp" pattern, consisted of a straight lever held upright in a harp-shaped frame, carrying a target on its upper end, the connecting rod being attached to the lever either above or below the pivot point of the latter. This simple device furnished a cheap and reliable means for holding and throwing the switch rails and, during daytime, showed plainly enough the position of the switch, since, when set for the side-track, the lever had to be thrown out of its normally vertical position. It was not, however, adapted for a conveniently arranged switch light, for which reason it long ago went largely out of use on main line and other tracks where night indication of the position of the switch became important. Old stands of this pattern are now sometimes seen in yards, and in a few instances it has been fitted with an attachment for a switch lamp and is used on main line, such being the case on some parts of the Baltimore & Ohio and Baltimore & Ohio Southwestern roads. This attachment usually consists of an upright rod carrying the lamp, the rod being revolved by means of a crank in gear with the lever or with the main connecting rod.

The switch stand in general service for main track is the revolving stand, consisting principally of four parts—an upright frame, a shaft, a lever and a target. The shaft usually stands in a vertical position, the bottom end being turned up for a crank, to which is attached a rod connecting with the switch rails. The shaft is usually held in an "open" or "closed" cast iron frame secured to the headblock. The "closed" pattern frame is usually a cast iron shell or cylinder, and is sometimes called a "column stand." A lever, which can be thrown around horizontally, is attached to the shaft. The upper portion of the frame is usually flanged out to form a "table" or "top plate," the edge of which is notched to provide rests to hold the lever firmly in certain positions corresponding to the different positions of the switch, provision being also made to lock the lever fast in any of these positions. The lever is usually hinged to a collar which is keyed to the shaft, so that the outer portion of the lever can be turned down when being placed in the rest notch, thus leaving no parts projecting; this arrangement is commonly known as a "drop lever." As far as moving the switch is concerned these three parts—the frame, the shaft and the lever—are the important parts, and each should be composed of as few pieces as possible; multiplicity of parts gives rise to lost motion. The frame or stand proper should, if practicable, be in one solid casting, and the shaft and crank, one piece or forging; the lever, if hinged, must consist of two pieces, one of which is usually a collar projecting outward from the shaft, the outer end of the lever hanging vertically for the normal position. Near the upper end of the shaft, or on another shaft geared to it, is placed a banner or target to denote the position of the switch. The foregoing general description applies particularly to what is commonly known as a rigid stand.

General Principles of Design.—With any stand rigidly attached to the switch rails two things, among others, are required for satisfactory operation, namely an exact throw, corresponding to that of the switch, and, as far as possible, absence of lost motion. A poor stand used with a stub switch is a costly affair. The cost of derailments caused by lip, and the time spent driving keys, adjusting the position of stand, headshoes, etc., will soon amount to more than the difference in cost between a good and a poor stand. With point switches using a spring connection with the stand, thus affording a means of adjustment for taking up lost motion, the throw of the stand need not be so exact, and some stands might serve the purpose quite well which would not answer at all for rigid connections. Rigidly-connected switches whether point or stub, require closely-throwing stands, but good stands should be provided in all cases, because stands are sometimes changed about, especially in yards or in temporary construction. Besides being well designed, switch stands should be well and carefully made. A forged shaft connected to castings in the rough will soon wear and accumulate lost motion, no matter how close the fitting at first. The parts of the shaft which fit into the casting should be turned in a lathe, the bearings in the casting should be reamed, and all joints whatsoever should be made to fit closely and accurately. The crank pin should be turned and the eyes of the connecting and head rods should be reamed to fit the bolts closely. All joints where there is movement of parts should be either accessible or provided with oil holes, for switch stands, to work easily, should be kept oiled. A good stand cannot be made without considerable machine work.

An important point too often overlooked in the design of switch stands is in regard to the throw. A stand whose crank is the same length as the throw of the rails, and which is made to be revolved through 90 deg. from a position of the crank which is either perpendicular to or parallel to the switch rails, will really move the rails more than the desired throw, when the crank is turned out of a position perpendicular to the switch rails, *from* them; or out of a position parallel to the switch rails, *toward* them. When turned out of a position perpendicular to the switch rails, *toward* them; or out of a position parallel to the switch rails *from* them it will move the rails less than the desired throw. To make this matter clear we refer, in Fig. 108, to a concrete example. Let D E represent the near moving rail, C H the head rod, C B the connecting rod and A B the crank of the switch stand. Suppose $A\ B$ to be 5 ins. and $B\ C$, the connecting rod, 55 ins. in length; then the point C is distant from the fixed point A, $55+5=60$ ins. Now turn the crank around 90 deg., or from the position $A\ B$ to $A\ B'$. C will then move to position C' and the distance from A will be the square root of $(55^2-5^2)=54.77$ ins. The point C and the moving rails have then moved a distance$=60-54.77=5.23$ ins., or about $\frac{1}{4}$ in. farther than the intended throw—enough to give bad lip, unless there is lost motion in the stand or the turnout lead rail fits the headshoe loosely enough to be keyed over that much to meet it. The variation between the throw of the rails and the length of the crank is the same for the other ways spoken of and is determined in the same manner.

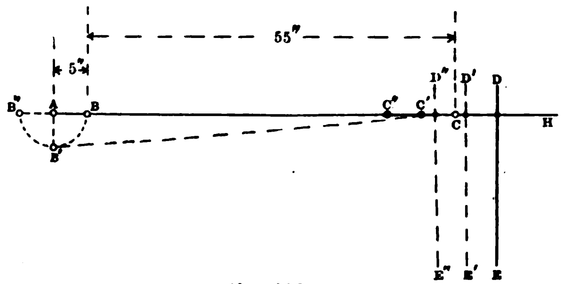

Fig. 108.

Manufacturers sometimes leave enough lost motion in the stand to make up for this variation, but it works in only two out of the four possible ways the stand may be used, as heretofore enumerated. In the other two ways, the real throw being less than the intended throw (equal to the length of the crank), the movement in the rails will fall short of the intended throw by the variation just calculated added to the lost motion, thus making matters all the worse. And so it is that trackmen in setting switch stands sometimes have difficulty in getting the stand to throw the rails without lip: they have struck one of the two ways in which the lost motion works in a manner contrary to that intended. Now, no crank of length other than the throw will answer for this stand, for while in the two cases of increased throw a shorter crank would do, in the other two cases of decreased throw a longer one would be needed, and obviously it could not be both for the same stand; and for convenience every stand of this kind should be so made that it can be set either to push or pull the moving rails when turned from a position in which the crank stands on the dead center or perpendicular to the moving rails when set for the main line. This is called setting the stand "the strong way for the main line," referred to again further on. As lost motion only makes the difficulty worse in two cases out of the four possible ways of using the stand, and is objectionable for other reasons, evidently this kind of stand cannot give entire satisfaction in two-throw stub switches as they are found.

These problems of adjustment can be overcome by setting the crank so that it turns through an angle of 90 deg., from a position in which it stands at an angle of 45 deg. to the direction of the moving rails before throwing. It will be seen, in Fig. 109, that if the connecting rod BC be perpendicular to the moving rail $D\ E$ before being thrown, it is practically perpendicular after being thrown, and $C\ C'$ is therefore practically equal to $B\ B'$. The triangle $B\ A\ B'$ being necessarily isosceles, and the angle $B\ A\ B'$, 90 deg., $B\ B'$ (the throw) being the hypotheneuse of an isosceles right triangle will be $\sqrt{2}$ or 1.41 times the length of crank, in every case. This manner of setting the crank is the better arrangement for a quarter-turn stand and hence the better one for two-throw switches in general, although it does not permit setting the crank on the dead center for any position of the switch.

Referring again to Fig. 108, let us consider a stand for use with a three-throw switch. It must be revolved through an angle of 180 deg. while passing over from its extreme position one way (AB) to the other extreme position (AB''); and as the connecting rod in both positions is perpendicular to the moving rail (practically so) the throw is right for these two positions. The position of the crank when properly set for the middle track, however, will not be midway between, or 90 deg. from, these two positions (if the throw from the middle track each way to the others be equal, as it always is) for the same reason which applied to the two-throw switch, heretofore explained. The position of the crank for the middle track will be a certain number of degrees measured around from B'', or B, accordingly as the stand is on the left or right hand as one stands at the headblock looking toward the frog, the exact number of degrees depending upon the length of the connecting rod BC. With the throw 5 ins. and the connecting rod 55 ins. long, the angle would be 87 deg. 24 min. For a three-throw switch, then, the stand, to work satisfactorily, should be right or left, having the middle lever-rest slightly to the right or left of the midway position, according to the same rule just cited for the crank.

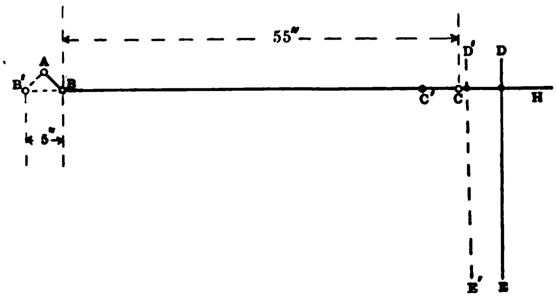

Fig. 109.

A stand having the middle lever-rest 90 deg. from the other two rests or a stand not having the crank of the shaft just exactly the right length for the throw desired, can be made to satisfactorily operate a three-throw or a two-throw switch by setting it slightly skewed on the headblock. The position can be easily found by trial. It will readily occur to anyone that by slightly turning the stand about the axis of the shaft the perpendicular distance from the switch rail to crank-pin will be changed for the middle lever-rest but practically not for the lever in the two extreme rests, since as the stand is skewed around through a small angle either way the crank pin in either of these positions moves parallel to the track. This slight skewing of the stand presents a rather unsightly appearance, when observing it from near by, but it permits of a more satisfactory throw to the rails and it may not seriously interfere with the service of the target; if it does, the target may be moved around slightly. All switch stands for the main track on the same road should throw alike—that is, to avoid confusion, they should all throw either in the same direction as the movement of the switch rails or all in the opposite direction to such movement. The feature of design which determines this matter is whether the lever and crank are both on the same side of the shaft or on opposite sides of the same.

Locating and Setting.—The location of the switch stand on single track is a matter of some importance and has been discussed a good deal.

For convenience of train operation the stand should be on the engineer's side when approaching the switch in the facing direction, as then it is seen to best advantage when "flying in" cars. For stub switches this is undoubtedly the better arrangement, but for split switches the safest arrangement is to put the stand on the turnout side of the track. The explanation in the latter case is that with the stand on the turnout or frog side the connecting rod when holding the switch points to the main-track position is in a state of tension, and any bending of this rod by derailed wheels or dragging parts of cars only pulls the points against the stock rail more firmly. If, however, the stand was on the opposite side, the connecting rod for the same position of the switch would be in compression, and any bending of the same would shorten the rod and tend to open the points. It is also probably true that with two or more switches close together trainmen are not so liable to throw the wrong switch when the stands are arranged in this manner. In some cases, however, it might be advisable to disregard these rules, in order to give the engineer the best view of the stand when approaching the switch; as, for instance, where the switch is so located that the trains must approach it around a curve in a cut, or where the view is obstructed by trees or buildings, in which case the stand would usually be seen to best advantage by placing it on the same side as the outside of the curve. On double tracks at usual distances between centers it is of course necessary to put switch stands of ordinary hight on the outside, and as this is the engineer's side (except in the case of left-hand running) it is, for another good reason, the better arrangement. The stand for a switch on the middle one of three tracks is sometimes placed on the outside and connected by means of a long rod extending across the intervening track, between the ties; otherwise, or if placed between the tracks, a low stand or ground lever must be used.

The stand should be set a good distance clear of the track, so as to avoid being knocked down by a derailed car running out of line. Six feet from the rail is considered a safe distance. Where there are two or more stands near each other on the same side of straight track the shafts and connecting rods should be of variable lengths (by about 2 ft.), so that both targets or both switch lights may be seen distinctly by an engineer approaching the switch. On double track it is well to place the lowest stand in the advance. At switches the roadbed or ballast on the stand side should be graded level with the tops of the ties sufficiently wide for a runway, which should extend about 100 ft. each way from the headblock.

Switch stands should be secured to the headblock by lag screws or by bolts passed up through from below, so that the nuts will be on top where they may be seen. The holes through the base or foot flanges of the stand should be drilled or reamed out so that the lag screws or bolts fit snugly. The way to set a stand properly is to connect it to the switch rails set for main track, square it with the headblock and tack spikes around the sides of the base to hold it temporarily, so that it may be thrown for trial. If lost motion is found it should be taken out before permanently securing the stand. When the stand throws properly for both main track and turnout the position of the bolt holes in the base may be marked, the holes may be bored and the stand bolted fast. In resetting a stand the old bolt or spike holes should be plugged and new holes should be bored. The best plan, however, is to pull the spikes from the headshoes and shift the headblock 2 or 3 ins. lengthwise, so as to get clear of the old holes. A switch stand designed by Mr. A. A. Robinson while chief engineer of the Atchison, Topeka & Santa Fe Ry., has a commendable feature in the shape of depending flanges at the sides of the base, which fit over the edges of the headblock and hold the stand square with the block. Wherever it is practicable to do so, the stand should be so set that when it is turned for main track the crank will stand perpendicular to the direction of the track. In this way the sidewise pressure from the moving rails bears directly against the shaft and its bearings, where otherwise it would operate to revolve the crank. This is called setting the stand "the strong way for the main line" and the arrangement is of importance, since it saves much wear to the parts of the stand by lessening the tendency of the shaft to being revolved by the jarring of passing trains.

Safety Arrangements.—One danger ever present with the switch which has but a single connection with the stand is the liability of the breaking of the connecting rod or the breaking of a bolt in one of the connections of the rod, in which event the jarring effect of a passing train would very likely open the switch. In the case of a switch on straight track, with proper connections carefully attended to, the risk is not great, but on curves the connecting rod of stub switches should not be depended upon to hold the moving rails to place, especially where the throw is toward the outside of the curve; for by reason of the necessary absence of spikes along the moving rails the outward pressure against the rod is consid-

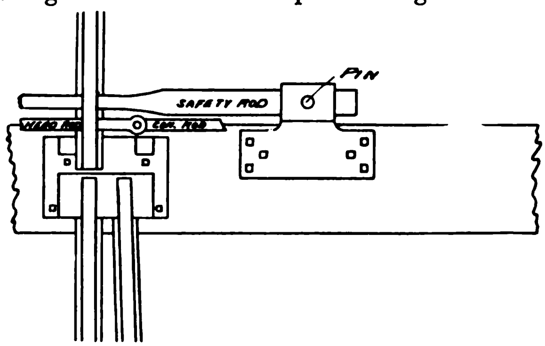

Fig. 110.—Stop Device for Stub Switch.

erable. A stop device frequently used to relieve the connecting rod consists of a switch rod extended a short distance beyond the rail on the stand side, the portion of the rod outside the rail being flattened to slide through a slot in a cast or forged block made fast to the headblock. The stop is effected by a hole and pin, as shown in Fig. 110, the hole in the block coming even with that in the rod for the main-track position of the switch. There should be only one hole in the rod. A latch arrangement used on the Canadian Pacific road consists of a flat notched rod sliding through a block similarly to the one just described. There is a notch in the block even with that in the rod when the switch is set for main track, and in this notch rests a weighted foot lever pivoted to the headblock. It is perhaps more convenient than the rod and pin arrangement. It is the practice with some roads to use a stop or safety attachment on all stub switches. It is questionable, however, whether any device requiring extra manipulation in throwing or locking the switch is to be recommended further than for switches from curves. They are necessarily the cause of some delay in throwing the switch, from which results an occasional blunder and derailment when "flying in" cars. Nevertheless mistakes of this kind cannot offset the security which such appliances afford to fast trains at switches from curves.

With the Flickinger ground-lever switch stand, which is used with both stub and split switches, the safety attachment, although independent of the connecting rod, is operated by the action of the switch stand itself, so that no extra attention need be given to the safety or stop device. Referring to Fig. 111, the barrel or cylinder *A-A* is provided with a screw and turns within the larger cylinder *B*, the latter being provided with a suitable female thread. The pitch of the screw is such that a half revolution (a complete throw of the lever from one side to the other) moves the cylinder a distance corresponding to the throw of the switch. The switch target is placed upon a vertical shaft housed in the frame of the stand, or cylinder *B*, and is revolved by the action of a crank on the cylinder *A*. For use in yards the lever is thrown into latched rests and the mechanism as thus far described constitutes all of the necessary parts of the stand. For use on main line there is an extra piece, marked "safety rod" in the figure, which is attached to the switch rail and slides underneath the stand in coincidence with the movement of the cylinder *A*. The safety rod is adjustable and the pivotal end of the lever is provided with an arm on either side which fits into a

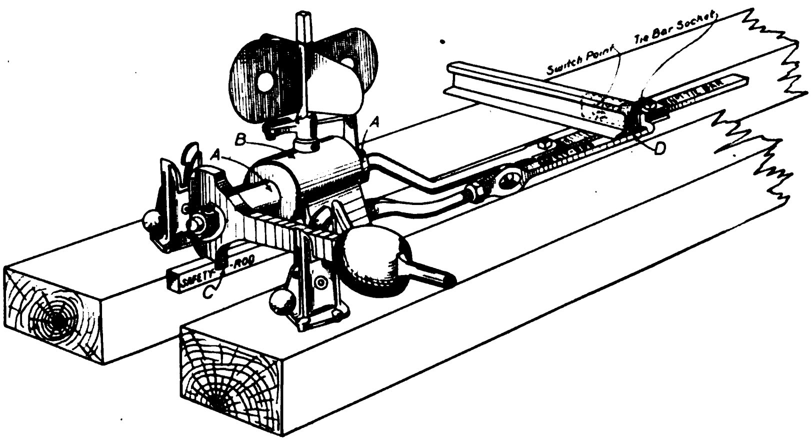

Fig. 111.—Flickinger Switch Stand, L. S. & M. S. Ry.

notch in the safety rod at *C* when the lever is thrown down into its rest. This arrangement insures the holding of the switch rails in their closed position in case the connecting rod should break or become disconnected. This stand is in use on the Lake Shore & Michigan Southern, the Pittsburg & Lake Erie and other roads, on both main line switches and in yards.

Where there is only one connection or means for holding the switch to the main-line position extra precaution is necessary to guard against the accidental disengagement of the connecting rod from the stand or the switch rails. The bolt through the connecting rod and head rod connection should be passed up from below and the nut should be secured with a cotter pin or jamb nuts, or the thread should be ruptured outside the nut. In addition to this a piece of tie or block of suitable size should be embedded in the ballast close under the rod, extending under the range of movement of the bolt, so as to prevent it from dropping out in case it should break or the nut become loose. Whenever the headblock is to be tamped this piece of tie must be taken out, but it can be put back without much trouble. It is considered safer practice, however, to have the connecting rod join directly with the switch rail instead of the head switch rod, as then one connection is avoided and there is one less joint for the development of lost motion. This can be done by using

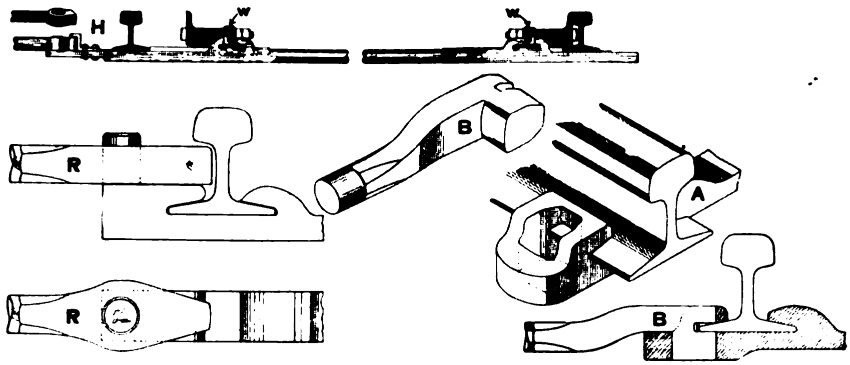

Fig. 112.—Switch Rail Safety Connections—Fig. 113.

a connecting rod which gripes the flange of the rail after the manner of an ordinary switch rod; as does Bar *D*, Fig. 105, or Connecting Rod *A*, Fig. 118. Figure 112 (*R*) shows a head rod connection for stub switches adopted at an early day by the Atchison, Topeka & Santa Fe Ry. and later by the Southern Pacific road. The head rod has a 1½-in. pin projecting upward near its end (Bar *C*, Fig. 105) and the connecting rod is extended to pass under the head of the rail. With the head rod in place the connecting rod must be swung parallel with the rail in order to be connected with, or disconnected from, the former; the connection cannot be broken, therefore, so long as the connecting rod remains attached to the stand. The Elliot company has a similar arrangement known as the "safety end" head rod. As shown in Engraving *H*, Fig. 112, there is a large pin near the end of the head rod, with a "safety clip" to hold the connecting rod from disengagement except when swung parallel with the track.

Figure 113 (*B*) shows another safety connection, used also on the Southern Pacific road. Rods *A* and *B* are locked together and slipped over the end of the rail, from which neither can become detached without reversing the process. Still another arrangement for dispensing with the use of a bolt at the connection between the head rod of a switch and the rod connecting with the switch stand is in use on the Gulf, Colorado & Santa Fe Ry. It was designed by Roadmaster M. O'Dowd and is

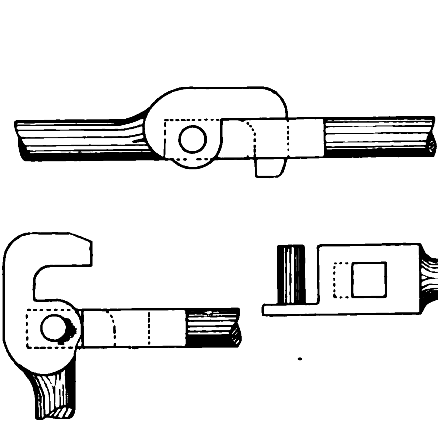

Fig. 114.—O'Dowd Switch Connection, G., C. & S. F. Ry.

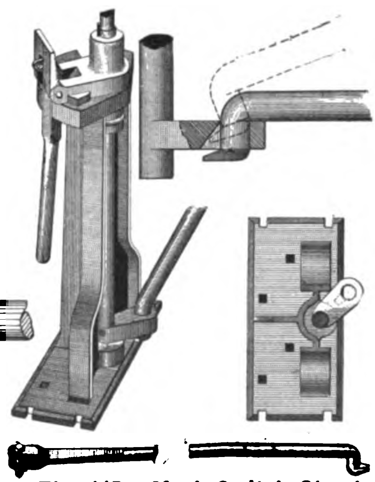

Fig. 115.—Mark Switch Stand.

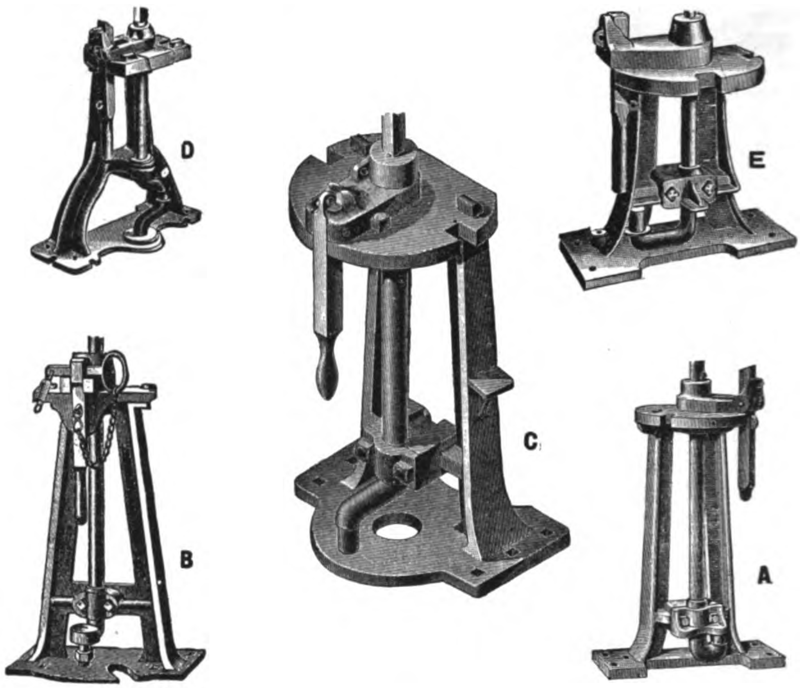

Fig. 116.—Safety Arrangements for Switch Stand Cranks.

used with split switches. Rod No. 1 of the switch, as shown by the lower engraving at the right in Fig. 114, terminates in a head which seats a pin, and through this head there is a rectangular hole. The rod connecting with the switch stand is hinged on this pin and terminates in a hook which enters the hole when the rod is swung to its normal position to be attached to the stand. The two parts thus become interlocked and the rod cannot be swung to the position of disengagement without taking the switch stand from the headblock. Longitudinal stress on the connection is taken by the hook, the pin acting merely to prevent the hook from slipping out of engagement. On some switches of the Baltimore & Ohio Southwestern R. R. the head rod is flat, standing edgewise vertically, and the end of the connecting rod is flattened to correspond, the two being connected by bolting together with two bolts. The connecting rod used with some of the vertical-lever switch stands of the harp pattern on the Baltimore & Ohio R. R. is one solid rod from switch stand to the farthest switch point rail, being fastened to the clips of the point rails and thus serving for both connecting rod and head switch rod.

If the crank pin projects upward, so that the weight of the connecting rod is carried by the crank, a key or cotter put through the pin and spread will secure the connecting rod; but if the pin hangs downward from the crank a key or cotter alone should not be depended upon to hold up the connecting rod. A strip of wood, fish plate or other device should be spiked across the headlock so as to project underneath the rod near the stand, for all positions of the rod, and thus make it impossible for the rod to drop down and become detached from the pin. With the foregoing points in view several of the manufacturing companies have designed stands with special reference to avoiding the use of pin, cotter or nut at the crank pin connection. In the Buda stand *B* and the Weir stand *C*, Fig. 116, the base of the stand is extended so as to embrace the range of motion of the crank. The crank pin hangs downward and meets this extension of the base, so that in stand *C* the rod cannot be disconnected without first taking the stand apart; in stand *B* a notch in the base will permit the rod to be dropped from the crank pin by bringing the crank over the notch and swinging either the stand or the rod around out of its normal position, without disturbing the shaft fastenings. The stand shown as Fig. 117 was got up on the same idea. It was designed in 1881 by the late Mr. W. G. Curtis, engineer maintenance of way of the Southern Pacific road, for use with the connecting rod shown as Fig. 113 (*B*). For an up-turned crank pin the Elliot and Buda stands *A* and *E*, respectively (Fig. 116), provide a "safety bottom cap" in the form of a projection from the lower housing of the shaft, said projection covering the crank pin in the "rest" positions of the crank. On stand *A* the rod can be detached by simply lifting it when the crank is thrown half way, but to do this with stand *E* the crank must be partially thrown and the housing disconnected. It will be noticed that in stands *A, C* and *E* the pin is formed by bending the end of the crank, the shaft, crank and pin constituting a single piece or forging—a simple and commendable arrangement. In stand *D* the shaft is bent into a double crank, to which the rod is attached by a strap connection, as is also the case with the Banner stand, Fig. 118. Rod *A* is used to connect with stub switches and rod *B* with point switches. The Whittemore switch stand (*S*, Fig. 119) is similarly designed respecting the crank and the connection with the same, and the crank and lever throw 180 deg. for a single movement of the switch. The corresponding quarter revolution of the target is effected by means of the gear wheels shown. The lever is attached direct to the crank shaft, or the one to which the smaller gear wheel is keyed. With the Mark switch

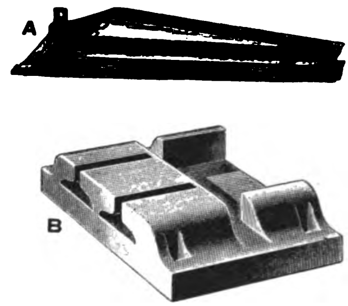

Fig. 120.—Ramapo Headshoe; Green Foot Guard.

stand (Fig. 115) the connecting rod cannot be detached from the stand without first disconnecting it from the switch; it must then be tilted, as shown by the dotted lines, in order to disengage it from the crank.

Targets.—Targets, or day signals used on switch stands to indicate the position of the switch, are arranged in many shapes, but in general they may be divided into three classes; namely, position targets, color targets and shape targets. By the first named term is meant a target formed by a single disc or sheet of metal or other device, which, by its position, indicates the position of the switch; by a color target is meant one having two target sheets or plates set at right angles, the position of the switch being indicated by the color displayed; and a shape target is one which indicates the position of the switch by the shape of the plate

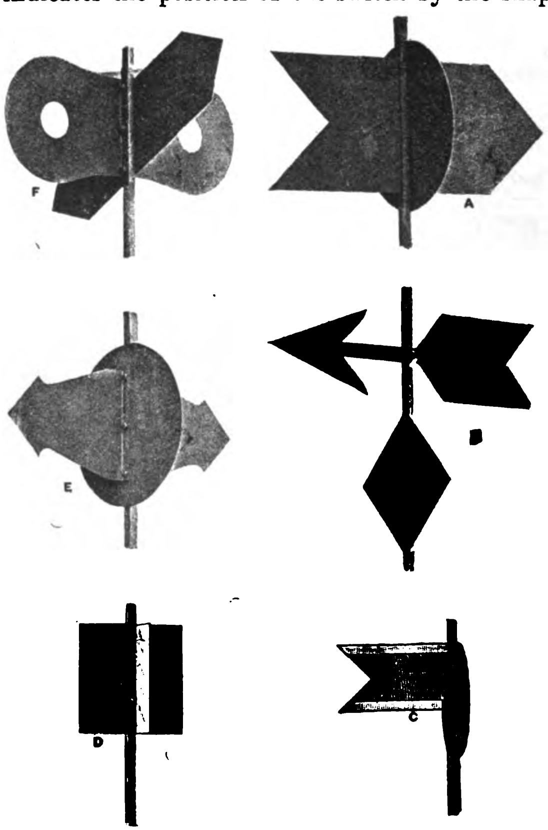

Fig. 121.—Switch Stand Targets.

facing the direction of the track. As a rule the two features of shape and color are combined. On a good many roads the preference is for a position target or signal, a simple form of which is a single piece of sheet metal (Fig. 123) set parallel with the track for the main-track position of the switch, so that it does not show in the direction of the track except when the switch is set for the turnout. This is commonly known as a "blind" target, or one which "shows its edge for safety." It is usually painted red, sometimes with a white trimming, although the color is obviously a secondary matter. There is seemingly only one objection against the use of this target, and that is that in case the target should become detached from the shaft there would be nothing in day time to indicate an open switch. If the target is properly riveted to the shaft this objection is not serious, because the probability of its being knocked or torn off and remaining unnoticed for any considerable time is remote, to say the

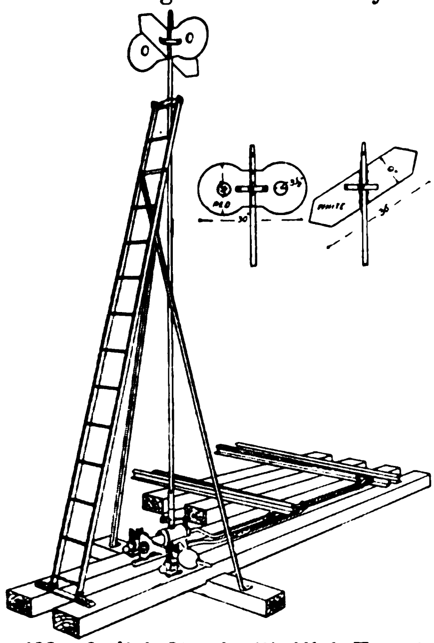

Fig. 122.—Switch Stand with High Target.

Fig. 123.—Elliot Snow Cap Stand.

worst, and, in any case, the same may be said of a target of any kind. Of course it is widely recognized as safe practice to regard the absence of a signal, where there ought to be one, as a danger indication, but as this rule presupposes that the engineman will be able to locate the switch and will bear it in mind before reaching it, the system cannot be considered faultless. As for a night indication there can be no question about the advisability of showing a light for each position of the switch, because it is not an unusual occurrence for switch lights to go out. The standard switch signal of the Chicago & Northwestern Ry. is of the blind target form, but the method of indication is peculiar in that the target shows blind for danger (open switch), or the reverse of ordinary practice. At night, however, the lamp shows green for safety and red for the open position of the switch.

Targets which show both ways should be composed of two entirely distinct shapes. Target *D*, Fig. 121, for instance, is a very undesirable form. During stormy weather or when smoke or steam is blown in front of a target, or at night, the shape is distinguishable more readily than the color. For this reason all the targets on any road ought to be of the same shape, and both position and color targets should not be used on the same road. The position target gives the safer indication at night, and if the switch light has gone out it is at least of some service. Another idea in shape targets is to separate the sign plates for the two indications, as in Engraving *B*, Fig. 121. The standard switch target of the Union Pacific R. R. is a rectangular white plate with a round red plate at right angles and underneath.

The Chicago, Burlington & Quincy and Cleveland, Cincinnati, Chicago & St. Louis ("Big Four") roads use a target having the white plate in the form of a comparatively narrow strip hung to the shaft at an angle of 45 deg. with the horizontal, in which position it somewhat resembles a semaphore arm set at clear. The red plate is set horizontally, or corresponding to the position of a semaphore arm set at danger. In one sense it might be termed a position signal. A target of this description is shown in Fig. 122. It is sometimes called the "semi-semaphore" target.

The target for a three-throw switch stand, where main track is the middle track, is sometimes made to point to the side toward which the switch is thrown. The fish-tail notched targets, *A* and *C*, and the arrow-shaped target *B*, Fig. 121, are examples of this kind. Stands should be set far enough from the track to have the target clear of trainmen hanging to the sides of cars; and, of course, the larger the target the greater must be the distance. Rivets are a more satisfactory fastening for securing the target to the shaft than are bolts, for bolts are the more liable to work loose, and even a slight looseness permits considerable swing in a thin metallic plate or sheet. On sharp curves, on double track, switch targets are sometimes set skewing to the track, so as to show to better advantage at a distance around the curve.

White for the closed position of the switch and bright red for the open position are the colors used almost universally for the targets of switch stands on main track. On double track the back of the white plate of a color target may be painted black or mud color, but for the security of "back-up" movements it is well to have the red plate show both ways. On blind targets there should be a disk or ring of white on the red, as the contrast shows off to good effect at night, red paint not being visible as such in dim light. It is important to have targets show plainly at night; for although switch lamps ought to be used (on all facing-point switches, without any question) they go out sometimes, especially where there is no night watchman or track-walker to care for them. To prevent confusion of signals to trains on main line it is to some extent the practice to avoid the use of red to indicate the open position of switches leading from side-tracks. In some cases of this kind green is substituted for red to show that the switch is open to the main side-track. On the standard switch stand of the Lake Shore & Michigan Southern Ry. the closed position of the switch is indicated by a circular target 16 ins. in diam., painted white for main line and green for side-tracks. The red target, showing the open position of the switch, is rectangular (16x24 ins.) for both main line and side-tracks.

To keep switch targets looking fresh and distinct in color they should be frequently painted. The rules of some roads require such painting to be done every six months or during the spring and fall of each year. A sheet of rusty iron does not readily catch the eye at a distance in cloudy weather. Targets are discolored by the greasy hands of lamp lighters and of brakemen who take hold of the target when throwing the switch. The appearance of the targets may be much improved, therefore, by washing them about once each month or two, when the paint may be made to appear nearly as fresh as when first put on. This practice of washing targets at intervals of a few weeks is in vogue on some roads. On a few roads, one of which is the Grand Trunk Ry., enameled switch targets have been used experimentally, the idea being that by cleaning them occasionally, repainting is unnecessary.

Dwarf and Ground-Lever Stands.—The most usual hight of switch stands for main track is 6½ to 8 ft. to top of target staff. When particularly designated, such is known as an "intermediate" stand. In yards, where the tracks are close together, there is not room for stands of intermediate hight, so that dwarf or pony stands (2½ to 4 ft. high to top of target) and ground or horizontal stands must be used. A dwarf switch stand extensively used in yards and side-tracks on the Denver & Rio Grande R. R. is designed with a yoke lying horizontally over the top of the stand casting or frame and keyed to the upright shaft. A circular red

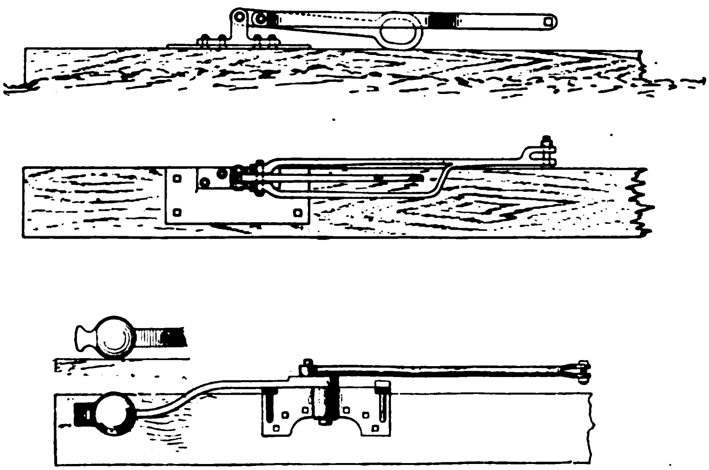

Fig. 124.—Ground-Lever Switch Stands.

target, to show the open position of the switch, is attached to each end of this yoke and hangs at the side of the stand. The arrangement thus provides a red target at each side of the stand, lower than the top of the stand casting and out of the way of poling. There is no target showing when the switch is closed, as when it is in that position the red targets show edgewise. Lights should be placed on dwarf stands to prevent trainmen from running into them in the dark.

In the less frequented parts of yards a simple ground-lever stand or tumbling lever is much used. One form has a heavy ball on the end of the lever (Fig. 124) so that the switch may be held in place without locking or latching. Such are commonly known as "drop-lever" stands. With ground levers weighted at the end it is not necessary to throw the lever as far as the dead center in order to hold the switch to place, and so for unusual pressure, as when point rails are trailed through, the stand will throw automatically, if not latched or locked. Figures 124, 125, 126 and 127 show other forms of ground-throw stands, those in the last two figures being for three-throw stub switches. With these stands either one of the double levers may be thrown to move the switch into the middle position, and then by throwing the other lever the switch is moved into the second position. By throwing both levers at the same time the switch may be moved from one extreme position to the opposite extremity. Figure 125 shows a ground lever equipped with a target and lamp rest, being low enough to permit the poling of freight cars over it when the lamp is on. For lack of room ground-lever or drop-lever stands are sometimes placed in the middle of the track, as in Fig. 135, being attached to the head switch rod by means of a short connecting rod. In this position the stand is not conveniently placed for flying in cars.

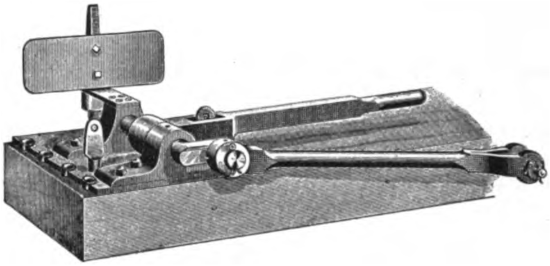

Fig. 125.—Ground-Lever Switch Stand with Target.

The standard switch stand of the Pennsylvania R. R., for both main track and sidings, is a simple ground lever attached to the switch points through a Lorenz spring on the head rod. Revolving stands are not used. On some of the divisions on the main line of this road the use of signals at trailing switches at outlying points and at stations where but little switching is done is dispensed with, there being neither targets nor switch lights. The practice of dispensing with switch lights and targets on trailing point switches on double track is also standard with the Pennsylvania Lines West.

By a bevel gear or other arrangement the levers of some ground stands are made to throw in a direction parallel with the track. They are the safer stand to use while cars are moving on an adjoining track, since the operator is in danger of being struck while handling a lever which throws crosswise between the tracks. The upper stand in Fig. 128 is of this kind. It is provided with a latch to hold the lever securely in the main-track position. The latch, shown in detail as Engraving *H*, Fig. 119, is weighted to swing over the lever. To release the lever the latch must be raised, which can be done either with the hand or the foot. A foot tripping device is shown on the latch illustrated with the "Low-Target Pattern" in Fig. 129A, and more in detail in Fig. 132A, the side of the casting in the latter case being broken to show the engagement of the foot trip with the latch. By means of a spring key inserted through a hole in the base casting the latch may be held out of engagement with the lever, permitting the stand to act automatically. For locking the

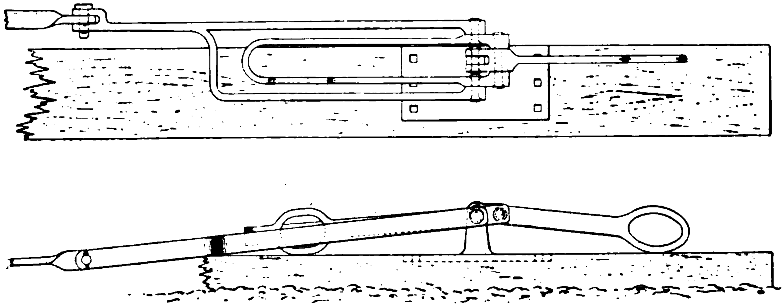

Fig. 126.—Three-Throw Ground-Lever Switch Stand.

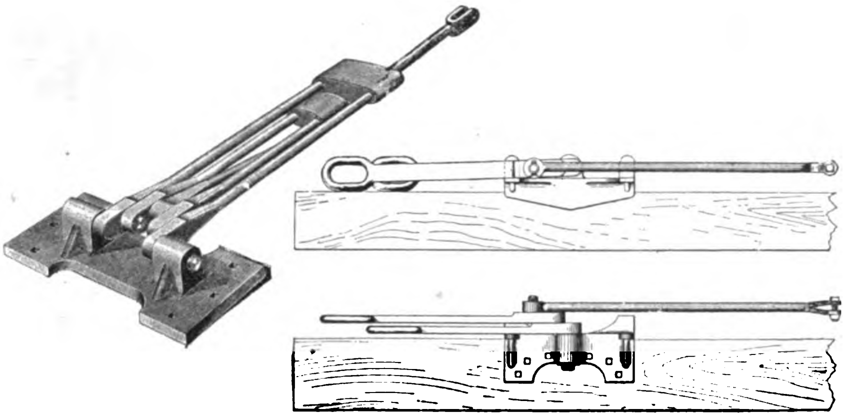

Fig. 127.—Three-Throw Ground-Lever Switch Stands.

switch there is a hole near the top of the latch in which a padlock may be used.

There are several patterns of parallel-throw ground stands working on the bevel-gear principle. Among the devices in service are the "Crown," the "Globe" and the "New Century" stands. The last named of these is illustrated in Fig. 129A. A semi-circular iron case encloses a bevel pinion on the axial shaft of a weighted lever, which engages with a bevel gear segment on the vertical crank spindle. The end of the weight on the lever has a deep recess providing a convenient hand hold for raising the lever. When not latched or locked the stand will permit automatic operation of the switch. The upper edge of the target stands 17 ins. above the tops of the ties. By means of a coupling shown in the engraving at the right of the figure, a target staff may be attached to the vertical spindle of the stand, supporting a target at the ordinary hight (about 7 ft. above the ties) for main-line service. On several of the southern rail-

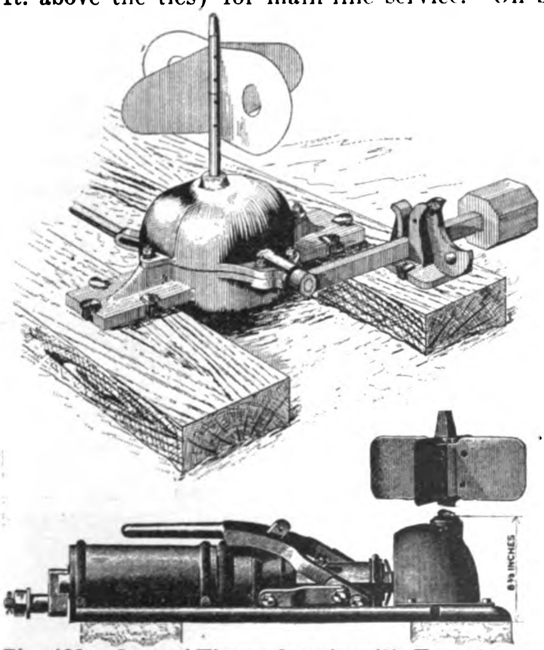

Fig. 128.—Ground-Throw Stands with Targets.

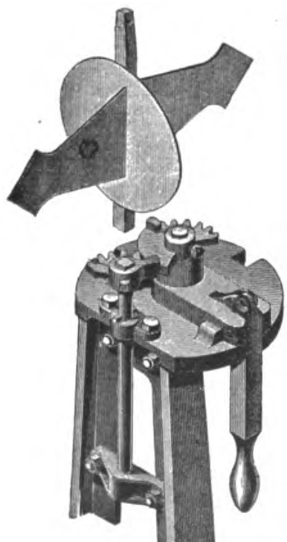

Fig. 129.

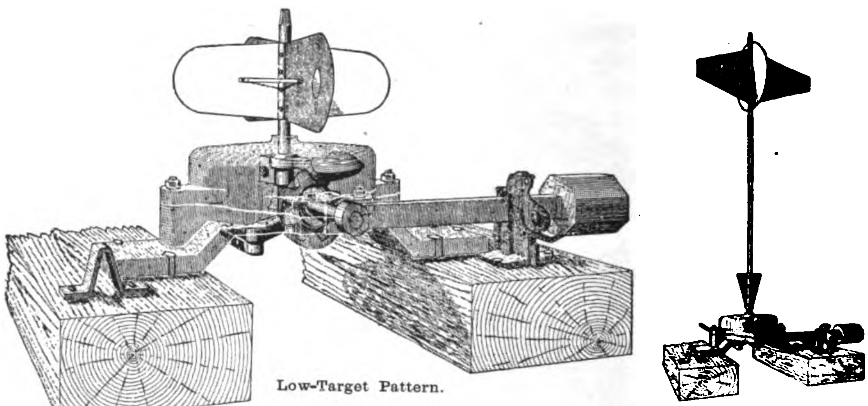

Seven-Ft. Target Pattern.

Fig. 129 A.—New Century Switch Stand.

roads this "7-ft target pattern" is the standard for main-line switches. The side projecting flanges of the coupling serve for a step when placing the lamp in position.

Another parallel-throw ground stand with low revolving target is the Odenkirk pattern, in use on the Pennsylvania and the New York, Chicago & St. Louis ("Nickel Plate") roads. Referring to Fig. 130, the base or main casting which forms a box enclosing the working parts is cylindrical, and within this cylinder a so-called cam *C* revolves, the throwing lever being attached at the right-hand end of the shaft *S*. This cam is a round casting with a helicoidal groove 2 ins. wide running half way around on each side. A sliding rod *O* operates directly beneath the cam, the inner end of the rod carrying a pin *P*, upon which revolves the roller *R*. As the cam is turned over by the lever this roller follows the groove, moving the sliding rod to and fro. The connecting rod running to the switch rails is joined onto the sliding rod by the bolt *T*. The distance *A-B* is the throw of the switch. The mechanism is simple and includes no gears. The roller is case-hardened and is supposed to stand the wear very well, operate easily and with practically no lost motion. The banner signal is revolved by means of a small crank at the lower end of its shaft, the crank being moved by a projection on the sliding bar *O*. All these parts are tightly enclosed within the base casting and are free from dust, snow and ice. They are accessible by removing the cover plate *L* from the end of the base casting by taking off the three nuts shown in the figure. The same stand with a low sema-

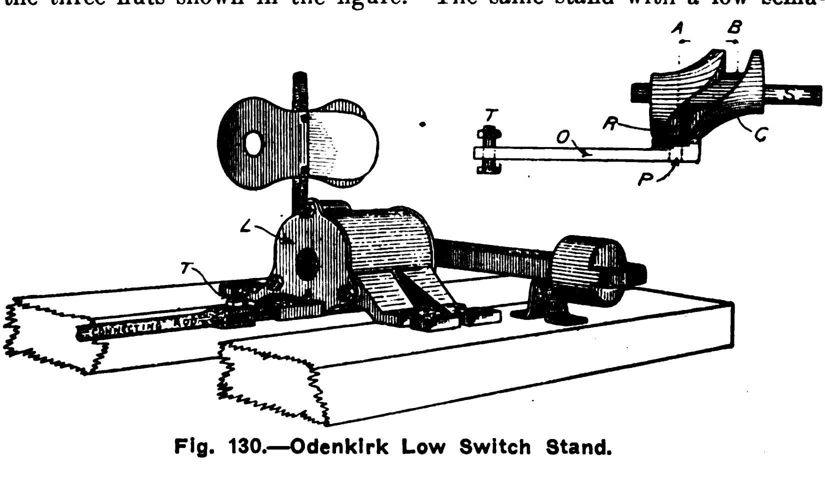

Fig. 130.—Odenkirk Low Switch Stand.

phore arm is shown as Fig. 131. By a slight modification in the shape of the cam and the omission of a lock or latch the stand is made to throw automatically when the switch is "run through." The lower stand in Fig. 128 is the Ramapo pattern, the automatic feature of which is explained farther along. The lever of this stand, after being lifted from its rest, is thrown in a direction crosswise the track. In point of construction it is essentially a vertical stand laid horizontally.

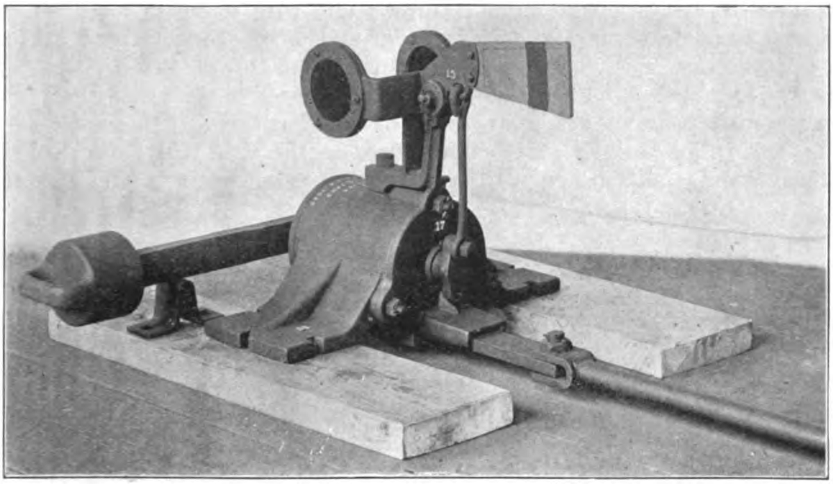

Fig. 131.—Odenkirk Switch Stand with Low Semaphore.

Another style of low switch stand operating on the cam principle consists principally of a drum and slot. The Stoney drum switch stand, designed by Chief Engineer E. W. Stoney, of the Madras Ry. (India), and extensively used on that road, is shown as Fig. 132. This device comprises a cast-iron cylinder or barrel which turns on an axle fixed in a suitable casting, being actuated by a weighted lever handle centered on the same axle, and passing through a short slot in the drum. The switch is moved direct by a roller on a pin fixed to the connecting rod. This roller fits in, and is driven by, a spiral slot S in the drum. The handle requires only a light weight to

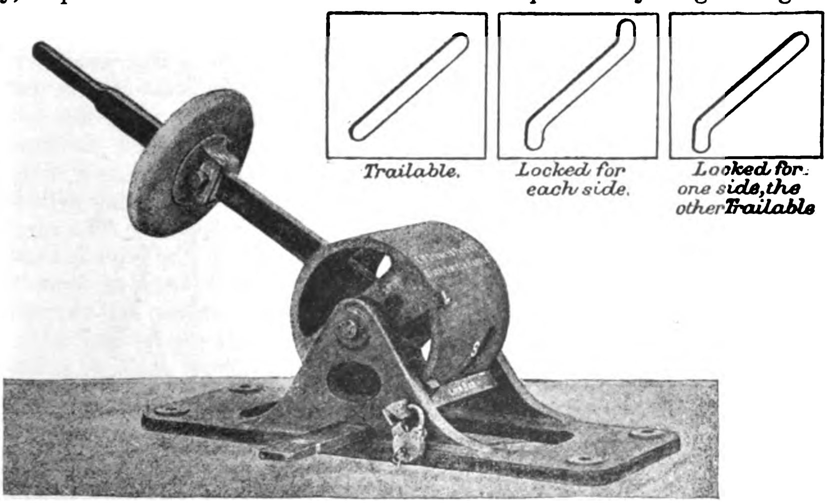

Fig. 132.—Stoney Drum Switch Stand.

hold the points and works easily. It is made either trailable, or, by simply turning the lever over, to lock the switch dead to one or both sides, or so that it shall be locked for one side and trailable for the other. This arrangement is effected by simply altering the shape of the slot in the drum which actuates the connecting rod, as explained by the line engravings in the figure and the accompanying legends. The drum may be further locked, so as not to be moved, by a simple sliding locking bar secured by a padlock, as shown. In this country there are switch stands designed on the same principle. One of these devices is a Weir ground-throw stand with weighted lever, which, when not padlocked, is automatic, like one style of the Stoney stand, and, as is also the case with the Stoney stand, the lever throws parallel with the track. The Weir stand has a revolving target geared to the barrel shaft, and its general appearance is similar to that of the Weir three-throw switch stand Fig. 163. The Wrigley switch stand, used on the Erie R. R., has, like the Stoney stand, a slotted drum, which operates a balance lever attached to the

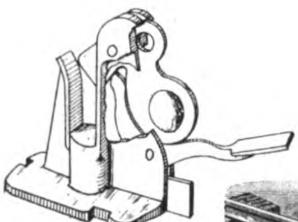

Fig. 132 A.

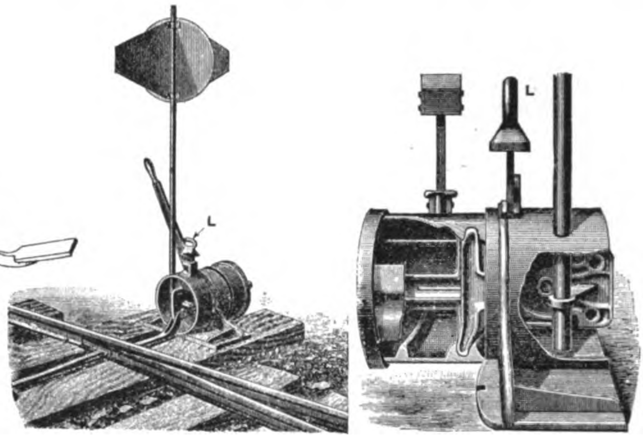

Fig. 132 B.—Monitor Switch Stand, Hocking Valley Ry.

switch connecting rod. It can be made to throw automatically in one or both directions. It has a revolving target 17 ins. above the tie face and has an attachment for working a detector bar, if desired.

The Monitor switch stand, which has been standard with the Hocking Valley and the Baltimore & Ohio Southwestern roads a long time, works on the principle of a screw. The stand and parts are shown in Fig. 132B. The frame of the stand consists of a base plate and cylinder cast in one piece. This stationary cylinder is grooved to receive the end of a revolving cylinder. The revolving cylinder is closed at the outer end, and through a slot in a head or partition of the stationary cylinder there is a sliding bar worked by a disk fitting a screw on the inside of the revolving cylinder. This sliding bar is coupled to the connecting rod of the switch. The revolving cylinder is provided with a socket for a lever, and as the lever is turned the sliding bar is actuated by the screw and moves toward or from the track in a straight line. There are no springs or gear wheels, and the working parts are completely housed from snow and ice. It can be used with or without a staff and target. For yard service the revolving cylinder is fitted with a weighted drop lever, which will permit the stand to throw automatically if the switch points are trailed when wrongly set. For main-track service there is a hand latch (L) which drops automatically into a notch in the sliding bar as soon as the switch is thrown home. This latch relieves the screw mechanism of all strain from passing trains. In throwing the switch it is necessary to first lift the latch from its seat. The stand is locked by securing the latch with a padlock at a notch in the latch sleeve. If the stand is to be used for an automatic trailing switch for main line it should not latch when thrown for the siding. In that case a weighted drop lever is used to hold the switch in position. The target shaft fits the socket of the shifting arm in a square hole, and if, in setting the stand, the colors of the target are not right, it is only necessary to raise the staff out of the socket and give it a quarter turn.

For three-throw switches, where the main line is the middle track, an ordinary stand throwing 180 deg. will answer, because by setting the target to show safety for the middle position it or the switch light will show danger when the stand is turned for either of the other tracks. By a specially arranged target the signal will indicate in daytime to which of the two side-tracks the switch is set. As already shown, the target is sometimes made arrow-shaped, so as to point toward the side on which the switch is set. The necessity for arranging the target to indicate the position of the switch, however, is not as great as a corresponding arrangement for the switch light, for on straight track the position of the switch may easily be seen a considerable distance in daytime, whereas such is not the case at night. The photographic view in Fig. 134A shows an arrangement used by the Duluth South Shore & Atlantic Ry. to indicate the position of a three-throw switch at night. The switch is of the stub pattern, and the switch stand is of ordinary construction, with the top table notched for three positions of the lever. The target is of the ordinary pattern which shows a disc when the switch is set for main track and blind when the switch is set for either siding. Bolted to one side of the switch stand there is an upright frame (*BB*) carrying at the top a rectan-

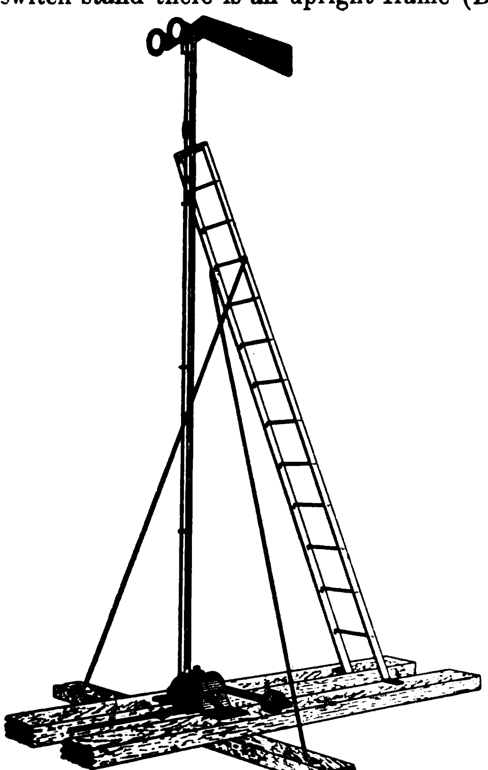

Fig. 133.—Ground-Throw Stand and High Semaphore.

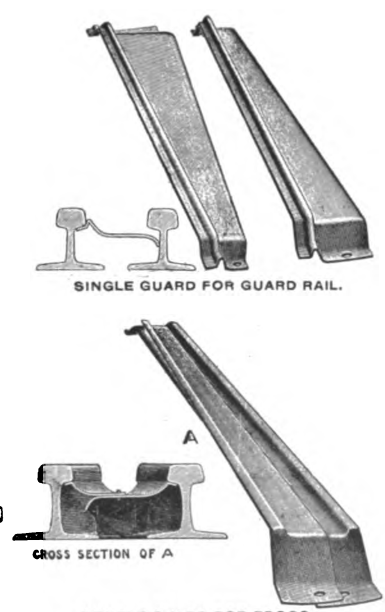

Fig. 134.—Sheffield Foot Guard.

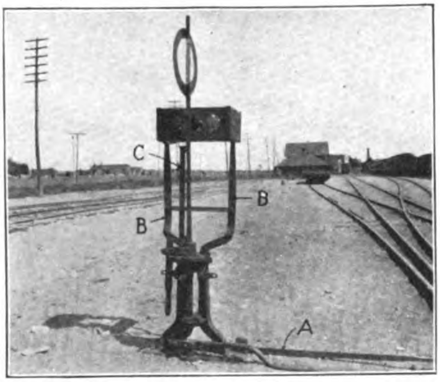

Signal Lights for a Three-Throw Switch, D., S. S. & A. Ry.

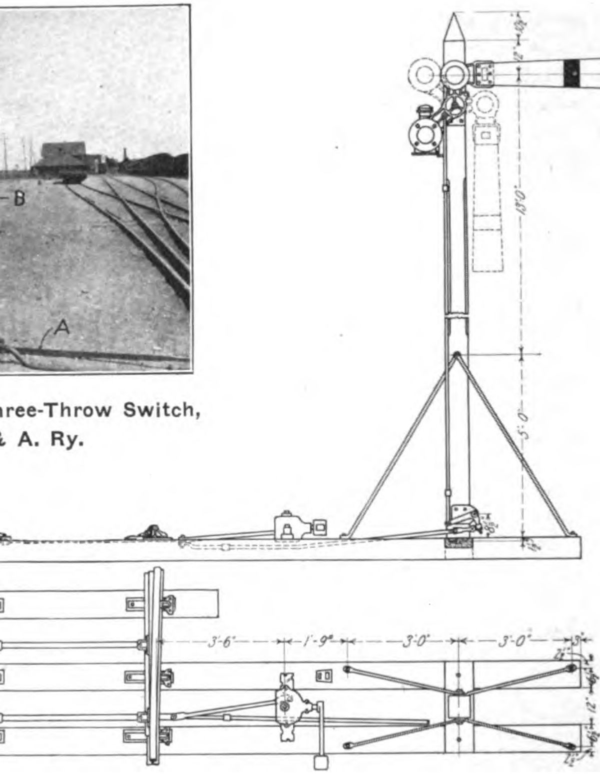

Fig. 134 A.—High Semaphore Switch Signal, Pennsylvania Lines West.

gular wooden box open top and bottom. In two sides of this box there are three lenses in a row, the colors from left to right (as seen in the picture) being red, green and white. Attached to the moving rails of the switch there is a rod (*A*) sliding through a guide at the bottom of the switch stand and bent to stand in an upright position (*C*). This upright rod (*C*) carries the switch light inside of the box. In any of the set positions of the switch this light shines through one of the bull's-eyes and indicates by the color of the light the position of the switch. For instance, if the switch is set for the main track the light will shine through the middle or green bull's-eye, giving a green light. If the switch is set for the left-hand siding there will be a red light, and if it is set for the right-hand siding there will be a white light.

When both turnouts are on the same side of the main track an ordinary stand thrown to the first shows danger but when thrown to the second it shows safety. For a switch of this kind a stand having a specially arranged target-revolving device is required, so that danger will be shown when the stand is thrown for either turnout. There is a Weir stand of this kind having the target arranged upon a separate shaft, which is so geared with the main shaft of the stand (see Fig. 129) that when turned from the main track position to that for the first turnout it is thrown out of gear and locked fast against further turning when throwing the stand for the other turnout. When thrown back to main track the gears engage, as the idle quarter of the driving gear is passed, and the target revolves back to safety. Stands for three-throw point switches and automatic stands for point switches are taken up in connection with those subjects, further along in this chapter (§ 71 and 68).

High Targets.—The question of safety for high-speed trains has led some roads into the use of high switch targets that may be seen over the tops of cars, over shallow cuts in curves, or other obstruction; or at a long distance on straight line. The usual arrangement consists of a ground-lever stand connected to a braced target rod or shaft 12 to 18 ft. high. The target shaft is braced by an inclined ladder running from the end of a long headblock and stayed sidewise by angle irons or pipes footing into a cross piece framed into the headblock, as shown in Figs. 122 and 133. On some roads the target is set on a collared shaft resting in bearings on a post or framing independent of the stand, so as to be free from the jarring, which might put out the switch light. The shaft is then connected with the switch rails or to the stand. The ground-lever type of stand used in connection with a high signal is coming more and more into use, and is standard on the Southern Ry., the Pennsylvania Lines West, the Cleveland, Cincinnati, Chicago & St. Louis and other roads. On the Southern Ry. the standard arrangement for throwing and signaling switches is a New Century switch stand with a large revolving target on a staff about 17 ft. high, braced with ladder and stay rods as in Fig. 122. On the P. L. W. the standard switch signal at high-speed points is a semaphore blade 18 ft. high on a wooden pole standing 8½ ft. from the rail, at the switch. A parallel-throw ground-lever stand is connected with both switch and signal, as shown in Fig. 134A. A similar or like arrangement is also in use on the Peoria & Eastern division of the C., C., C. & St. L. Ry. Under dangerous conditions the P. L. W. use a distant switch signal in addition to the semaphore at the switch (See also §213, Suppl. Notes).

Switch Locks.—The almost universal arrangement for locking switches is to padlock the lever of the stand. Numerous devices have been invented to dispense with padlocks on switch stands and the extra movements attending the use of the same when locking or unlocking the stand, but such have never come into extensive service. There are, however, in practical use a few patterns of switch stand designed with a self-contained lock. A number of stands of this description have been in use on the Burlington & Missouri R. R. since 1896, giving satisfactory service. The stand was designed by Mr. T. E. Calvert, general superintendent, and in addition to the permanently attached lock it is also arranged to permit the automatic operation of the switch when the stand is set in either of the rest positions. Referring to Fig. 134B, there is a hollow lever *S*, one end of which encircles the main shaft of the stand without being rigidly attached. At the outer end of this lever there is hinged a handle *M*, which normally drops to a vertical position into a notch in the outer rim of the stand table *R*. Rigidly attached to the main shaft *T* by means of a bolt and key there is a star-shaped interlocking head or pinion *N*, and fitting tightly into one of the recesses of this head is an interlocking bolt *L* with an arrow-shaped head. At the other end this bolt terminates in a stud, as shown in the perspective view, Sketch 9. A coiled spring holds the head of the bolt into engagement with the interlocking head under all conditions. The lock *P*, Sketch 1, is in an opening in the side of the lever, being slipped into place from the inside before the interlocking bolt and spring are inserted. It is then held in place by a coiled spring. When the handle *M* is in the normal position the bolt *Y* of the lock, Sketch 5, fits into a slot in the head of the handle made by cutting away on one side of the radial opening *m*. A perspective view of the handle and the locking slot is shown as Sketch 8. In this manner the handle is locked in position. After the key has been inserted, the locking bolt *Y* pulled back and the handle raised, the solid face of the circular head on the handle holds the lock bolt back (Sketch 6) and the key cannot be turned to be withdrawn until the switch has been moved to such position that the handle may again be dropped to its normal position; so that the handle must be in the rest notch at one side of the table, and in normal position, before the key can be removed. Where it is desired that the key may be withdrawn only when the switch is set and locked for main line, a small bolt *W* is screwed into the rest notch at the side-track side of the table (Sketch 7), so as to prevent the handle *M* from dropping to normal position on that side, and make it impossible to withdraw the key when the switch is set for side-track. This arrangement necessitates throwing the handle back to the main-track side and the locking of the stand before the key can be removed.

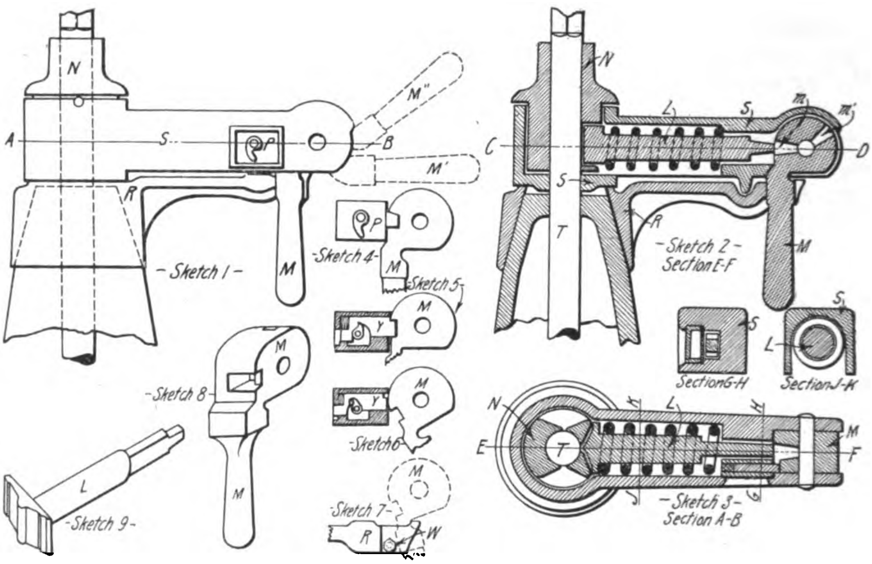

Fig. 134 B—Automatic Switch Stand with Self-Contained Lock, B. & M. R. R. R.

Another aim in getting up the design was to make a stand which would be automatic when thrown and locked, but rigidly connected while being thrown, so that if snow or other obstruction should prevent the switch point from closing against the stock rail the switch stand lever could not be thrown into the rest position and locked. As a means to this end, the head of the handle *M* when raised to the horizontal position, as shown in Sketch 1 at *M′*, bears tightly against the interlocking bolt, holding the same into rigid engagement with the interlocking head *N*, so that while the switch is being thrown this bolt is prevented from any backward movement and the shaft *T* cannot revolve except with the lever. In the head of the handle *M* there is a radial opening *m* (Sketch 2), and when the handle is dropped to the vertical or normal position this opening stands opposite the stud end of the interlocking bolt *L*, permitting the bolt to recede from its normal position in case sufficient force should be applied to the crank of the stand to revolve the interlocking head against the action of the interlocking bolt and spring. Thus the stand is rigidly connected while being thrown and automatic when locked. For automatic operation the tips of the interlocking bolt are so shaped that during the first part of the automatic action the switch starts hard. The movement then becomes easier until the center of the throw is reached, when a rib at the extreme end of the bolt again resists the throwing action until considerable force is applied. If the switch is moved past the center the pressure of the spring on the bolt will quickly force around the interlocking head and complete the throw of the switch, but if pressure on the switch points is released before the center point is passed the action of the spring on the interlocking bolt will operate to quickly throw the switch back to place. Thus, should a car or locomotive trail against the switch points when set in the wrong position, without running through them far enough to throw the tip of the interlocking head past the dead center, the points will be returned to place against the stock rail as soon as the train backs away. It will be noticed that the interlocking head has three recesses (Sketch 3), two of which are disposed at right angles to the one shown in engagement with the interlocking bolt. This arrangement allows the shaft to be turned a quarter of a revolution in relation to the interlocking bolt, thus permitting the throw of the stand to be changed from right to left, or vice versa, without changing the position of the stand. In order to return the interlocking bolt *L* to its proper recess in the head *N* after the switch has been "run through" and thrown automatically, there is a second radial opening *m'* in the head of the handle *M*, Sketch 2. By turning the handle up to the position *M''* (Sketch 1) this opening is brought opposite the stud end of the interlocking bolt *L*, permitting the bolt to recede and the lever to be swung around on the interlocking head, thus bringing the interlocking bolt and head again into their customary relative position.

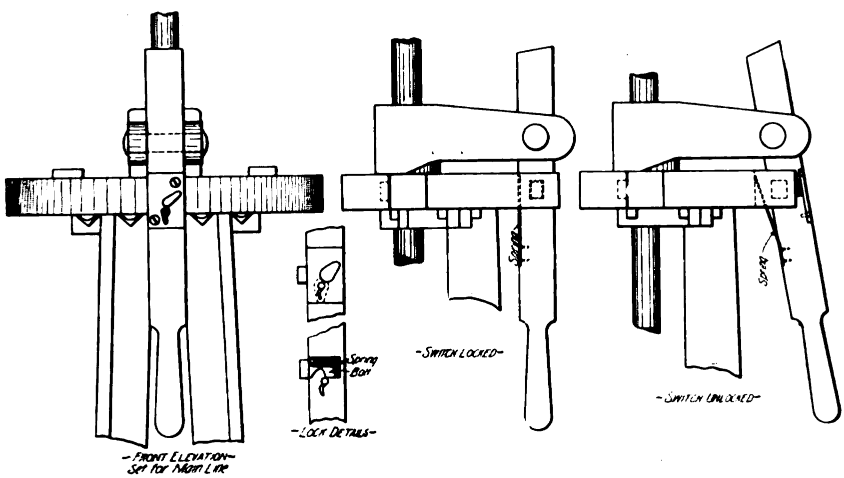

Fig. 134 C.—Cafferty-Knox Lever Lock for Switch Stand.

The Automatic Safety Lock switch stand has, like the one already described; an enclosed lock within the lever of the stand. This stand, with its lever, latch and cap are shown by the three engravings in Fig. 136. A vertical cover actuated by a coiled spring affords protection to the keyhole. This cover moves directly upward between guides, thus making it possible for trainmen to introduce the key, unlock and throw the switch with one hand, as at night, when carrying a lantern. The lever is released by pulling the safety latch, after unlocking the stand with the key. Engravings *A* and *B* show the two positions in which the latch may be set. The latch catches in one position (Engr. *A*) before the locking bolt comes into action, and in that position it secures the switch without locking the stand. This arrangement is for convenience when shifting cars. Permanent locking is effected by compressing the latch and throwing the lever up against the shoulders of the locking stud, whereupon the locking bolt falls and the switch cannot then be thrown without the use of the key. The stand in the locked position is shown by Engr. *B*. It is used on the Mexican International and some other roads.

The Cafferty-Knox lever lock for switch stands, designed by Mr. T. S. Cafferty, roadmaster with the Atchison, Topeka and Santa Fe Ry., and Mr. Wm. F. Knox, is a simple locking mechanism consisting of an ordinary spring bolt lock, placed within the switch stand lever and engaging with a lock notch cut into the side of the lever rest in the table of the stand. As the lever locks automatically when closed into the rest notch, a spring is provided which holds the lever outward to prevent it from locking when it is not pressed home, or as it would be left while switching. The lock is applied to the lever by planing or filing out a recess in the front side and covering the same with a plate screwed on. It can be applied to any drop-lever stand that works in the ordinary manner. It is

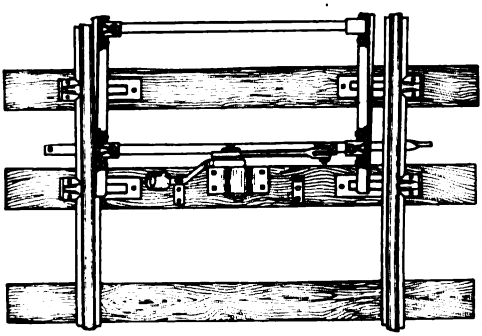

Fig. 135.—Ground-Lever Stand in Track.

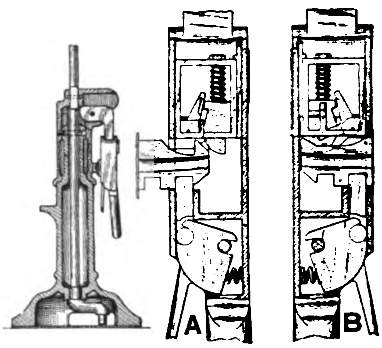

Fig. 136.—Automatic Safety Lock Switch Stand.

not necessary that a new handle be used, as the lock can be placed in the old handle equally as well as in a new one, after which all that is necessary to do is to chip a notch in the top plate of the stand to receive the bolt from the lock. Figure 134C shows the lock as applied to a stand of ordinary pattern. The engraving at the left shows the position of the keyhole in the front of the lever, and the small engraving shows the lock details. The engraving at the right of the figure shows the position of the parts when the switch is unlocked, with the lever still resting in its notch in the table, as it would be left while switching.

Advantages claimed for switch stands with enclosed locks, additional to those already indicated, are that the lock is boxed in out of the way, where it cannot be knocked off or easily tampered with by malicious persons; it cannot fall down into the mud or snow; and, what amounts to a matter of considerable economy, it can be used only for a switch lock. It cannot be used for locking a boat, a barn, a coal shed or other private property, whereon may usually be found no small percentage of the switch locks issued by railroads from time to time.

It is a good plan to lubricate the inside works of switch locks with a few drops of oil occasionally. With such treatment they will work easier and last longer. When locks get dry or rusty, so that the key turns hard, or if the parts become so worn that the key will not work the first time, the train men are quite likely to break them.

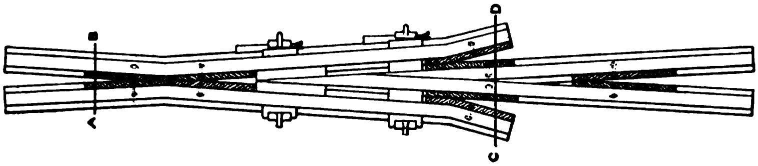
63. Headblocks.—Fifteen feet is the usual length for headblocks, and 8x14 ins. or 8x16 ins. about the proper size. Eight inches thickness gives good stiffness. It is difficult to properly tamp a headblock which is thicker than this; and for the same reason the adjoining ties each side of the headblock should not be too close. A good width is the best provision against settlement. Sawed headblocks are the better, but hewn ones do very well if the upper face is not winding. In laying a headblock the bed should not be dug out for it quite as deep as the combined thickness of headblock and headshoe under base of rail. It is better to leave it above ½ in. high, on a firm bed, after the headshoes are in place. Headblocks should be placed squarely across the main track and the joints between switch and lead rails should be exactly opposite. The headblock for point or split switches is often made double or of two pieces, each about 6x8, or 7x9 ins. in size, placed far enough apart to let in the Lorenz spring, if one is used on the head rod, and framed together at the ends.

64. Switch Ties.—Switch ties vary in length from 8½ ft. next the headblock of stub switches or at the heel of point switches, up to 14 ft. under the frog. Except for appearance, though, the first five or six ties under the lead rails next the headblock in a stub switch, may just as well be the common 8-ft. ties. It adds much to the appearance of things to have all the ends on the turnout side cut off the same distance from the lead rail of the turnout, or at any rate to have the lengths vary uniformly between the headblock and the last long tie under or beyond the frog. Where this is not done it is usual to base the order on 36 ties, in sets of three each, varying in length by 6 ins., from 8½ ft. up to 14 ft. and if more or less are needed one tie is added to or taken from each of so many of the sets of three. For a No. 9 frog 39 6x8-in. ties, or 38 7x9-in. ties, spaced 12 ins. apart in the clear, in either case, would be needed, the extra three being accounted for by including an extra tie in that many of the sets. Extra sets of 14½-ft. and 15-ft. ties (and in some instances 15½-ft. and 16-ft. ties) should be included and be placed beyond the frog, to avoid running the short ties of the side-track in between the ends of main-track ties where the two tracks separate. The number of ties required in any case is readily ascertained by dividing the whole distance by the sum of the space in the clear and the width of one tie face.

Ties for ordinary three-throw switch turnouts vary from 9 ft. next the headblock, up to 20 ft. at the heels of the two main frogs. The length of any tie may be found by doubling the length of the corresponding tie in a single turnout and subtracting the length of the standard track tie. The same number is required as for a two-throw switch. In laying switch ties for three-throw switches the middle of the tie should be placed on the center line of the middle track. This is readily done by marking the middle of the tie and using the track gage to get center. In three-throw switches where the main frogs are not placed opposite each other the length of any switch tie may be found by adding the two tie lengths corresponding to that position in both turnouts and subtracting from such sum the length of the standard track tie. The middle of the tie will then not come at the center of the middle track, but on that side of the center which is toward the shorter turnout, a distance equal to half the difference between the lengths of ties corresponding to its position in the two turnouts.

In two-throw switches it is not always advisable to put in long switch ties. If the turnout is laid for only temporary use it is a waste of labor and material to take out short ties, put in long ones, and then again to replace the long ones with short ties when the turnout is torn up. Short ties answer just as well for *ties* in turnouts as long ones do, the difference being that in case the track between headblock and frog gets out of surface long ties can be much easier and better tamped than short ones;

because the short ties in main and turnout leads must be so interlaid that there is little room left between them for tamping, except to work lengthwise under their ends. For six or eight ties next the headblock the main-track ties answer for the rails of both tracks, so that when short ties are used instead of long ones no ties for the turnout should be placed between the main-track ties as far as the turnout rails can be properly spiked to the main-track ties. The outside rail of the turnout curve should in any case be spiked to an occasional main-track tie, to prevent the turnout rails being crowded out of line in case of derailment. Whichever kind of tie is used (long or short) the spacing under the frog should be such that the toe and heel are made supported joints and a tie is placed directly under the point of frog, or as nearly thereto as may be allowable, with clamp frogs. Under point switches the ties must be spaced with reference to the tie rods.



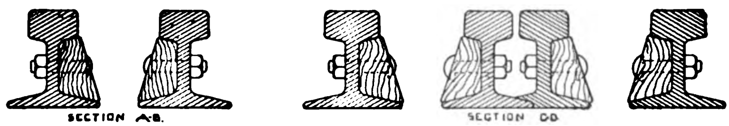


Fig. 137.—The Hart Foot Guard.

Where long switch ties are used in turnouts from the outside of curves, the elevation of the main-track curve comes the wrong way for the turnout curve. While this does not matter for the speed ordinarily made through turnouts, it makes a bad sort of arrangement in the turnout track where it leaves the switch ties, beyond the frog; for at this point the inside rail of the turnout curve is necessarily quite high. By using short ties instead of long ones a much better arrangement for the turnout curve can be made throughout, as it can then be made level across, opposite the frog, or the inside rail of the turnout curve may then be made lower than the outside one, without regard to the elevation in the main track.

65. Foot Guards.—Between two rails lying less than about 6 ins. apart in the clear, at the heads, there is a bootjack space from which one's foot, if caught, cannot be quickly released. Many trainmen have been trapped in such places while coupling cars and have been killed or injured. The laws of many of the states now require some form of guard to prevent feet from being caught in this way. The wings, mouth, and heel of frogs; guard rails, the lead rails at the toe of stub switches or the heel of point switches; or wherever the heads of two rails are more than 2 ins. and less than 6 ins. apart—should be blocked in such a manner that a foot cannot get caught between the lower corners of the rail heads.

Pieces of plank cut wedge-shaped to fit the space to be filled do very well. Such blocking after being driven snugly to place is made fast either by spiking to the ties or by drilling a hole through the webs of the rails and bolting it fast. The latter method is the better one, because it permits of removing the block without splitting it. The work of surfacing and other repairs occasionally requires the temporary removal of the guards. A wooden wedge guard for a plate frog must either be secured in this way or else be made long enough to reach a tie to which it may be spiked. The block for a guard rail should extend some 8 or 12 ins. beyond the end of the guard rail, so that it may be sloped down. Figure 137 illustrates a method of blocking the openings in frogs, guard rails and other places with wood, known as the Hart foot guard. The blocks of wood may be bolted to the web of the rail as shown or they may be secured by 60d wire nails driven through ¼-in. holes in the web of the rail and clinched on the block. The objectionable lower corners of the rail head are rendered harmless and dirt or other material falling on the frog has more room in which to be crowded out of the way of wheel flanges than is the case where the guard fills the whole space to the under sides of the rail heads. On roads where wooden guards are used it is quite customary to saw out the pieces to shape in the car shops from waste pieces of lumber and thus send them to the section foremen ready made. Where such is the practice the guards are cut to a few standard patterns and come very cheap. Cinder filling is also used for foot guards. It answers the purpose well enough, but snow and ice are not readily cleaned from it in winter, and in case it becomes necessary to remove the guard it is something of a job to pick out the frozen cinders.

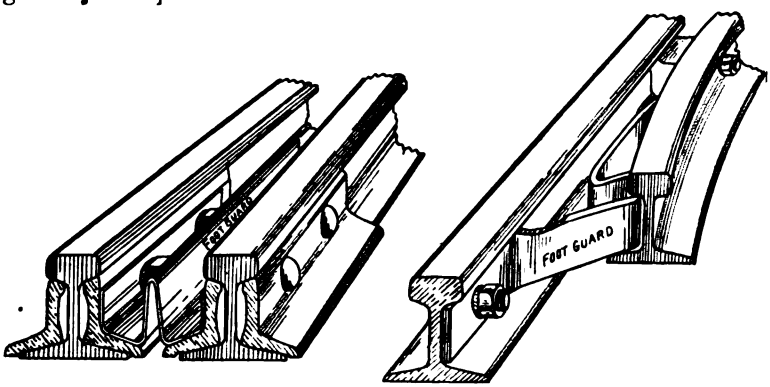

Fig. 138.—Looped Metal Foot Guard.

Of metallic foot guards there are several kinds, a common feature consisting essentially in adjustable wedges, spread apart either with or without springs. The Green guard (*A*, Fig. 120) has two flat plates, one above the other, held apart between the flange and head of the rails by spiral springs. The National guard consists of a telescoping box open on the under side, the two halves being spread apart by spiral springs. The Sheffield guard (Fig. 134) is a fan-tail device consisting of pressed steel plates ⅛ in. thick spiked to the ties. For guard and frog wing rails and lead rails the foot guard is of suitable length and in one piece, but for heel and mouth guards for frogs the device consists of two parts adjustable to the different angles of frogs ordinarily in use. No spring is used with this guard. In cases where the end of the guard does not reach a tie a hook extension with a hole for spiking is used. Figure 138 shows two forms of looped metal guard, that at the right, consisting of an iron strap or bar standing edgewise and looped back and forth between the rails, being known as the Nevens foot guard. The lead rail guard of this type consists of a bar presented edgewise and looped similarly at the wider end, but running straight for the greater portion of its length along the middle of the opening between the rails. The Weir foot guard is quite similar, consisting of a steel bar presented edgewise to the foot and held in position by brackets secured to the webs of the rails. Reference has already been made to a permanent solid guard for frogs made by extending the channel and mouth filling into the flare, as shown in Fig. 72. On some old-style rigid frogs in service on the Chicago & Northwestern Ry. the wing rails are not flared but are cut off short, and against the stub ends of the same a grooved cast piece is bolted to the frog, being shaped to form the filling of the channel and the flaring part of the wing, and therefore to serve as the foot guard. If the hight of the rail will permit it, the blocking of the heels of frogs, split switches, and derails can be much facilitated by entering the bolts of the splice bars so that the nuts come on the gage side of the rail; moreover, the nuts can then be more easily got at when loose. The laws of Canada permit railway companies to remove foot guards from frogs and guard rails during the winter months, subject to the approval of the railway committee of the privy council. The idea is that the removal of the guards facilitates clearing the parts of snow and ice, but all of the railways of Canada do not avail themselves of the privilege.

66. Switch Lamps.—Wherever night trains are run there should be lights to indicate the position of the switches. On single track, or where there are stub switches or facing-point switches on double track, it is foolhardy to run trains at night without switch lights; nevertheless, on some roads this is done. The usual arrangement for holding the lamp in position is to shape the top of the target staff to fit a socket in the bottom of the lamp. To insure that the lamp will be put on with the lenses facing in the right direction the aperture of this socket should be of oblong section, or of such shape that the lamp cannot be put on to face toward the wrong quarter. A lamp having a heavy bottom or socket which fits down over the tip of the staff is a more stable affair than one which sets in a fork attachment held to the staff by a set screw. The jarring of the stand is liable sooner or later to work such a contrivance loose, and it is easily bent. In the case of either of these conditions the lamp is tipped from the upright position and the glow of the lens strikes the ground within a comparatively short distance of the stand or is sent skyward, thus misdirecting the intensity of the light. It is a good scheme to fit a spiral spring or block of rubber into the lamp socket, for in putting a lamp in position the wick may be jarred down if the lamp is dropped suddenly to place. Lights are most liable to be jarred out over stub switches, and unless the lamps for such places are provided with spring sockets or with spring-supported oil pots it is sometimes difficult to keep the lights burning. In any case it is necessary to look carefully to the surfacing of the headblock and watch the joint opening on the headshoes. At low or wide joints on the headblocks of stub switches the oil pots of the switch lamps have been known to turn somersaults or flop bottom up, and rigidly supported lamps have been thrown off the stand.

Color.—In the largest practice the colors for switch lights correspond with the colors of the switch stand targets; that is, a closed switch is indicated by a white light and an open switch by a red light. In order to give a distinct indication for switches not on main line some roads use white and green for switches from side-tracks and in yards. Where such switches are used at night only occasionally it is the practice of some roads not to light them at all, and, as a rule, such is undoubtedly the best practice to follow. On a goodly number of roads green and red are the colors for switch lights, and the practice is growing in favor. Notwithstanding that green is the standard color for caution it is nevertheless preferable to white for the safety indication of switch lamps, since it is not so liable to be mistaken for some lantern, house light or other white light. Another objection to the use of white is the possible breaking or falling out of a red lens, in which event, the light, if not extinguished, would show white and thus give a wrong indication. A green light is not visible as far as a white light but it can be seen far enough for all the purposes of a switch light.

On single track it is necessary to have switch lights show both ways; consequently two white or green and two red lights should show from each lamp. But on double track it is well to dispense with the back safety light, so that the lamp shows safety only on the side facing approaching trains on its track. There is no necessity for showing a safety light to trains which do not use the track on which the switch is located. Unnecessary lights tend to confusion, where many are near together; and when seen at a distance, around a curve, there is no visible evidence to an engineer as to which of the lamps are showing for his track. By retaining the two red lights there will be positive evidence of danger when, as sometimes happens on double track, trains running both ways must temporarily use the same track. Some, however, prefer the use of only one red light, so as to avoid showing danger to an approaching train on the opposite track when the switch is set for the side-track. It is evident that where one or more of the lenses in a switch lamp is dispensed with the lamp should fit the socket in only one way out of the possible four—that is, the same lens should always face the same quarter for the same position of the switch. To insure that no mistake will be made in placing the lamp one corner of the tip of the switch stand shaft may be chamfered and the corresponding corner of the socket filled, or one side of the tip may be grooved for a rib in a corresponding position in the socket.

Lamp Construction and Design.—Switch lamps are made of tin, sheet iron, galvanized iron, sheet steel or cast iron. Heavy galvanized iron or sheet steel is more durable than tin, as it is not so easily warped when heated or so easily jammed out of shape in handling. The lamp should be put together with rivets in preference to solder, as then if the oil pot explodes and burns out, the lamp will not fall apart from the melting of the solder. The Monitor switch lamp has a cast iron body, in one piece, without solder or rivets. In general, switch lamps are composed of three principal parts; namely, a case for holding the lenses, a base, to which the socket is usually attached, and an oil pot and burner. Quite frequently the case and base are one piece or are permanently joined together, the oil pot being removed through an opening in the top which has a hinged cover, or through a hinged or vertically sliding door in the side. Where the case and base are separable the attachment is usually by means of a bayonet catch lock (Engraving *E*, Fig. 139). In some lamps, however, there is no base proper, the case being supported upon a fork attachment to the switch stand which fits into tubes at the side (Engravings *S*, Fig. 139), the oil pot then being inserted into the bottom of the case and held in position by means of a spring snap (Engravings *P* and *S'*, Fig. 139). If the top is hinged or removable the opening should be large enough to admit one's hand, because the surest way to light a switch lamp in a hard wind is through the top.

Figure 139 shows several designs of switch lamps. Engravings *H* and *G* show two patterns of Gray switch lamps, the latter being used on the Boston & Maine, Central Vermont, New York, New Haven & Hartford and other roads. On this lamp the lower part of each lens guard is omitted, the object being to remove any support on which snow might lodge and partially obstruct the light. The lenses in lamp *H* are not guarded. En-

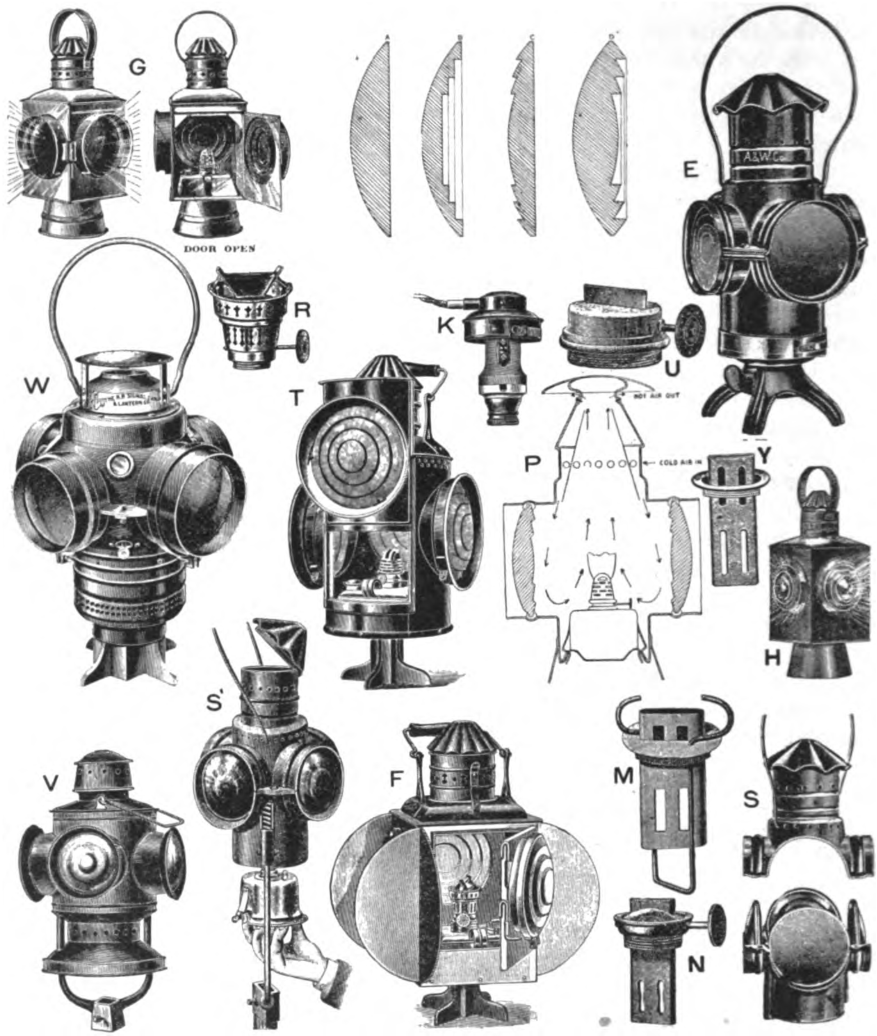

Fig. 139.—Switch Lamps.

gravings *E, S* and *S'* show two designs of the Bessemer heavy sheet steel lamp, the first being provided with a malleable iron base with socket, and the second and last with a fork socket or fork tubes with spiral springs in the tops of the tubes (*S'*) to relieve the jar. Both of these lamps are ventilated at the top by the Watt "upper draft, non-sweating" system, shown by diagram in Engraving *P*. The manner of placing the lenses is shown by Engraving *S*, and the manner of removing the oil pot by Engraving *S'*. Engraving *W* shows the Armspear switch lamp, provided with a spring socket, to relieve the lamp from the jar of passing trains, and with a hinged top. The spindle for adjusting the wick extends through the case, so that it may be turned from the outside, and there is a glass covered peep hole for observing the hight of the flame. In this lamp the safety and danger lenses are of different size, thus rendering it impossible to make a mistake when replacing broken lenses. Engraving *V* shows an Adams & Westlake switch lamp with spring-seated fork tube socket, the oil pot being removed from the bottom of the lamp. On low or dwarf stands where the lamps are attached in this way it is quite customary to reverse the fork on the top of the shaft, turning it up side down, and leaving it in that position during daytime, so as to get the prongs out of the way.

Engraving *T* shows one pattern of Dressel switch lamp, with sliding side door. Engraving *F* shows the standard switch lamp of the Pennsylvania R. R., including the Philadelphia, Wilmington & Baltimore R. R. It is a combined lamp and target, and is used on all facing-point switches and all switches within yard limits, whether facing or trailing. On trailing switches outside of yard limits no switch lamps are used, as stated in connection with switch stands. On some divisions of the road the practice of dispensing with lights and targets on trailing switches at outlying points is not standard, as the advisability of so doing is left to the discretion of the division officers. The targets are of steel, riveted to the square lamp case and painted to correspond with the color of the lenses. This lamp is placed upon a low spindle 4 ft. outside the rail, opposite the second switch rod, to which the spindle crank is attached by a connecting rod passing under the stock rail. The lamp remains in place during daytime, being permanently fixed to the spindle, and is filled, cleaned, lit and painted on the ground. On the Denver & Rio Grande R. R. there is in extensive service a switch stand designed with a large cast iron bulb in a break in the crank shaft about half way between the hinge of the lever and the target. In four sides of this bulb are placed the lenses, and inside it are the font and burner for the switch light.

Lenses.—The ordinary size of lens for main-line switch lamps is 4½ to 5⅜ ins. diam. For yard switch lamps 4 ins. in diam. is a common size of lens for intermediate switch stands and 3 ins. is the ordinary size for dwarf stands. The blue lenses for back lights in dwarf stands are usually 2 ins. in diam. Bridge lamps and pot lamps for tunnels have lenses as large as 8 or 8⅜ ins. diam. Lenses for switch lamps should be plano-convex or double convex rather than flat panes, as the two former concentrate the rays into a parallel beam and throw it stronger and farther. Generally, concentric portions of such lenses are taken out to lessen the weight. The absence of these portions from either face does not affect the efficiency of the lens, for when taken from the convex face the convexity is not changed, being simply telescoped. But if taken from the outer face the creases will catch dust and sleet or snow, impairing the efficiency of the light at times. It is better therefore to have the broken or "corrugated" surface inside the lamp, even though such adds some difficulty to the cleaning of it. Figure 139 shows three forms of plano-convex lens, *A, B* and *C,* the first being known as a "solid" lens and the other two as "corrugated" lenses. Engravings *D* and *P* show double convex lenses. The lens, of whatever color, should be one solid piece. Colored lenses are sometimes built up like the classification lamps of engines, by sliding a thin pane of colored glass behind a white bull's-eye. Such is a dangerous arrangement for switch lamps, for if the flame of the lamp becomes too high the thin colored glass may break from the heat and drop out of place, allowing the lamp to show a white light and thus give a wrong indication. It is important to have the flame of the lamp at the focal point of the lens; otherwise the light will not show so strongly. The focal length of each lens is usually marked on the glass.

Oil and Burners.—Kerosene is better than lard oil for switch lamps, because the former will burn all night without a readjustment of the wick, whereas lard oil not always will, particularly if of poor quality. It is seldom that lard oil, one time with another, runs uniformly. If there is too much mineral oil in the mixture it will smoke, heat up the oil pot and explode or throw out the burner; and if there is not enough of it the oil will thicken or freeze in cold weather. On some roads where lard oil is used it is the practice to increase the mineral ingredient in winter time. The Minot heater for lard oil burners (Engr. *M*, Fig. 139) consists of a wire looped to reach down into the font, with the tip ends bent around to touch or nearly touch the flame. The heat conducted along this wire warms the oil and prevents it from thickening. The ordinary plain flat burner for lard oil lamps is shown as Engr. *Y*. Style *N* is the same burner with a ratchet for adjusting the wick and Style *U* is the Dudley burner. The burners for switch lamps using kerosene oil are usually made with a flame spreader (Engr. *R*) which dispenses with the use of a chimney. The spindle for raising the wick should extend to the outside of the lamp, so as to enable the light to be adjusted out of doors in windy weather without opening the lamp.

To save cost of attendance a long-time burner, known as the Dodson switch and signal lamp, is used on a number of roads, among which are the Norfolk & Western, the Delaware & Hudson and the Atchison, Topeka & Santa Fe. The features of the lamp are a large oil pot, a small flame and reflectors to concentrate the light. The oil pot or reservoir holds about a quart and the wick is round and about ½ in. in diam., burning a flame about ¾ in. high. There is a short tubular chimney, and below and above the flame there are reflectors (the chimney extending through the upper one) shaped to throw the light into the lenses. The so-called lamp consists of the oil pot and burner with its reflectors and globe, and is made to fit any switch lamp. In actual service, with a good quality of oil, it burns continuously about seven days without refilling, trimming or attention of any kind. If the oil is poor the wick will crust over and require attention more frequently. The volume of light from this lamp is not as great as it is from ordinary switch lamps.

Electric Switch Lights.—In yards where there is a large number of switches, it is a convenience and a saving of a great deal of labor to light the signal lamps by electricity. If there is an electric light plant, an electric light circuit or a night-operated power plant in the vicinity the extra expense for the switch light service is not usually excessive, and the wiring of the necessary circuits is a simple matter. Incandescent lights of 8 candle power and 4 candle power are the ones most frequently used. Matters of particular convenience are that the lamps, which do not require cleaning, do not have to be taken down during the daytime, and remain permanently upon the switch stands; and the duty of lighting up or extinguishing the lamps on all the switches may be performed just at the proper time, by simply throwing a circuit switch in the power house. In lighting up the switches of a large yard with oil lamps it is necessary to begin placing the lamps an hour or two before they are needed, and, likewise, in taking them down in the morning, part of the lamps burn a considerable time in daylight. Engraving *K*, Fig. 139, shows the Dressel electric attachment for switch lamps, being an incandescent lamp socket suspended from a cap fitting over the top of the lamp case.

In order to show something of practice in the arrangement of electric lights in switch lamps and the connections therefor, the details of two or three installations of the kind will be described. In the yards of the Atchison, Topeka & Santa Fe Ry., at Ft. Madison, Ia., the switch lamps are of the ordinary pattern, with an incandescent electric light of 8-candle power, fitting a socket inside. As first installed, the wiring was brought to the switch stand in an underground pipe line, which was tapped by a branch pipe standing vertically 3 or 4 ft. clear of the stand and arching over so as to enter the top of the switch lamp. Some trouble was experienced with this method of bringing the circuit to the lamp, as the switchmen, in throwing the switch, took hold of the pipe with one hand and the lever of the switch stand with the other, with the result that the pipes were frequently pulled over and the circuit broken, the lamp socket short-circuited, or the filaments of the lamp broken by the jar. Accordingly, this method of leading the circuit to the lamp was changed and by the new plan the circuit was run up the switch stand so as to enter the lamp casing from below.

In the yards of the Ogden Union Railway & Depot Co., which serve for the terminals of the Union Pacific, the Southern Pacific and the Oregon Short Line roads in Ogden, Utah, the switch signals are lighted by 16-c. p. incandescent lamps on a 110-volt circuit from a plant owned by the terminal company for lighting the depot buildings, freight houses, transfer sheds and the grounds. The top part or casing of an ordinary oil switch lamp is used, on a fork attachment, as shown in Fig. 139A, and the wires, which are brought in under the hinged ventilation cap, are suspended from a pole set 5 to 7 ft. from the switch stand. These poles, which do not appear in the view, are high enough to carry the wires, where they cross the tracks, well above the cars. The lamp socket is rigidly attached to a cup made to fit the inside of the top part of the lamp case.

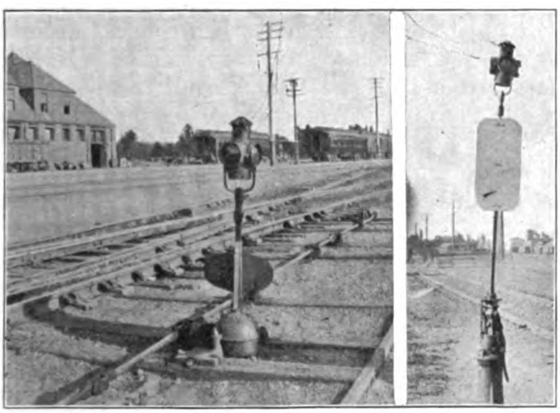

Fig. 139 A.—Electric Switch Lights, Ogden Union Ry. & Depot Co.

In the Chicago Clearing Yard (Fig. 214A), operated by the Chicago Union Transfer Ry., the lamps on something like 425 switches are lighted by 8-c. p. incandescent electric lights. These lights are arranged on four circuits running separately from the power house. The electric current on the circuits as they leave the power house is at high potential, and transformers are distributed at points along the yard, from which secondary circuits radiate to the switch stands. These secondary circuits consist of lead covered cables laid in iron conduits, making a water-proof arrangement. The switch lamps have special castings for the electric attachments, so as to facilitate the removal of the electric bulbs and make them easily accessible for inspection or repairs. At the power house there are special instruments installed, one for each circuit, showing at any time the actual number of lamps burning on the circuit, thus giving a constant check at the power house to show whether or not any individual lamp has burned out in service. The importance of this arrangement may be appreciated when it is considered that much time would be required to go over the entire lot of 425 lamps to find whether or not all were burning.

In connection with the Taylor system of interlocking, electric lights of one-candle power are being used in the switch lamps. Such were adopted after a sufficient number of trials to demonstrate that an electric light of this power, placed at the focus of the lenses, is satisfactory. Four of the lights are arranged in series on a 110-volt circuit. The current used is $\frac{1}{5}$ ampere.

Care of Switch Lamps.—All dirt, oil and soot should be wiped from the lenses and other portions of the lamp daily, and the font should be emptied and rinsed as often as the oil in it becomes greenish or dirty. The wick should be trimmed by scraping off the burnt portion with the fingers or with a match stick, and not by cutting. While the lamp is not lighted the wick should be turned down so that its top is within the tube, to prevent overflowing of oil. The wick should be long enough to reach the bottom of the font and the latter should not be filled higher than a half inch below the top. The air vents of the burners should be kept open, and when the wick becomes clogged with refuse matter a new wick should be substituted. Trouble from clogging of the wicks is usually caused by dirty oil or oil of poor quality, the impurities in which are separated by the seepage process in the wick. After lighting a lamp it should be allowed to burn for a time and heat up the burner before the wick is finally adjusted. As the burner warms up the flame naturally increases in size, and the lamp should not be left until the wick is properly adjusted; otherwise the lamp may smoke, after a few minutes. In foggy weather it is customary to light switch lamps earlier than usual and permit them to burn later before taking down in the morning. Where switch lamps are numerous within carrying distance it is a good plan to take them all to some central point for cleaning, filling and lighting before they are distributed in the evening. Light hand cars (described in § 133, Chap. IX) are much used for carrying switch lamps.

A convenient arrangement for carrying switch lamps by hand is to hang them on a pole and carry a pole-load in each hand. In order to load the poles to a balance at the middle, notches may be cut or nails driven into the top side of the pole to indicate regular spacing intervals. By means of a stout leather strap buckled to the poles and passed over one's shoulders a heavy load of lamps may be easily carried. If, however, the switches are widely scattered it is a waste of time to carry the lamps back and forth, and the best plan is to have a box under lock at each isolated switch and at each point where a few switches are grouped within convenient distance, to which the lamps may be taken to be cleaned and filled and sheltered during the daytime. If lard oil is used which tends to thicken in cold weather it will save trouble to carry a can of warm oil from box to box and fill the lamps just before lighting them, in the evening. The most trouble in this respect usually comes from the practice of filling the lamps in the morning, so that the oil remains in the cold lamps all day. If the oil is of fair quality and thin when the lamp is lighted the heat of the burner will usually prevent it from thickening. In putting up or taking down switch lamps the track-walker or lamp tender should keep his greasy hands off the targets. To enable lamp tenders to clean lamps properly and keep them in neat condition they should be supplied with clean new waste.

The Michigan Central and the Atchison, Topeka & Santa Fe roads have complete sets of rules governing the care of switch and other signal lamps. On the A., T. & S. F. road there is a standard lamp body for all signal purposes, and all signal lamps, including semaphore, switch, order board, train marker and engine classification lamps, are in charge of the signal department. To see that the signal lamps are properly cared for there is a lamp inspector reporting directly to the signal engineer and also to the various superintendents, trainmasters and roadmasters. His duties are to travel over the road continually, visit all points where signal lamps of any description are used, inspect them carefully and report their condition to the official in direct authority over the man caring for the lamps. He also instructs persons in charge of lamps as to their proper care and is supposed to see that the rules are obeyed.

All new lamps on the line are issued from Topeka, and at that point also all the damaged and defective lamps are repaired. Once a month the lamp inspector returns to Topeka to inspect and test all new and repaired lamps and to mark with a special stamp all those which pass inspection. The storekeeper is not permitted to issue lamps which do not bear the stamp of the inspector. Adjacent to the shop where all the lamps are repaired there is a suitable testing room equipped for the use of the lamp inspector. Close to the repair shop are two vats, one filled with lye and one with hot water, and near-by is a room provided with a number of hooks at one end and a small bin at the other. All lamps and burners that come in off the road are placed in one end of this room, the burners being put into the bin. Once a month the lamp inspector visits this room and carefully inspects all the lamps and burners, throwing out the worthless ones for scrap and laying to one side all that are worth repairing. These are then dipped in hot lye and afterwards in hot water, which removes the paint, oil, soot and dirt from the lenses and lamp. They are then dried and sent to the tinsmith, who makes the necessary repairs, gives them a serial number and letter, if they do not already have one, and then sends them to another room where they are painted and hung up to dry. When dry they are carried to the inspector's testing room, where they are subjected to the blower test for leaks, are examined to see if the lenses are in right, and are tried on the particular switch fork, bracket, or holder, to which they belong. If they are in proper condition the inspector marks them with a label, takes a record of the number and sends them to the storehouse to be issued on requisition.

In addition to the foregoing the lamp inspector is required to submit all new lamps and lenses used on any line of the system to the following tests: Blower test, under pressure measured on a Pitot tube the equivalent of a wind velocity of 80 miles per hour; and the color test. All lenses must be free from waves, air bubbles, or imperfections on the outer or inner convex surfaces. Ruby and green lenses and colored semaphore glass must be of the same color and depth of color, within the limits established as maximum and minimum standard colors. All color tests must be made with standard burners, with flame 1 in. high properly focussed on the photometer bar in the lamp inspector's office. There are, on an average, 250 lamps repaired and inspected each month, the repairs being made by one tinsmith and helper, including everything excepting the painting, which takes from six to ten hours a month for one man. The list of rules relating to the care of signal lamps on this road is given in §199, Supplementary Notes.

The rules of the Michigan Central R. R. are similar to those of the A.,

T. & S. F. Ry.; in fact the latter were largely copied from the former. The following is a blank form for a defective lamp report:

MICHIGAN CENTRAL RAILROAD.

DEFECTIVE LAMP REPORT.

____________ Station ____________ 190 __

To ____________

At ____________

Type of Lamp ____________

Trouble with Lamp ____________

If damaged externally, by what means ____________

NOTE.—A blank must be filled out and placed inside of each lamp sent in.

Signature ____________

Occupation ____________

This blank is printed on a stiff card $3\frac{1}{4}$x$5\frac{1}{4}$ ins., and, as required by the instructions, is filled out and placed inside of each lamp sent in to headquarters for repairs.

67. Clearance Posts.—Some mark or reference object ought always to be at hand to indicate the shortest distance beyond the frog at which a car standing on the side-track may be safely passed by trains on main track. Unless the track be heavily elevated toward the inside (a very unusual condition) 12 ft. between track centers will give ample room for passing. This distance between centers gives about 7 ft. between the outsides of the two near rails; some make it $6\frac{1}{2}$ ft. On the Chicago, Burlington & Quincy Ry. the standard clearance distance is 7 ft. for main tracks and 6 ft. $3\frac{1}{2}$ ins. for side-tracks. A post about 4x4x36 ins., standing about 8 ins. out of the ground, is sometimes set midway between the two tracks at the clearing point. The post is usually painted white with a black tip, the top corners being rounded off. In this position the post is a source of danger to trainmen running between the tracks after dark and for this reason they are often pulled up and thrown away. A better location for the post is outside of either main or side-track, opposite the clearing point, 4 or 5 ft. from the rail, and on the Canadian Pacific Ry. this principle is followed, the post being placed outside the turnout track. The sign is conspicuous, being a black board with two white disks, nailed to a tall post. The standard clearance post on the main line of the Southern Ry. is cast iron, of +-shaped section, flattening out into a plate at the top, painted white and lettered "C. P." in black. On some of the branch lines a wooden post, painted white and lettered "Clear this Post," is used. In each case the post is set between the tracks. On railways in India the standard reference for clearance is a whitewashed half-rounded tie laid across the space between the tracks.

68. Point Switches.—In computing the lead distance and radius of point-switch turnouts it has been quite commonly the practice to use the formula for stub switches. Without looking into the matter it is naturally enough supposable that the lead from headblock to frog in a stub-switch turnout will answer for the lead from heel of point rail to frog in a point-switch turnout, the throw in the one case being about the same distance as the spread in the other; and in practice this is what has actually been done to quite a large extent. While these lead distances from the two kinds of switch are nearly the same for frogs up to and including No. 9, still the problems are essentially different in the two cases, and within this range of frog numbers the turnout curvature for the point switch is considerably the sharper. In comparing the two types of switch it should be borne in mind that the stub switch rails when thrown for the siding form part of the turnout curve, while the point-switch rails do not, and this is why there is no close agreement of turnout curvature for the same frog in the two cases. With frogs of higher number than 9 the lead distances corresponding to the two kinds of switch and the same frog differ too widely to be overlooked, the stub-switch lead being too long for the point-switch turnout. The term "shortened lead," so largely in use among trackmen, refers to a point or split switch with a stub-switch lead—that is, a lead calculated for a stub switch, with the heel of the split rail spliced on at the point corresponding to the position of the headblock of the stub switch. As the point switch of ordinary length (15 to 18 ft.) is shorter than the stub-switch rail for all frogs of higher number than $6\frac{1}{2}$, a point switch used with a stub lead falls short of the point corresponding to the heel of the stub switch (point of curve), and hence it is commonly supposed that the "theoretical" lead is "shortened." In a strict sense the term is a misnomer, for the stub lead is not the "theoretical" lead for a point-switch turnout.

With the point switch the turnout curve begins at the heel of the point rails. It meets here a straight switch rail at a tangent, and on the headblock the switch rail meets the main-track rail at an angle, the degree of which depends upon the length of the switch rail and the spread at its heel. In a comparatively few instances the switch rail is curved to the turnout, but such is not general practice, and nothing of account is gained by curving the point rail between the end of the planed portion and the heel. In Fig. 140 let $A\ L$ and $K\ F$ be the gage lines of two main-track rails, and let the gage be represented by g. Let F be the frog point and let the angle $D\ F\ K$ represent the frog angle, which we call F. Let $A\ B$ be a switch point rail, of length p, making an angle with $A\ L$ which we will call P. Let $B\ C$ be the spread at the heel B. and call it h. The conditions require that a circular curve be drawn through F tangent to the line $D\ F$ and meeting at the other end (B) a straight switch rail at a tangent when the switch rail is in the position of open switch. The formulas for the measurements necessary to lay out the switch appear below. For the derivation of the same the reader is referred to the Railway and Engineering Review of Apr. 2, 1898.

(1). Lead distance $K\ F = \dfrac{(g-h)(\cos F+\cos P)}{\sin F+\sin P}$

In words, the lead distance from heel of switch rail to frog point is the quotient of two quantities, the dividend being the gage of the track less the spread at the heel, multiplied by the sum of the cosines of the frog and switch point angles, and the divisor the sum of the sines of these two angles

(2). Radius of outer rail $B\ F = r+\frac{1}{2}g = $ also $\dfrac{g-h}{(\sin F+\sin P)\ \text{tang}\ \frac{1}{2}\ (F-P)}$

(3). Chord $B\ F = \sqrt{[(K\ F)^2+(g-h)^2]}$

(4). Middle ordinate $O\ N = (r+\frac{1}{2}g)\ \text{vers}\ \frac{1}{2}(F-P)$

Substituting the values of $\sin F+\sin P$ and $\cos F+\cos P$ in other terms these formulas are rendered calculable by logarithms and we have:—

(1′). Lead distance $KF = \dfrac{g-h}{\text{tang}\,\frac{1}{2}(F+P)}$

(2′). Radius of outer rail $= r + \frac{1}{2}g = \dfrac{g-h}{2\sin\frac{1}{2}(F+P)\sin\frac{1}{2}(F-P)}$

(3′). Chord $BF = \dfrac{g-h}{\sin\frac{1}{2}(F+P)}$

(4′). Middle ordinate $ON = (r+\frac{1}{2}g)\,\text{vers}\,\frac{1}{2}(F-P)$

$$= \text{also}\ \frac{(g-h)\,\text{tang}\,\frac{1}{4}(F-P)}{2\sin\frac{1}{2}(F+P)}$$

Tables XIII and XIV (see index for page number) give the lead distances and other measurements for point-switch turnouts corresponding to frogs of different numbers, various lengths of switch point, spread at the heel etc.

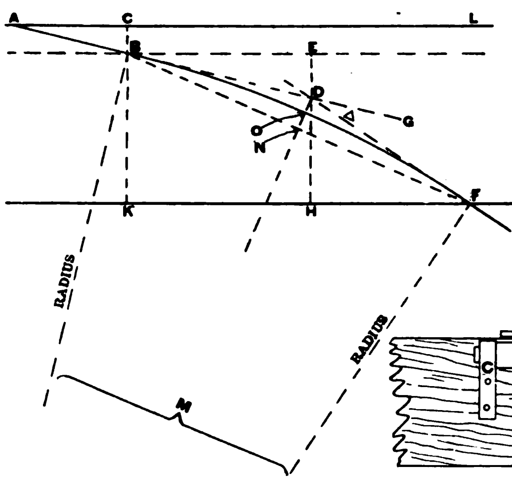

Fig. 140.

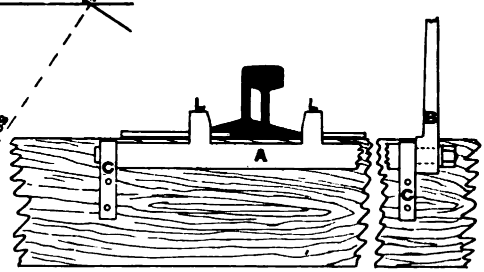

Fig. 141.—Switch Point Lock.

When the toe of frog or other point on the frog leg, instead of the point of frog, is made or assumed as the end of the lead curve, as is sometimes done, certain modifications of the above formulas, as applying to lead distance and radius of curvature, are necessary. In that case the value of g in the formula must be decreased by an amount found by multiplying the distance from frog toe or end of lead curve to frog point (call this distance k) by the sine of the frog angle F. The lead found by using this value of g must then be increased by $k \cos F$. We then have:

(1″) Lead distance $KF = \dfrac{(g-h-k\sin F)(\cos F+\cos P)}{\sin F+\sin P} + k\cos F$

$$= \text{also}\ \frac{g-h-k\sin F}{\text{tang}\,\frac{1}{2}(F+P)} + k\cos F$$

(2″). $r+\frac{1}{2}g = \dfrac{g-h-k\sin F}{(\sin F+\sin P)\,\text{tang}\frac{1}{2}(F-P)} = \text{also}\dfrac{g-h-k\sin F}{2\sin\frac{1}{2}(F+P)\sin\frac{1}{2}(F-P)}$

(3″). Chord (heel of switch rail to toe of frog) $= \dfrac{g-h-k\sin F}{\sin\frac{1}{2}(F+P)}$

(4″). Middle Ordinate $=(r+\frac{1}{2}g)$ vers $\frac{1}{2}(F-P)$

$$=\text{also } \frac{(g-h-k\sin F)\tan g\frac{1}{4}(F-P)}{2\sin\frac{1}{2}(F+P)}$$

Mr. Wellington B. Lee has developed a set of arithmetical formulas for finding the lead and radius in point-switch turnouts which are based upon the frog and switch-point numbers. These formulas, in connection with an article of some length, were published in the Engineering News of Apr. 21, 1898, and subsequently reprinted in the switch and frog catalogue of the Ramapo Iron Works, Hillburn, N. Y. The formulas are given below. Employing as far as possible the foregoing notation, the switch number (n) is the length of switch rail (p) divided by the spread at the heel (h), or $p\div h$. Let the frog number be represented by N, the gage by g, and the spread at the toe of the frog by f. We then have

(A). $d=g-h-f$

(B). Chord of outer rail in turnout, from heel of switch rail to toe of frog, $=a=2dnN\div(n+N)$

(C). Main lead, heel of switch rail to toe of frog, $=b=\sqrt{(a^2-d^2)}$

(D). Radius of outer rail of turnout $=r+\frac{1}{2}g=anN\div(n-N)$.

(E). Middle ordinate of chord $a=a^2\div 8(r+\frac{1}{2}g)$

In the case of a frog having the turnout leg curved between toe and point of frog the spread (f) at the toe becomes zero, for the purpose of the formulas, and the chord distance (a) and lead distance (b) then extend from heel of switch rail to point of frog.

The middle ordinate of the outside rail of the point-switch turnout does not remain constant for different frog angles, as it does with the stub-switch turnout, but decreases with decrease in the angle of the frog (although not in the same ratio) until that angle equals the angle of the switch point, when the middle ordinate becomes zero and the turnout curve becomes a straight line throughout, from point of switch to point of frog. And unlike the formulas for stub-switch turnouts, those for point or split-switch turnouts do not apply with a close degree of approximation when the main track is curved. The following modifications of the same are reliable, however, and give results which, within the range of the frog numbers in common use, are very close to the exact values and certainly near enough for track purposes. First, when the turnout is *with* the curve, the degree of turnout curve is increased very approximately by the degree of curve of main track; but the lead distance is longer than that for straight main track; and the change in middle or quarter ordinate of outside rail, per degree of curve of main track, is not found by dividing the ordinate for straight track by the degree of turnout curve for straight track, as in the case with the stub switch. The difference in lead may be found by dividing the square of the frog number by 144 and multiplying the quotient by the degree of curve of main track ($Dn^2\div 144$). Add this result to the lead distance for straight track. To find the change of middle or quarter ordinate per degree of curve of main track, divide the ordinate for straight track by the degree of turnout curve for straight track and multiply the quotient by $1\frac{1}{4}$; that is, (ord.$\div D)\times 1\frac{1}{4}$. Multiply this result by the degree of curve of main track and add the product so found to the ordinate for straight track.

When the turnout is *against* the curve, the degree of turnout curve is not decreased approximately by the degree of curve of main track, but at a faster rate. The proper lead distance is found by subtracting from the lead distance for straight track an amount equal to $Dn^2 \div 144$, where n is the frog number and D is the degree of curve of main track. The change in middle or quarter ordinate per degree of curve of main track is found by dividing the ordinate for straight track by the degree of turnout curve for straight track and multiplying the quotient by $1\frac{1}{8}$; that is, $(\text{ord.} \div D) \times 1\frac{1}{8}$. Multiply this change so found by the degree of curve of main track and subtract such product from the ordinate for straight track.

Finding Lead without Computation.—The lead distance of a point-switch turnout may be found quite readily and with sufficient accuracy by a little rough surveying on the ground, or by a scale drawing on paper. Referring to Fig. 140, it will be noticed that the condition essential to a circular turnout curve between frog and switch-point rail is that the two tangents BD and DF shall be of equal length. All that is necessary, then, to find the proper location of the switch, after establishing the location of the frog, is to ascertain by string measurements what position of the switch rail will bring these tangents equal. This work the trackman may go about in the following manner: First determine upon the location of the frog point (F) and then stretch out and stake down a string in the direction of the turnout gage line of the frog. This direction may be found by placing the frog on top of the rail in proper line or by setting a stake on a line which diverges from the main rail according to the spread of the frog legs. If the turnout leg of the frog is curved the proper spread may be given to the string by knowing the frog number; as, for instance, if a No. 9 frog is being used set a stake 2 ft. from main rail (FK) at a distance of 18 ft., or 3 ft. from that rail at a distance of 27 ft., from F. With the string stretched through the points D and F, fit the switch-point rail against the main rail and stretch out a string along the gage side straight beyond, shifting the point rail back and forth until the intersection point D is equally distant from B and F; or from B and the toe of the frog, in case the latter point is made the end of the turnout curve. This method applies to the problem of laying a turnout in either straight or curved track. In case the main track is curved the spread of the tangent line DF should be measured not from the main rail FK but from the gage line of the main rail of the frog produced.

Regarding the alignment of the turnout from toe to heel of frog some engineers set forth views and specifications more finely drawn than any necessities of the case would seem to require. The old idea was that there should be a piece of straight rail in advance of the frog to swing the car trucks into line with the same and thus avoid any centrifugal tendency in the wheels and side pressure against frog or guard rail. Accordingly, it was to some extent the practice in the early days to lay the turnout leg of the frog straight and continue the track straight for a few feet in advance of the toe of the frog. The advantage in this arrangement is more fancied than real, for the centrifugal force in the body of a car does not disappear until the whole car has passed out of the curve; and the piece of tangent in front of the frog appreciably sharpens the turnout curvature for the same frog angle. Moreover, the path traveled by a wheel over a frog is not fixed altogether by the alignment of the frog, but quite largely, if not entirely, by the guard rail opposite, so that, in any event, the wheel is not likely to take a straight course through the frog. With frogs of proper length it is feasible to spring the leg to the curvature of the turnout within 3 or 4 ft. of the point of frog, and when such is done it is not worth while to consider the straight piece separate from the curve, in the computations. And finally, it has already been pointed out that the turnout leg of spring-rail frogs may just as well as not be curved when the frog is made, and the construction of frogs in this manner is growing in practice.

The advantages in favor of the point switch are that it cannot run tight from expansion in hot weather nor is its serviceability or safety affected by contraction in cold weather; there is no joint at the headblock to be pounded out of surface; and cars cannot be derailed in trailing the switch when it is open. There is only one way in which cars can be derailed at a point switch, and that is when the switch (of ordinary design) is partly thrown and the car or train meets the switch facing. In this event the wheels on one side of the track take the main rail and the wheels on the other side follow the turnout rail, thus resulting in derailment. But such an occurrence cannot result from forgetfulness. It is also to be considered that the point switch breaks the continuity of the main rails on only one side of the track, and then not by a squarely-cut joint, whereas the stub switch breaks the continuity of the rails on both sides of the track. The point switch is therefore a safer switch than the stub switch and should be maintained at less expense. About the only respect in which the point switch is inferior to the stub switch is that during winter time more attention is required to keep the switch clear of snow and ice. With the stub switch snow cannot be confined so as to interfere with the movement of the switch rails to the same extent that it can with the point switch. The stub switch is still considerably used in main track, particularly on mountain roads, the generally accepted explanation for the practice being that the heavy snowfall of such regions obstructs the operation of point switches more frequently than the switches can be properly looked after. On this question a brief quotation from an article by Mr. Jerry Sullivan on "Weather Conditions as Affecting Track in the Rocky Mountains," published in the Railway and Engineering Review of Apr. 22, 1899, is to the point. Mr. Sullivan says, in part:

"I do not see why split switches are not more generally used in the mountains. I believe the average number of delays to trains per year would be less with split than with stub switches, because the number of warm days in summer is many times greater than the number of stormy days in winter, and as between a tight switch and one covered with snow the time consumed in getting into a siding is much less in the latter case, because the brakeman can step to the engine and get a scoop and broom or coal hammer and get the points clear in less than 5 minutes; while in hot weather I have known trainmen to spend 15 minutes hammering with a coal pick, or trying to butt the rails over with a piece of scrap iron. Again, the rails of a stub switch may appear to be all right when the section gang passes over in the morning and they will not come back to look after it during the day; whereas, if split switches are used the foreman will send a man to clean them out in case of snow In this case he knows to a certainty when the weather will interfere with the working of a split switch, but in the other case he does not know when the stub switch will get tight. A snow storm in the mountains is usually limited in area, and may interfere with 50 or 75 miles of track, but a hot day will tighten switches on 300 or 400 miles of track. . . . I think the snow is a bugaboo; and I believe that later on our roads will use point switches and spring frogs and find them superior in every way, even at high altitudes."

Point Switch Construction.—The point or split switch consists of a pair of movable rails planed to wedge points and set to work against two fixed rails. A plain switch of this type, of ordinary design, is shown as Fig. 142. The rails *A* and *B* are the main-track rails, the latter being a lead rail. Rails *C* and *D* are in the turnout lead and the rails *P* and *P'* are the *point rails* or *split rails,* usually planed back on the head a distance of 6 or 7 ft. The switch is shown in the closed position, or set for main track. Rail *A* is known as the *through rail* and rail *E* as the *stock rail.* The latter is on the frog side of the track and is bent to the switch angle or to fit the planing of the point rail; some trackmen call it the "knee rail." The bend at *E* is sharp or angular, being put in with a jim-crow, and is usually made 10 to 15 ins. ahead of the end of the point rail, thus allowing for some thickness in the end of the point rail and for creeping steel. The track at *E* should therefore be right for gage. In addition to bending the rail at *E* it is quite widely the practice to "crank" it or kink it at the bend, so as to "house" or shield the end of the point rail behind the kink. While this "cranking" of the stock rail, as the English call it, permits the point rail to extend into the recess behind the kink, close to the bend and at the same time lie in even alignment with the general gage line, it is nevertheless objectionable wherever creeping steel is bothersome. If the stock rail creeps frogward or the point rail creeps in the opposite direction the kink will spread the point, and if the stock rail creeps from the point rail the kink will then protrude beyond the alignment of the point rail.

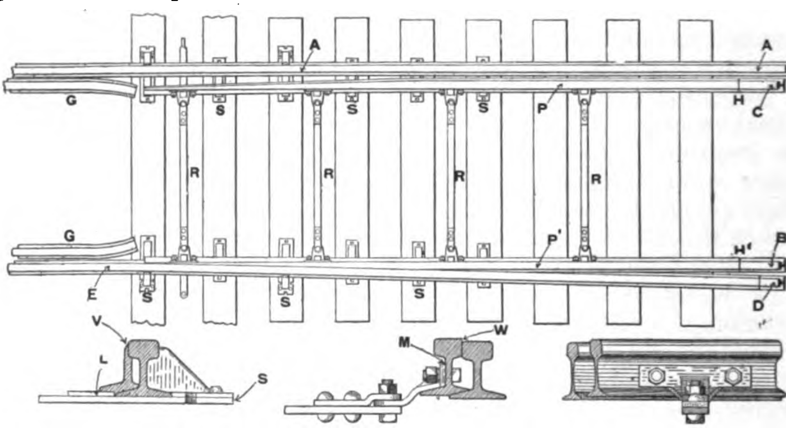

Fig. 142.—Point or Split Switch.

The most common length of switch point is 15 ft. This length is suitable, and the fact that a 30-ft. rail will make two 15-ft. points makes it a convenient length for the manufacturer. Point rails 18 ft. in length are quite common, however, and 20-ft. points are used with ordinary frogs to some extent. At end of double track 24-ft. and 30-ft. point rails are used in a few instances. In yards 10-ft. and 12-ft. point rails are sometimes used. The spread at the heel—that is, the distance between gage lines at the joints *H* and *H'*—is about the same as the throw at the toe of a stub switch, depending upon the width of the rail base. With rails of small section the spread may be 5 to 5½ ins., but with rails of 80-lb. section or larger the spread is usually 5½ to 6 ins. for 15-ft. points and 6 to 6½ ins. for 18-ft. points. A point rail 15 ft. long spreading 5½ ins. at the heel meets the main-track rail at the point of switch at an angle of 1 deg. 45 min.

The form of split switch now in general service is patterned after the Clarke-Jeffery design, which was worked out by Mr. Leverett H. Clarke, while chief engineer of the Illinois Central R. R., and Mr. E. T. Jeffery, then an employee of the same road and later president of the Denver & Rio Grande R. R. The distinctive features of this switch are: (1) The planing of the base of the point rail in a manner to seat it on the flange of the stock rail or main rail; and (2) the crowning of the point rail above the top of the stock rail (or main rail) at the point where the tread or tire of a wheel just reaches the gage side of the latter. The arrangement of seating the base of the point rail on the flange of the stock rail is shown in Fig. 142.

At the end of the point rail it is necessary to plane the head entirely away, both sides, down to the web, and in order to do this and have the gage side of the point rail straight the rail must be bent inward (toward the gage side), at the point where the planing of the head begins. From this point the gage side of the point rail head is then planed straight away to meet the web at the point end. To avoid heavy pressure from the wheels on the thin portion of the point rail the top of the same is planed down on a slope to bring the end ¼ in. or such matter lower than the top of the stock rail. This sloping of the top of the point rail is carried back 15 to 18 ins. from the end, and sometimes farther, as is presently explained. The idea in view is that the point rail should not extend as high as the stock rail until a point is reached where it is strong enough to bear the whole load. The effect of carrying the load on the point rail where it is too thin or too narrow is to crush the top surface, causing the metal to flow against the stock rail and spoil the adjustment. It is also customary practice to plane out the inside face of the point rail along the top edge (*V*, Fig 142), leaving a shoulder on the web to be housed under the head of the stock rail. This arrangement permits the full thickness of the web to be carried to the end of the point rail, thereby making possible much stronger construction than would otherwise be the case. In England a new method of making split switches is being tried, the points being rolled to a taper, out of ordinary rail, instead of planing the rail down. The idea in avoiding the use of the planing machine is to preserve the skin or original rolled surface of the rail intact, which is supposed to be tougher, and therefore better able to stand wear, than the planed surface of point rails made in the usual way. The taper-rolled rail is also supposed to be stronger than the planed one. Some of these rolled point switches are in use on the Midland Ry.

On each tie, at least as far back as the point where the bases of the point and stock rails separate, and sometimes a tie or two farther, the point and stock rails rest upon iron or steel plates (*S*) known as *slide plates.* These slide plates should extend under both point and stock rails, on the one side, and under both point rail and through rail on the other side. A short slide plate passing under the point rail only and abutting against the flange of the stock rail is not satisfactory under heavy traffic. Slide plates should also be of good width—at least 5 ins. They are frequently made so narrow that they settle into the timber when the ties become old, and in such cases one end of the plate usually dips and leaves the point and stock rails unevenly supported. As far as the point rail rests upon the flange of the stock rail or is higher than the stock rail the plates are stepped or thickened by a riser (*L*, Fig. 142) to make a proper bearing for each rail and hold the rails at the desired relative hight. This stepping of the slide plates is done either by shouldering a solid plate or by pressing up a portion of the same, or by riveting a shim to one end of a plain plate. The solid plate is preferable, as if the rivets in the built-up plates work loose they are liable to stick up and catch the point rail when the switch is thrown. As the risers decrease in thickness from the point toward the heel, or vary in thickness according to the position of the plate, it is important to lay the plates in their proper order, and to avoid mistake the plates should be stamped with numbers consecutively from the point toward the heel. Usually part of the plates (sometimes alternate ones) or all of them are extended outside the stock rail far enough to support a rail brace, which may be riveted to the plate or backed by turning up the end of the plate. An efficient brace may be made by splitting in halves that portion of the plate which extends outside the stock rail, punching a spike hole in one of these parts and then bending up the other half to hold the flange of the rail.

We now come to the second principle of the Clarke-Jeffery design. To prevent guttered tires or wheel treads from fouling the stock rail when trailing the switch, the point rail is cambered and raised $\frac{1}{4}$ or $\frac{3}{8}$ in. higher than the stock rail at the point where the overreaching tread meets the gage line of the latter; from this point it should slope down gradually both ways to the level of the stock rail. The difference in hight shown at *W* in Fig. 142 is not so necessary at that point as it is farther back where the rails are separated—say at the last tie bar *R*. Ordinarily the humping of the point rail to carry false flanges trailing the switch so that they will pass over the stock rail without spreading it is done in the following manner: The top or head of the point rail, in a length of about 5 ft. from the point end, is planed down on a gradual slope, striking $\frac{1}{2}$ to $\frac{3}{4}$ in. deep at the end. This planed top then slopes from a point $\frac{1}{4}$ to $\frac{3}{8}$ in. lower than the top of the stock rail to a point $\frac{1}{4}$ to $\frac{3}{8}$ in. higher than the top of the stock rail at the end of the 5 ft. For the next 5 ft. the top of the point rail runs level and $\frac{1}{4}$ to $\frac{3}{8}$ in. higher than the top of the stock rail, and in the next 3 to 5 ft. it drops, on risers of varying thickness, without planing, to the level of the stock rail. In this connection it is important that the joint at the heel of the point rail should be kept in fair surface. If this joint is permitted to get low when the point rail is humped it leaves the track in rough condition, and if the point rail is not humped a low joint at the heel tends to cause the stock rail to spring up and stand higher than the rear portion of the point rail. An objection urged against the humping of the point rail is that it forms rough surface in the track and gives rise to a lifting sensation when riding over it at high speed. On a goodly number of roads the practice is not followed, but the effect of badly worn tires on trailing point switches is well worthy of consideration. Derailments have been known to happen from the fouling of the stock rail by badly worn wheels, where the point rail was not high enough to lift the wheel tread clear of the stock rail. To provide against this danger without putting the point rail out of surface it is the practice on the Burlington & Missouri River R. R. to plane down the stock rail $\frac{1}{4}$ in. for a distance of 2 ft. covering the fouling point.

The two point rails are connected by tie rods (*R*, Fig. 142), the one nearest the point ends being known as the head rod or "Rod No. 1"; the rod farthest from the point ends is sometimes called the "heel rod." The head rod, whether the switch stand connection comes at the end or not, is usually extended both ways under the main rails, to provide against the possibility that the point rails might in some manner be lifted. In some instances a "carrying bar" (2 ins. x $\frac{3}{4}$-in.) bent to set under the head rod, across the tie spacing, is spiked down near each end of this rod to hold it to place in case it should become disconnected from either point rail. In some designs of point switch, now considerably out of date, the solid ends of the tie rods are formed into an "L" or a "T" and bolted to the web of the point rail direct; but such an arrangement is not approvable, for the reason that the creeping of the rails brings a strain upon the rods and is liable to break them off at the shank. In general practice the connection with the point rail is usually made by means of a T or L-shaped lug or clip bolted to the web of the rail and hinged to the tie rod. It may be stated as a principle to be followed generally that the tie rods should not be rigid against creeping rails. If the tie rods are flat horizontally or of round section they should be hinged to the point-rail fastenings, but if the rods are of flat section and stand edgewise vertically, hinged connection with the fastenings is not so necessary, as the spring in the rods will take care of a considerable amount of creeping without dangerously cramping the parts. It may be well to explain that the hinging of horizontally flat tie rods is precautionary rather than always necessary. As the lead rails from the heels of both switch points run to the frog, it is not possible, where there is proper construction, for one point rail to be pushed out of true with the other by creeping steel. If, however, the switch is used with a spring-rail frog that is not provided with an effective anti-creeping attachment, or if the closure rails of the turnout lead are not cut to a proper fit, leaving an excess of open space at the joints, the creeping of the frog is likely to drive one point rail ahead of the other.

An advantage claimed for tie rods which are edgewise vertically is that they stand the rigid way to oppose canting of the point rails. Tie-rod clips should preferably be attached to the web of the point rail, as connection with the flange cannot be made so secure or so rigid against canting of the rail; and as the bolts are in shear against a thin bearing the vibration of the parts under traffic tends to wear the bolts, enlarge the holes and cause the rods to loosen and rattle. It is a good feature of switch design to crook the clips or the ends of the tie rods so that the latter set lower than the tops of the ties, where they will have protection against derailed wheels or anything dragging. On the Michigan Central R. R. the usual practice of placing the switch rods as low as, or below, the tops of the ties is followed, and then 2x10-in. oak blocks with the corners chamfered are spiked to the ties, on either side of each rod, to protect it from derailed wheels and dragging parts. When in this position and creeping of the lead rails takes place, it is necessary to keep close watch of the rods. If they become shoved against the ties the switch will not work freely until the ties are moved or the lead rails are driven back.

One of the most frequently discussed questions concerning the design of split switches is in reference to the number of tie rods. In the largest practice the preference has always been for four tie rods on 15-ft. point rails. Late years there has been some tendency to decrease the number of rods or tie bars on point switches, but the change has not been general. Tie rods are some hindrance to the tamping of the switch ties and also to clearing the switch of snow and ice, but otherwise they are not objectionable. They serve to brace and stiffen the point rails, and as their number is decreased reinforcing straps and stop blocks are used to make up for the loss in stiffness. In yards a single tie rod connecting reinforced point rails, or one or two tie rods without the reinforcement are customary arrangements, but for main track it is essential to have at least two rods, for the reason that if the head rod should break or become disconnected from one of the point rails there would be nothing to hold the point rail to place. Where two rods are used and the first one breaks or becomes disconnected the second one will still perform the necessary functions. In the absence of reinforcing straps four tie rods will serve to hold the pieces of a point rail in place in case of a break, and have frequently done so. The number of tie rods depends to some extent upon the length of the switch points. On point rails longer than 18 ft. it is quite customary to have five rods, and in some instances five rods are used on 18-ft. points (Fig. 142 A). In the matter of tie rods with some of the English railways a distinction is made as to the character of the switch, three rods being used on facing switches and only two rods on trailing switches.

So far as the determination of the lead distance and the running of the lead curve are concerned, the throw of the point switch is unimportant. As already explained, mathematically, the turnout measurements and curvature depend upon the number or angle of the frog and the length and spread of the point rails. The throw, however, must be sufficient to keep the free end of the open point well clear of the wheel flanges. In practice the throw ranges from 3½ to 5½ ins., but most frequently it is 4½ ins.; 4 ins. is about the least approvable distance unless guard rails are used ahead of the points. On roads where both point and stub switches are in service it is well to have the throw of the point switches the same as the standard throw for the stub switches, as then the switch stands will be interchangeable. As a matter of economy there is some advantage in the maximum throw for point switches, as increase in the width of the flangeway lessens the side pressure of the wheel flanges along the rear portion of the point rail (say from some point near the heel to the point where the planing runs out), and consequently there should be less straining of the rods and fastenings, less wear on the connections and less frequent repairs.

Switch-Point Guard Rails.—If the throw is less than 4 ins. guard rails should be placed in advance of the points, as shown at *G* in Fig. 142. These guard rails serve to keep the flanges of loose or improperly-gaged wheels away from the open point when they approach from the facing direction, and also to protect the points from damage by dragging brake beams, etc. The ends of such guard rails should be placed as near the ends of the point rails as safe clearance will permit, taking into consideration the extent of the rail creeping, and the flangeway in this case need not be as narrow as with guard rails opposite frogs; 2 or 2⅛ ins. is close enough. It might be well to again emphasize the importance of using a guard rail of proper length, say not less than 15 ft., especially because so many seem to think short guard rails in a place like this are sufficient. Except under extraordinary conditions short guard rails should not be used anywhere. For its own security alone the guard rail should not be shorter than the length stated. A guard rail should always be laid with the expectation that it is going to stay. The short insecure guard rails laid in front of facing-point switches have been the cause of derailments and wrecks, the accident usually happening in this way: A derailed wheel or part of a car truck dragging in the track would strike the end of the guard rail and drive it ahead, causing the flared end of the guard rail to force aside the open point rail, which would pull open the point rail on the opposite side and split the train. It is therefore very important that guard rails in front of switch points should be made secure against dislodgment by end blows. As a means to this end the flange of the guard rail may be notched and slot-spiked and the end farthest from the switch point should be sloped down to the ties (Fig. 98).

Guard rails ahead of split switches are not used as much as formerly, and if used at all it is frequently the case that only one is laid, and that ahead of the open point when the switch is set for main line. In some cases where only one such guard rail is used, however, it is made 30 ft. long and placed ahead of the closed point, to guard the wheels from the end of the point rail which is closed when traffic enters the switch, and to afford additional security to trains coming out of the switch at good speed, until the trucks are swung into line with main track. Where heavy traffic passes out of a siding, and particularly where the turnout curve is sharp, it will usually be found that the wheel flanges cut into the through rail in front of the switch and cause abnormal side wear. This action is due to the resistance of trucks to slew under heavily loaded cars that are down on the side bearings, and if there is a guard rail on the stock-rail side set to a proper flangeway (1¾ ins.) it will take the wear which otherwise would have to be received by the through rail. One of the roads whereon the matter of switch-point guard rails has received careful study is the Philadelphia & Reading Ry. The practice there is to place a guard rail in front of the open point at all facing switches, and at end of double track a guard rail is laid in front of both points. At the ends of lay-off sidings that are much used and at other points where switches are used trailing as a rule, a guard rail is placed in front of the closed point, to prevent side wear to the through rail from wheels trailing out of the switch. Guard rails so placed are laid to a flangeway of 1⅞ ins. At ordinary facing switches they are laid to a flangeway of 1⅞ ins., and at facing-point junctions the flangeway is made 2 ins. (for standard gage). The guard rail in any case is 9 ft. long, with the end 3 ins. from the switch point, and the rail is well spiked and braced. At the switch-point end the guard rail is flared to an opening of 4 ins., in a distance of 1 ft., and at the other end it is flared to an opening of 5 ins., in a distance of 5 ft.

At all facing-point or "point-on" switches leading to the outside of curves (which of course includes all such switches on single track) there should be a guard rail of good length ahead of the open point, on the inner side of the curve, set at standard guard rail distance, so as to act in restraint of the outward tendency of the wheels and protect the end of the outer point rail from undue wear. The end of the guard rail next the point should be curved rather more suddenly than is usually the case, so as to guide the wheels as long as possible before they reach the end of the point rail. It should not be curved inward past the line of the guard side of the open point; to be on the safe side it is well to keep it slightly within that line. In a case of this kind the end of the point rail should be well shielded behind the bend of the stock rail.

In order that the guard rail may be laid to fully protect the facing point on the outer side of the curve until after the wheel is well past the end of the same, it is quite largely the practice to have the point rail on the outer side 2 to 3 ft. longer than, and extend that distance in advance of, its mate, so as to make room directly opposite for the guard rail. The guard rail opposite the extended end of the long point rail, if set to a proper flangeway, will relieve the end of that point rail from wear. The connecting rod is attached to the long point rail near the end and slides through a slotted block or guide of some kind under the base of the rail opposite. To obtain the necessary strength for the extended end of the long point that rail should be reinforced.

The Vaughan point switch consists of long and short point rails gaged to prevent cars from "splitting" or "straddling" the switch. Referring to Fig. 142A, there is a pair of 18-ft. switch points with five tie rods, of the ordinary construction, except that the planing of the head of the main point rail is run out bluntly 2 ft. 9 ins. in rear of the point end; the web and base of this point rail, however, are carried the full length, or to a point opposite the end of the mating switch rail. At the end of the short point the gage out to out of point rails is 4 ft. 6¾ ins., which corresponds to the standard distance from the back of a wheel flange to the gage line on the flange fillet of the opposite wheel on the same axle. It is thus clear that after a wheel has taken either side of the long point the wheel on the opposite end of the same axle must necessarily take the same side (right or left) of the short point; it is impossible for a pair of wheels to take both sides of the points (reference being had to the wheel flanges, of course). In other words, if a wheel takes the flangeway side of the long point it is impossible for the mating wheel to take the flangeway side of the short point; and, after a wheel has taken the gage side of the long point the mating wheel is compelled to take the proper side of the short point. With the points in any position the wheels cannot get off the rails. Should the short point by misadjustment, accident or carelessness in throwing the switch remain slightly open, the wheel flanges cannot get behind it, as the flange of the mating wheel, behind the long point, will crowd it over and complete the throw of the switch. An extra heavy tie rod strut is used at the short point to preserve the proper spacing of the point rails. The throw of the switch for standard-gage track is $3\frac{1}{2}$ ins. and the long point rail, from rod No. 2 to the end, is slightly curved. As the service end of the short point rail ordinarily comes about $3\frac{1}{2}$ to 4 ft. in rear of the bend in the stock rail, the gage of the track directly at the

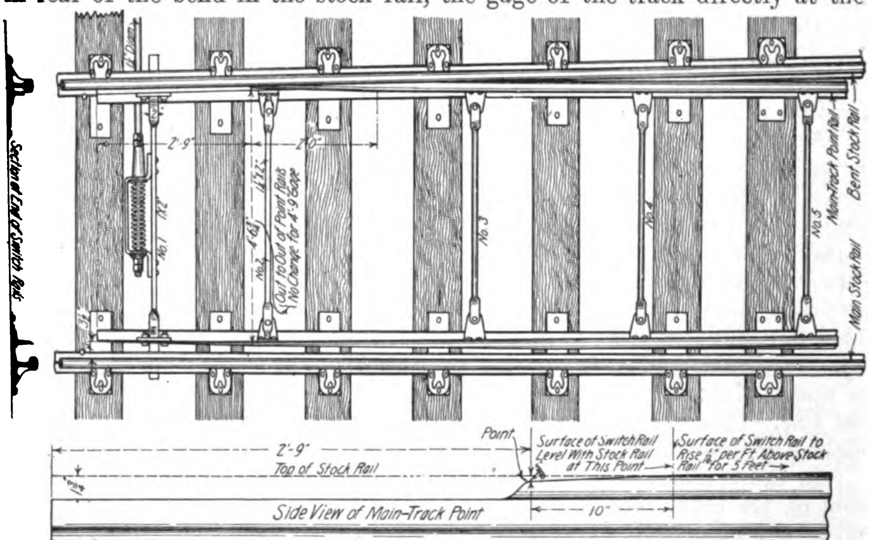

Fig. 142 A.—Vaughan Split Switch, West Jersey & Seashore R. R.

short point is necessarily wide, being about 4 ft. $9\frac{3}{4}$ ins., or $1\frac{1}{4}$ ins. wider than standard. The tapering of the short point rail from the general alignment is made in a distance of 2 ft., as shown, so that the widening of the gage extends only a comparatively short distance, and cannot affect the riding of any switch turning from tangent or from the inside of a curve. When the turnout is from the outside of a curve the best alignment for the outer main-track rail is obtained by using the long point for main track, or the reverse of the arrangement shown. This arrangement does not afford the full protection to be had from this style of switch when used normally, but still provides a switch which cannot be "straddled." Whenever it is feasible with facing-point switches, the short point is used for main track, as shown, in order to have the long point act as a guard rail for it. It is therefore customary to order these switches made right or left hand. The bend in the stock rail comes at the usual distance in advance of the switch points, or about 16 ins. ahead of the extended base and web of the short point rail. In other words, a pair of points of ordinary construction can be lifted out, and a Vaughan switch of equal length dropped into the same place will fit without further bending or changing of the stock rail. Referring to the side view of the short point rail, shown in the figure, it will be noticed that the web portion which extends beyond the service point, is $1\frac{3}{4}$ ins. lower than the top of the stock rail. The service end of the short point rail is $\frac{5}{8}$ in. lower than the top of the stock rail, and the top of the rail in rear of this point is planed back on a slope which rises to a level with the top of the stock rail in 10 ins. and to a point $^5/_{16}$ in. above top of stock rail in a distance of 5 ft. further, so as to carry the outer flange of badly worn wheels clear of the fouling point in the angle where the split and stock rails separate.

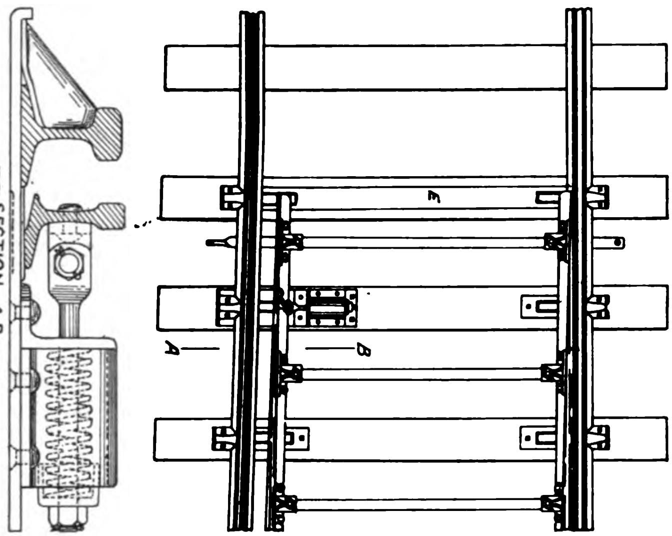
The protection which these switches afford has been thoroughly demonstrated by the large number of switches in practical use and also by tests in which the switch was only partially thrown and left in various positions while cars were thrown against the points. Special tests were also made by running cars against the points of the switch with the main-track point rail held open fully $\frac{3}{4}$ in. by blocks inserted between it and the stock rail, as would be the case if the switch was blocked with snow or with a bolt, piece of ice, or other obstruction dropped from a car. In every case all the wheels safely passed the open point. The main tracks of the Atlantic City division of the West Jersey & Seashore R. R. were equipped throughout with these switches when 100-lb. rails were laid, and a large number have been used in new work and for renewals in yards. There are also a large number of the switches in use on the various lines of the Pennsylvania R. R. east of Pittsburg and Erie. The designer of this switch is Mr. D. F. Vaughan, supervisor with the West Jersey & Seashore R. R., the same gentleman who designed the Vaughan spring-rail frog (Fig. 86) and the Vaughan sliding spring rail frog for yard use (Fig. 88).

Wherever the connecting rod is coupled rigidly to the head rod and to the switch stand, an accurate throw of the stand, to correspond to the throw of the points, is required; any lost motion from wear of bolts or other parts will leave the points loose. Loose points in facing split switches act in the same way that lip does in stub switches; as soon as the point becomes loose enough to catch a flange the wheel is derailed. The danger from this source is the more imminent where the switch turns to the outside of a curve, and to avoid trouble in such locations a switch point lock, otherwise called a "deadlock," is sometimes used on the main point and stock rail. Referring to Fig. 141, a shaft (*A*) is secured to the headblock by hangers (*C*) and is turned by a lever (*B*) placed opposite the switch stand. The shaft is crosswise the track, under the stock rail, a short distance back of the extreme point. This shaft has two lugs (*L*) which, when the shaft is turned up, straddle the point and stock rails and hold them securely together regardless of the connecting rod. The lugs should be beveled back a little from their ends so as to engage the rails without catching. By attaching the switch lock to a chain just long enough to reach the lever *B* in its raised position the lever is held up while the switch is locked and the shaft is kept from revolving and disengaging the lugs from the rails. When opening the switch the lever must of course be turned down, but before locking it again the lugs must necessarily be brought to engage the rail in order to get the lever up and the lock to its place. The switch cannot be locked, therefore, unless the point is resting against the stock rail. On double track, at any rate, some such locking device should be placed on all facing-point switches. It will hold the switch securely in place in event the connecting rod should break or become disconnected, or the switch stand be broken down by a mail sack or baggage thrown from a moving train, or by a derailed car running out of line, or by a piece of lumber projecting from the side of a car, or by an unfastened car door hanging out, or in any other manner. With the closed point rail locked in this manner the dividing or derailing of a train, which sometimes happens when a derailed wheel strikes the open point rail and throws the switch under the train, can also be avoided. The Coughlin-Sanford point lock is described in §221.

An automatic switch point lock devised by Roadmaster W. E. Emery, of the Chicago & Northwestern Ry., has been used on that road. Referring to Fig. 155A, there is a fixed automatic padlock (*B*) attached to the outer flange of the stock rail by means of a short heavy bar (*H*) slotted for the hasp(*F*). The hasp is attached to the side of the head switch rod and when the switch is thrown to the main position the hasp enters the padlock and secures the point rail. The open position of the switch is indicated by the dotted lines. In opening the lock an ordinary switch key is used, as in any other lock, the lock automatically holding itself open until the switch is thrown over for the side-track. When it is desired to close the switch the point rails are simply thrown over, as ordinarily, and the lock closes automatically. When it is desired to render the lock inoperative for the purpose of switching cars the switch key is put into the lock, turned half to three-quarters of the way round and left in that position until the switching is done; the key is then removed before the switch is thrown for the last time. In designing this lock Mr. Emery had in view that switches provided with the same would not need an ordinary lock on the switch stand, and that the device could be used in combination with distant or home signals.

In point switches having plenty of throw, lost motion due to wear of parts or spread of gage, may be taken up temporarily by placing washers between the head switch rod fastening and the point; that is, in case the fastening is bolted to the web of the point rail, as shown at *M* in Fig. 142. The point rails are thereby spread apart, and as the shape of the fastening is usually such that it is most secure only when tightly bolted against the web and flange of point rail, the practice should be resorted to only as a temporary expedient. Sometimes trackmen take up lost motion by setting in the through rail or stock rail near the point of switch and bracing or respiking the same, but unless the main rails are wide for gage in the first place, the practice is not to be recommended, since it interferes with the gage and makes an unsightly jog in the alignment. Close gage should be maintained at the bend of the stock rail. It is usual to brace both main rails at this point to hold them to gage against the force exerted in throwing the switch tightly home, and also against the side pressure of the wheels in taking the switch. A very secure device quite frequently employed for this purpose is a stub-switch rod placed at or just in advance of the bend in the stock rail. A long bolt passing through holes drilled in the webs of the stock rails just ahead of the point rails has also been used to maintain the gage, but as such a device stands up clear of the ties where it is liable to be caught by dragging brake rigging, or cut by derailed wheels it is not so desirable as the switch rod. A long sliding plate or "gage plate" at the ends of the point rails, continuous under both main rails, is a good device and is now quite commonly employed. This plate may be turned up at the ends to serve as a backing for braces, as is the case with plate *E*, Fig. 143, or there may be seats planed out for the rails, as at *A*, Fig. 144.

Adjustable Switch Rods and Point Rails.—An arrangement for taking up lost motion, so as to hold the points closely to either main rail, or to adjust the throw of the points, sometimes made necessary by wear of parts or variation in switch stands, is the adjustable head rod, of which there are many patterns. On the Transit split switch (Fig. 144) use is made of an adjustable connection between rod and fastening, the points being spread apart or drawn in accordingly as the rod is advanced or moved backward along the diagonally-set row of holes in the fastening clip *B*. The Weir company accomplishes the adjustment by means of a turnbuckle placed in the head rod (*G*, Fig. 145). Both threads of this turnbuckle are right-hand, so that the adjustment cannot be affected by meddlesome persons who might tamper with the buckle. To adjust the points it is necessary to first disconnect the head rod from the point rail by removing the bolt from the fastening lug to which this rod is attached. This company has another device in the shape of a flat head rod (*H*, Fig. 145) in two pieces, one of which is drilled with bolt-holes at $1\frac{1}{8}$ ins. centers, and the other at $1\frac{1}{4}$ ins. centers, each rod being provided at the end with a slotted hole. Owing to the difference in the drilling of centers each change makes a difference of $\frac{1}{8}$ in. either in the lengthening or shortening of the head rod. When adjustment is necessary the bolts in the slotted holes are loosened, the center bolt withdrawn, and the rod moved as occasion requires—lengthening or shortening. It is possible to obtain any adjustment up to $2\frac{1}{2}$ ins., thus providing for widening



—SECTION A-B—

Fig. 143.—Spring Split Switch.

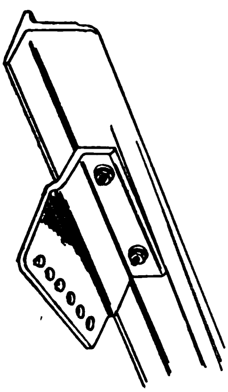


Fig. 144.—The Transit Split Switch.

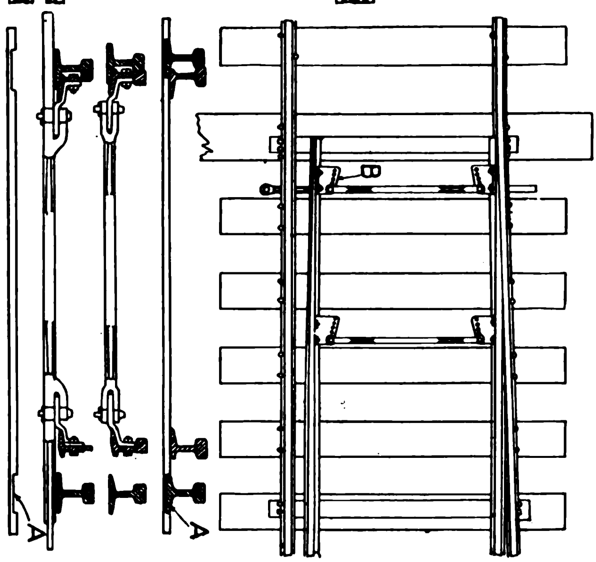

of gage and the difference in throw of switch stands. Another arrangement working on the same principle is by a differential drilling of the tie rod and the switch-point fastening or lug, as shown by Fig. 146. The lugs are drilled at 1¼ ins. centers and the switch rods at 1⅛ ins. centers, and by this difference in drilling an adjustment of ⅛ in. is obtained at each change of position. Either switch rail may be adjusted independently of the other, or both may be adjusted at the same time. It may here be noticed that an adjustment which takes place in the rod itself, between the point rails, affords a means for adjusting one point rail only, and that is the one on the side opposite the connecting rod; hence the advantage of an independent adjustment for each point rail.

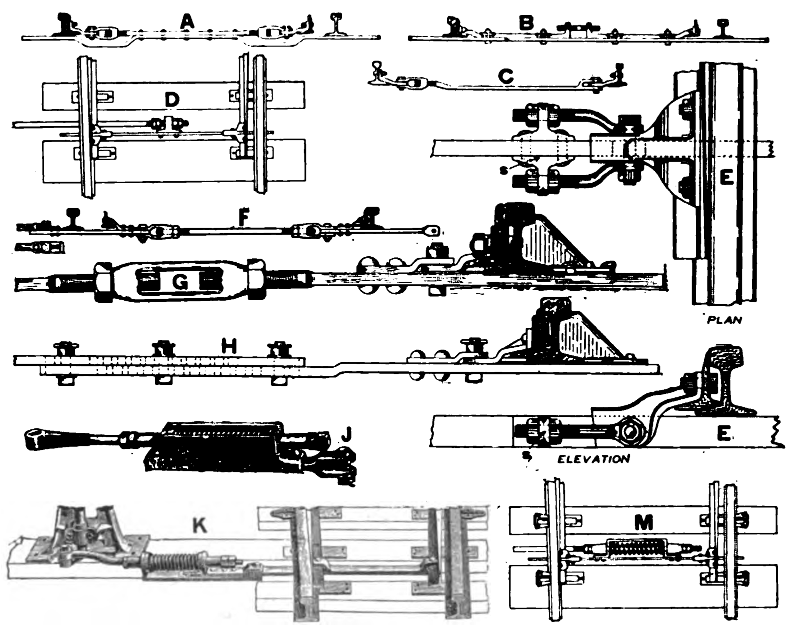

Fig. 145.—Switch Point Adjustments and Connections.

Device *F* (Fig. 145) operates in a manner similar to that of *G*. In device *B* the adjusting bolt passing through the two opposing lugs has threads cut right and left on its two ends, and the sliding bars attached to the point rails are slotted for the bolts which secure them to the head rod. Devices *A* and *E* permit of independent adjustment on either side. The former has the clevis adjustment, which is accomplished by removing the coupling bolt and twisting the turnbuckle-ended clevis. In the latter device the fastening lug operates as a sliding clip on the rod and it is changed by adjusting the nuts on the horizontal bolts passing through the fixed yoke *S*. A similar device is shown in Fig. 148. With device *D* the throw of the stand usually exceeds that of the points, the arrangement requiring that the connecting rod should slip loosely through the hub on the tie rod. By properly setting the adjustable jam-nuts the switch points can be thrown firmly against the stock rail at either side, it being possible to increase or diminish the throw of the points as desired or to compensate for any excess of throw of the stand over that of the switch. The standard device of the Union Switch & Signal Co. for adjusting the throw of switches is quite similar and is shown in Fig. 247.

On the Chicago & Northwestern Ry. a head-rod adjustment is effected by dividing the rod between the point connections and joining the parts by means of a sleeve coupling. For this purpose a piece of heavy pipe 7½ ins. long is welded to the end of one piece of the flat (¾ in. x 2 ins.) head rod and tapped out to receive the threaded rounded end of the other piece, the screw being 1¼ ins. in diam. Engraving *K*, Fig. 190, shows the application of this means of adjustment to the tie bars of a movable-point frog. The Elliot "key wedge" adjustment is shown by Engraving *H*, Fig. 112. The head rod forms the only tie rod between the reinforced switch points, and this head rod has two slots similar to those of a stub-switch rod, into which are fitted pieces of T-bar to which the switch points are attached.

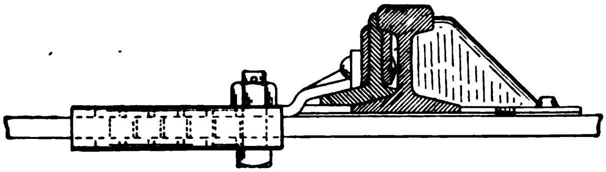

Fig. 146.—Weir Switch Point Adjustment.

The switch-point connection to the T-bar is by means of two bolts (one each side the head rod) through a filler block and an adjusting wedge *W*. The wedge is drilled with a series of holes properly spaced for the two bolts, and adjustment is effected by taking out the bolts and moving the wedge out or in, each movement over the distance of a hole spacing changing the gage ⅛ in.

Figure 147 shows the parts of the Eccentric switch rod adjustment and the application of the same to the head rod and remaining tie rod of the "Gauge" split switch. This adjustment, devised by Mr. Axel A. Strom, is effected by means of an eccentric washer at the connection of the tie rod with the clip fastening on the switch point. As shown in detail at the right in the figure, there is a boss on the under side of the washer which fits a circular opening in the clip. The hole for the connecting bolt is eccentric with this boss, and by rotating the washer the position of the point rail may be moved from or toward the tie rod, as desired. In order to lock the washer in the adjusted position it is provided on the under side with two stop studs which engage with holes on the clip. The connection with the clip and washer is between the jaws of the tie rod, and to adjust the position of the point rail it is necessary to disconnect the tie rod and reset the washer. On the clip there are 14 locking holes, corresponding to as many positions for the adjusting washer, and each successive position of the washer is adapted to a variation of $^1/_{16}$ in. in the gage of the switch points. It will be noticed that the consecutive numbers indicating the different positions of the washer alternate from side to side, the purpose of the arrangement being to use the same locking hole for two positions of the adjusting washer, thus making it possible to arrange within small compass a sufficient number of holes for an adjustment of desired fineness. In manipulating the washer for successive positions of minimum change, as when setting the points by trial, it is first turned to an assumed position; then in the opposite direction for the position next in sequence; back again beyond the first position, for the third trial; in the contrary direction, beyond the second position, for the fourth trial, and so on. The Bristol adjuster

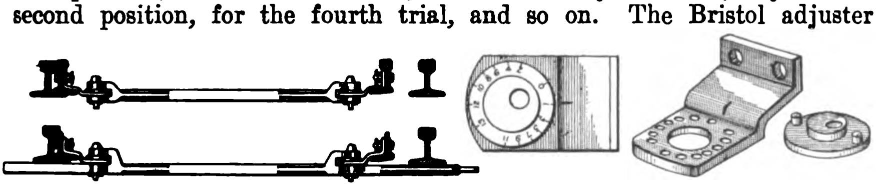

Fig. 147.—Eccentric Switch Point Adjustment.

works on a similar principle. It consists of a washer of octagon shape drilled eccentrically $^3/_{16}$ in. This washer is $\frac{1}{2}$ in. thick and fits into an octagon hole in the clip. To adjust the switch rail the clip is removed from between the jaws of the switch rod and the washer is taken out and turned the required amount.

Notwithstanding that rigidly connected switch points are still preferred on several of the large railway systems where track engineering has been closely studied, the advantages in the use of means for adjusting the point rails of split switches are well established. Adjustable switch rods and point rails are now very commonly used, being standard on perhaps a majority of the railroads of the country, and they are growing in favor. One objection urged against the use of these adjustment devices in general is the incompetency of section foremen, it being feared on the part of some railway managements that means for adjusting the switch rails might lead to ignorant or careless use of the same by men in charge. Some maintenance-of-way officials also profess to apprehend that in case the gage should widen at the stock rail their foremen might take up the lost motion by adjusting the switch points in place of regaging the rails. It is perhaps unnecessary to remark that men who are not equal to the adjustment of split switches might be expected to get into trouble with some other matters over which section foremen usually have charge; and, at best, they must be poor support to a roadmaster. The objection that adjustment devices give meddlesome persons opportunity to tamper with the switch carries but little weight, for persons maliciously inclined may find other ways for doing harm which are just as convenient. A weighty argument in support of adjustable switch points is the commonly observed fact that unless means of adjustment are provided the section foremen will improvise means of their own, placing nut locks, washers, telegraph wire, etc. between the clips and the web of the point rail. It is also to be considered that adjustment devices come handy when switches or stock rails are being renewed. Point switches made to the same standard drawing are not always closely enough alike in essential dimensions to fit the main rails in the same manner; and rails nominally of the same section are liable to vary slightly with wear of the rolls. In renewing a split switch with one having rigidly connected point rails or with no means of adjusting the throw of the same it is usually necessary to regage the main rails, reset the switch stand or tamper with the clips. It is to some extent the practice to interchange the point rails of switches, taking a worn point from the open side of one switch and exchanging with that of a switch that is not used a great deal, or the worn point from the closed side of one switch and exchanging

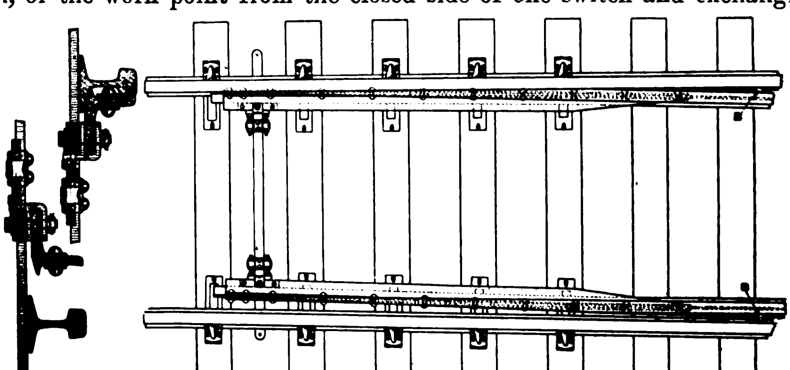

Fig. 148.—Reinforced Split Switch with Adjustable Points.

with the open point in another switch turning in the opposite direction that is not much used. Where this is done a means for adjusting the point rails is a decided convenience.

On some roads the matter of switch point adjustment receives very careful attention, as on the Santa Fe Pacific R. R., where the standard practice is to adjust the points so close to the stock rail that a sheet of ordinary writing paper between the two will be torn before it can be pulled out. As to the merits of the various devices for this purpose it may be said that several of those in service give satisfaction. Not a few prefer to use rigidly-connected points with an adjustable rod connecting the same with the switch stand, or to have the means of adjustment at the coupling of the connecting rod with the head rod. A fault sometimes charged against screw adjustment devices is that the threads wear and fail to hold, and another difficulty complained of is that where such devices are exposed to the drippings from refrigerator cars the turnbuckles or nuts soon become rusted fast by the brine and rendered hard to turn or adjust. In a committee report to the Roadmasters' Association of America, in 1900, it was recommended that devices for adjusting split switches should permit the adjustment of both point rails and that the limit of the adjustment should be restricted to the minimum throw of the points.

Reinforced Switch Points.—Switch points in main track should be reinforced, the necessity arising not from lack of strength, but from a demand for some means of holding together the disconnected parts in case the point rail should break. A record covering 950 point switches on the Chicago, Burlington & Quincy Ry. shows an average of one breakage every two years, the break usually occurring at a flaw in the rail. From various reported cases of broken switch points it seems that breakage occurs most frequently between the second and third tie rods, or about at the point where the switch rail begins to carry the full load when the wheels come facing. It is usual to reinforce both the main and turnout point rails, and the most common form of reinforcement is a wrought iron bar or strap $\frac{1}{4}$ to $\frac{5}{8}$ in. thick riveted to the web of the rail with $\frac{5}{8}$-in. or $\frac{3}{4}$-in. rivets, preferably on either side, as appears in Fig. 145 (Engravings *G* and *H*), Figs. 146 and 148. In some instances the straps are bolted on, with the intention of using them on a new set of switch points when the old ones become worn out, but riveting is the more secure and the preferable method. In extensive practice switch points are not reinforced farther back than the planed portion of the rail, but to afford desirable security the reinforcement should extend the whole length, or as far as the heel splice. Without a reinforcement a break in the switch rail anywhere back of the last tie rod is a very dangerous thing. For switches used in yards and in tracks where fast trains do not run it is not considered necessary to reinforce the point rails.

Figure 148 shows the Pennsylvania Steel Company's manner of reinforcing switch point rails. On the flangeway side of the point a plain, flat wrought iron bar is used for a reinforcing strap, while on the gage side there is an angle bar with a 4-in. horizontal leg, to which the switch rod is attached. As the three pieces are securely riveted through and through a high degree of lateral stiffness is imparted to the rail. The adjustable head rod is similar to type *E*, Fig. 145, and permits either point to be adjusted. The Wharton company controls the patent on a switch point reinforcement consisting of a channel. The back of the channel is riveted to the web of the switch rail and the switch rod connection is made by means of a pin through the flanges of the channel.

In the Channel split switch (Fig. 149), the standard switch of the

Atchison, Topeka & Santa Fe and other roads, each point rail is reinforced by a 10-ft. piece of 45-lb. rail, called a "supporting rail," the two being securely united by bolts and cast separating blocks, at such a distance apart that a foot guard is unnecessary. The head rod is attached to the supporting rails by the ordinary stub switch slot connection, and is held fast against slipping along the rail by the retaining block *R*. As may be seen, there are adjustment holes in the web of the supporting rail, thus permitting the rod to be moved up on the flared end, so as to take up wear at the points and lost motion in the connections. The gage plates *P* extend entirely across the track, forming slide plates for the point and supporting rails, and have seats planed out at the ends to receive the stock and through rails. As there is no wear on the supporting rails, and as they are the same size (45-lb. section) for point rails of all sizes, all that is required in renewing the switch is to bolt on new point rails. Such is a convenient arrangement, especially when the track is being relaid with steel of larger section. As the supporting rails make the switch very stiff it is not an easy matter to lock up the switch stand with an obstruction between the point rail and stock rail. With the ordinary split switch it sometimes happens

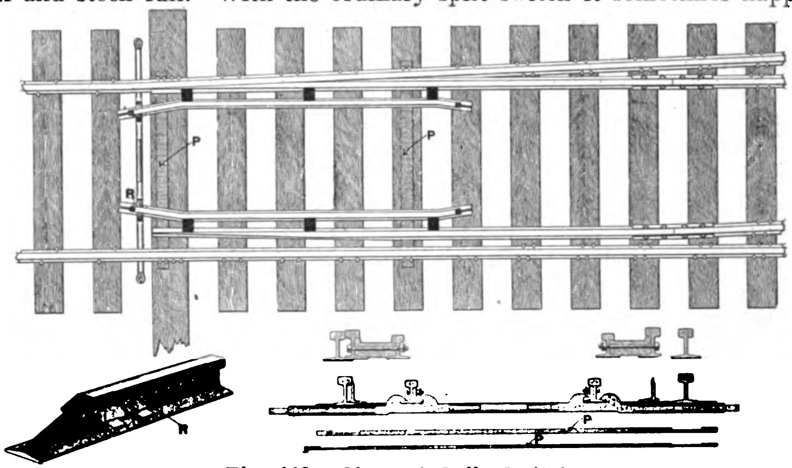

Fig. 149.—Channel Split Switch.

that the point rails will bend and permit this to be done. To prevent passing objects from catching on the supporting rails the ends of the same are sloped down to the base, as shown. As with the Elliot Key-Wedge Adjustment switch (Engraving *H*, Fig. 112), so with the Channel switch, the point rails are firmly held against any force tending to cant them and bend the clips or tie-rod fastenings. The "Curve" split switch (for turnouts to outside of curve) has a long point for the main switch rail, with a "supporting" rail of the Channel switch type; and a short point rail for the through-rail side, with a guard rail in front of the same protecting the extending end of the long point rail on the opposite side of the track. The short point has no supporting rail and the tie rods and clips are like those used on the Transit switch (Fig. 144).

A stop block or stop lug (*B*, Fig. 148) is a cast or bent piece bolted either to the point rail or to the stock or through rail to back up the point rail when it is thrown to that side. It is of sufficient thickness to block the space between the two rails when the switch is thrown to that side, and on 15-ft. points it is usually placed midway between the heel and where the planing starts. It is particularly serviceable on the main point of a switch which turns to the outside of a curve, on switches with less than four tie rods and on switch points longer than 15 ft., but it is a good plan to use it on all point switches. On extra long switch points it is customary to use two or more stop lugs. On the Michigan Central R. R. switch points 22 ft. long, used in connection with No. 14 frogs, have five tie rods and three stop blocks, and are reinforced both sides back to a point 2 ins. from the heel splice. To hold the rail in line in case of breakage between the reinforcement and the splice there is a flat bar of iron, called an "S-brace," fitted over the base of the point rail, butted against the web of the same at the 2-in. space and spiked to the tie. Point rails 24 ft. long used with No. 15 frogs at end of double track on the Chicago, Burlington & Quincy Ry. have five rods, and stop blocks, but the rails are not reinforced. The point switches for track of 100-lb. rails on the Duluth & Iron Range R. R. are 20 ft. long and have five tie rods spaced 3 ft. 2 ins. apart, the head rod coming 9 ins. from the point end. On each point rail there is one 3x⅝-in. reinforcing bar secured to the web on the flangeway side, with ⅝-in. rivets. This reinforcing bar is 6 ft. 9 ins. long, and extends to the third tie rod. The switch has no stop lugs.

The pushing of switch points by creeping rails leads to repair work sooner or later, usually to move the headblock and switch ties out of contact with the switch rods. It is desirable, therefore, to hold this creeping in check, and as both point rails lead to the frog the best way to go about it is to slot-spike the four sets of splice bars at the ends of the frog, the splices at the heels of the point rails and the intervening splices on the lead rails. In addition to this it is frequently the practice to bolt on a twisted anchor strap to the inside splice bar at the heel of each point rail and spike it to the three or four ties over which it extends. This is about all that can be done, conveniently, and unless the creeping is bad it will usually accomplish the purpose. Where creeping is bothersome it usually does more harm than good to anchor the heels of the switch points to the through rail and stock rail. This is sometimes done by means of a cast heel block or filler between the two rails, bolted through and through and used in lieu of a foot guard. In some places where such devices have been used they have given considerable trouble by causing the creeping rails to throw or crowd the joints out of line. The same results have also been experienced with spacing devices to hold the heel of the point rail at the proper distance from the stock rail. An arrangement sometimes used for this purpose consists of bolts through both rails with gas pipe collars to hold the rails at the proper distance apart. A better arrangement where creeping is bothersome is a shouldered tie plate with seats at the proper spacing for the two rails. The rails may then creep unhindered but will be maintained at the proper distance apart. As a matter of fact the creeping of the through rail or stock rail, if permitted to do so freely, is seldom bothersome. The creeping of the through rail, cannot affect the adjustment of the point rails, while with the stock rail a moderate amount of creeping may not require readjustment of the point rails, much depending upon the relative position of the bend in the rail.

In this country it is customary to bolt up the heel splice of point rails as tightly as at ordinary joints. On some of the foreign railways this splice is left sufficiently slack to permit the switch rail to work freely, or without bending the splice bar, while in other instances, as with the Netherlands State Railways, the point rails are hinged to heel castings without splicing.

Automatic Point Switches.—The term "automatic," as applied to point switches or switch stands, has reference to the action of the point rails for a car or train trailing the switch when it is set the wrong way. The wheel flanges crowd the points over against the direct or indirect tension of a spiral spring, so that no damage is done to the point rails or other parts, as would necessarily result were the connections rigid throughout. The term "safety" is sometimes used in the same sense, but its full meaning, as applied in every case, should be interpreted advisedly. Automatic action of the switch may be had by the use of a spring connection with the head rod, by a spring connecting rod, or by an automatic stand. The first-named device answers to the description of the Lorenz spring, contrived at an early date, being perhaps the oldest device, and certainly one of the best known devices, for permitting the automatic working of split switches when such are set the wrong way for trailing movements through them. It is shown as Engraving *A*, Fig. 105; Engraving *M*, Fig. 145; and in Figs. 142A and 157. A spiral spring is placed between two lugs or within a frame, on the head rod, and the connecting rod instead of being attached directly to the head rod is made to operate the points by acting on this spring. The rod is passed through the coil of the spring and through holes in the lugs, and acts against either end of the coil (depending on which way it is thrown) by means of a collared spool or sleeve backed by jam-nuts on the rod. If the throw of the stand exceeds the throw

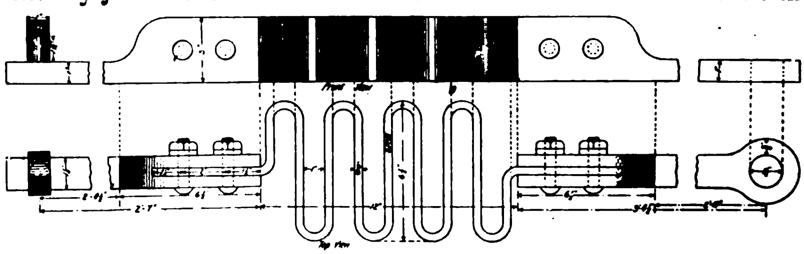

Fig. 150.—"P. O. D." Spring Connecting Rod, B. & M. R. R. R.

of the points (as it should with this device) these nuts may be so adjusted that some of the throw of the stand or connecting rod must be taken up in compressing the spring. Lost motion can thus be taken care of, the point rails being held firmly against either side to which they are thrown, and if trailed the wrong way they will yield to the wheel flanges and then return to the position in which they were last set. As a precaution against entire failure the spring is sometimes composed of two coils—one within the other—the probability that both springs will break at the same time being less, it is thought, than of the breakage of a single spring heavier than either. For security on facing-point switches springs attached to the side of the head rod should be placed on the side facing the frog.

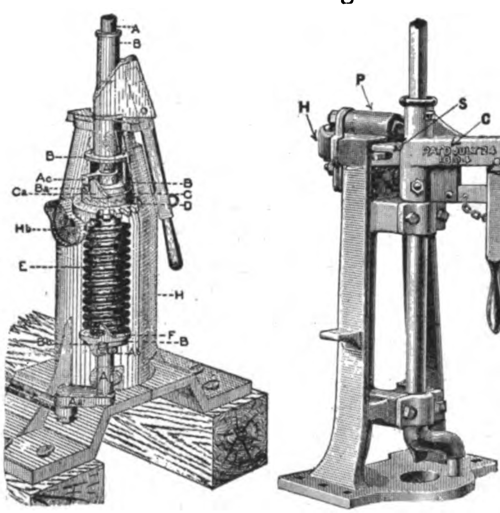
An objection raised against the use of an automatic switch on single track or an automatic facing-point switch on double track spring connected in the main-line position, in either case, is that, with hard-packed snow or some small obstruction between the point and stock rail it is possible to throw the stand completely without bringing the point rail quite up to its place. Moreover, should the spring on an automatic facing-point switch break the latter would at once become a dangerous affair. The same objections apply, of course, to spring connecting rods and to such types of automatic stand as can be locked without throwing the points clear home; also to any stand designed to hold the points to place by the agency of spring pressure or torsion acting directly on the shaft or the crank. With the foregoing dangers in view, so far as springs on the head rod and spring connecting rods are concerned, it is the practice on some roads to have one of the thimbles on the connecting rod bear directly against the solid lug on the head rod, for the closed position of the switch, and the other thimble against the spring, for the open position, thereby maintaining a rigid connection when the switch is set for main line and providing a spring connection when the switch is set for the side-track. A standard arrangement of the Pennsylvania R. R. is a Lorenz spring connected with the switch and with a simple ground lever in this manner, as illustrated in Fig. 142A.

The action of the spring connecting rod (*J* and *K*, Fig. 145) is essentially the same as that of the Lorenz spring, the only difference being that the spring is placed in the connecting rod instead of on the head rod. The Burlington & Missouri River R. R. has in use in some of its yards a spring connecting rod in which the rod itself is shaped to form the spring. The design was suggested by Roadmaster Patrick O'Donnell, and it is locally known as the "P. O. D." spring. By reference to Fig. 150 it will be seen that about 12 ins. of the rod is formed by a 3x⅜ in. steel bar looped eight times and securely bolted into slotted shanks in the two end pieces of the rod. The convolutions are 6½ ins. long and 1 in. apart. The rod is used with a rigid stand, and in case the point rails are trailed in the wrong position the rod will stretch or be squeezed together, permitting the points to be set over and the wheels to pass through the switch without doing damage to the points, and then return the points to position after the wheels have passed.

Figure 143 shows a "spring split switch," used mostly on electric railways in such places as passing sidings or loops, being intended to automatically switch cars to one side when they pass the switch in the facing direction and permit them to trail out when passing in the opposite direction. A housed spring attached to one of the point rails serves to hold the opposite point rail firmly against the main rail, and in this way serves as a slack adjustment device. A similar arrangement can be had by drilling through the webs of both point and stock rails and using a bolt and spiral spring similar to the spring bolt on a spring-rail frog. If the head of the bolt be made to catch the point rail, the coiled spring may be made to bear against the rail on the outside of the track or it may be placed in a housing. It must be obvious that either arrangement serves its purpose for one side only and tends to produce the opposite effect with lost motion on the other side. For this reason the device is seldom, if ever, used on point rails which are intended to be thrown by a switch stand.

Automatic Switch Stands.—Switch stands arranged for the automatic operation of point switches may be divided into two classes: the "fly-back" and the "set-over." Stands of the former class return the switch to its original position after being forced aside by trailing wheels; with the "set-over" stands there is provided a connection with sufficient resistance to hold the points for proper service, but the points are moved through a complete throw upon being forced aside. This arrangement thus permits of an automatic change in the position of the switch. The foregoing spring switches and spring connecting rods have the so-called "fly-back" action. With devices of the fly-back variety the switch is retained in one position, as locked, despite an automatic or improper use of it. With the set-over or complete-throw automatic stand, the switch, if misused by careless employees by trailing out of a side-track when it is set for main line, may chance to remain open in the face of main-line trains. In this respect, therefore, it is inferior to the fly-back device. It is considered, however, that it serves as a telltale on careless employees, whereas the other device does not; and that in case a train should trail part of its length through a wrongly set switch provided with this stand, and then back up, the train would not be broken in two by straddling the tracks, as it unavoidably would be with a fly-back arrangement. In instances of such culpable negligence, however, the fly-back device would act as telltale and, for such occurrences alone, despite the consequences to the train, it would seem to be the more valuable device for the company. Some complete-throw automatic stands do also have in their favor the advantage that the points are not held in position by direct spring pressure or torsional action on the shaft. There is therefore no direct stress on the spring and consequently less liability that it will break in service.

The Long "safety" stand is of the fly-back type. It is used on the Bangor & Aroostook, Chicago & Alton, New York, New Haven & Hartford, the Southern and other roads. Briefly stated, the shaft of the stand is engaged with a stiff spiral spring made of 14ft. of steel bar and coiled around the shaft. The hand lever for revolving the shaft is not engaged directly therewith, except when it is raised to throw the switch; normally it is engaged with the spiral spring. The crank is rigidly connected with the point rails. The spring around the shaft takes up all play or lost motion, so that the connecting rod is held by the force exerted by the spring. This spring will allow the shaft to turn and the switch to be thrown automatically should a car or train trail through it when it is set the wrong



LONG SAFETY STAND — WEIR AUTOMATIC STAND

Fig. 151.—Automatic Switch Stands.

way. More in detail, the shaft or crank spindle *A* (Fig. 151) extends in one solid piece from target to crank, through the tubular handle shaft *B*, outside of which the spring *E* and its collars *C, D,* and *F* are carried. In hand operation the handle is positively engaged with the shaft *A*, by its knife-blade end, which enters a slot in the shaft as the handle is thrown up, and all these parts move as one; they are locked in place by folding the handle into a notch in the frame *H*. Any obstruction between point and stock rails will not allow the shaft to turn far enough to permit the handle to be folded into the notch, and hence is detected at once. A spur *Bb*, on the lower end of the handle shaft *B*, holds the spring from unwinding, causing the spur *Ca*, on the upper spring collar *C*, to press against the arm *Ac* which is fixed on the crank shaft *A*, thus applying the power of the spring against the shaft, the switch rod and the switch. An automatic movement of the switch will move the rod in the direction of the arrow, and the power thus applied will act to wind up and increase the stress on the spring, the reaction of which will promptly return the switch to position after the wheels pass off. For an automatic action in the reverse direction, the switch and crank being in the other position, the spur *Ba* holds against the upper end of the spring, the power of which is applied against the arm *Ab* on the shaft below the spring. The tension of the spring is increased, when required, by forcibly turning collar *D,* under the collar *C,* against the spring, by a bar inserted under the step, the door *Hb* being removable to obtain access to the spring.

The Weir automatic stand, shown also in Fig. 151, is of the complete-throw type. It is used on the Chicago & Northwestern, Chicago, Milwaukee & St. Paul, Central of Georgia and other roads. On the back side of the stand there is a V-shaped box cast as part of the stand, containing spring pockets *P,* top and bottom. On the back of this box there is a hood *H,* held to place by bolts engaging with springs in the pockets *P.* The springs are seated in the back sides of the pockets and hence their action on the bolts tends to draw the hood towards the front of the stand —that is, towards the shaft. Within the lever casting *C,* which is rigidly fastened to the shaft, there is a sliding bar *S* connected by means of a link to the hood *H.* The other end of the sliding bar is operated on by the handle by a cam-like action which crowds the bar towards the hood when the handle is folded downward, but permits it to slide from the hood when the handle is thrown up to the horizontal. There is thus no strain on the springs when the stand is thrown by hand. The lever is not locked in any definite position, but upon being folded down, when the switch is thrown to either side, the sliding bar *S* is crowded backward, compressing the springs, the reaction of which produces a turning effect on the shaft and forces the switch points tightly against the stock rail. The stock or through rail thus acts as a final stop to the action of the springs; and should lost motion result from wear of parts or widening of the gage, the throw of the crank is automatically adjusted to the changed conditions. The tension of the springs can be regulated by a set screw in the back of the hood, which does not appear in the figure. In the automatic action of the stand the shaft is turned against the pressure of the springs until the sliding bar and link (which form a toggle-joint) are moved over the center, when the action of the springs sets the points entirely over the other way.

One of the best known, as well as one of the most widely used, automatic switch stands is the Ramapo device (Snow's patent), Fig. 152. Of the two stands shown that at the right is provided with a crank of fixed length and that at the left with a crank of adjustable length. In other respects the stands are of identical construction and their manner of operation is the same. The crank and shaft are rigidly engaged with the handle, so that in hand operation there is positive action between handle and switch. There is a "safety block" *B,* ribbed to fit into the grooved "safety cap" *C.* When the handle is raised to throw the switch the safety block is lifted by link motion and the handle cannot be lowered and locked to the stand until the points are thrown entirely home, permitting the safety block to slide into the safety cap. Any obstruction between a switch point and the stock rail is, therefore, readily detected. The under side of the cap or head *C* forms one jaw of a clutch, and the block *E,* sliding in a guideway in the frame of the stand and backed by a spring, forms the other jaw. Obviously, this block is held against turning. If the switch is set the wrong way for trailing wheels, the shaft and cap, being locked together, turn as one, forcing down the lower jaw of the clutch (see right-hand view in the figure), which, as soon as the teeth pass, being actuated by the spring, sets the points over to the other position. The projecting stud S is a stop which serves to limit the throw of the crank. The stand is also made with the crank upturned to meet the bottom of the base casting, so that the connecting rod cannot be taken off without releasing the shaft from its fastenings. If desired, the stand can be made to work automatically one way only, so that the points, if wrongly set for a train trailing them on main track, will be automatically thrown without damage, but not for a train trailing out of the siding when the points are set for main track.

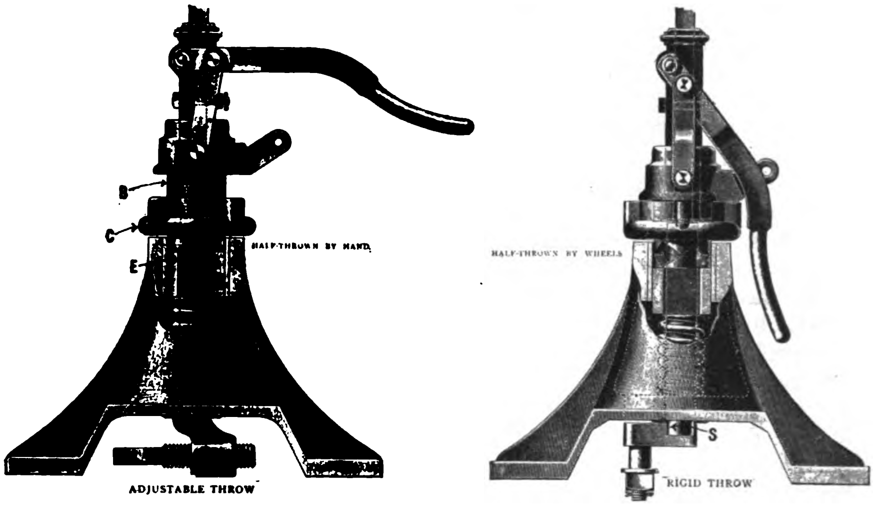


Fig. 152.—Ramapo Automatic Switch Stand.

The adjustable crank, above referred to, consists of a heavy eye bolt screwed into a stout shank at the bottom of the shaft. As this device permits a change to be made in the throw of the stand the advantage in the use of the same is readily seen. A switch stand with an adjustable crank will work with any switch with which it is desired that it shall be used, as the throw may be adjusted to correspond to that of the switch; whereas the crank of fixed length requires that the stand shall be specially made to fit the throw of the switch. Figure 153 shows an adjustable connecting rod intended for use with this stand. The rod has a screw jaw on one end, and this device, in connection with the adjustable crank, enables an adjustment of the points from one side to the other, so that in setting up the stand it may be firmly spiked to the headblock and the rod afterwards adjusted to the proper length to throw the switch to a close fit in either direction. The adjustable crank and the adjustable connecting rod thus obviate the necessity for adjustable head rods and adjustable points in split switches. The screw jaw on the connecting rod and the adjustable crank cannot be turned without disconnecting the two, so that the arrangement is not readily tampered with, and the parts cannot of themselves work loose and change the adjustment of the switch or stand.

The Axel stand (Fig 154) is similar in action to the Ramapo stand, and about the only difference in construction is in the position of the

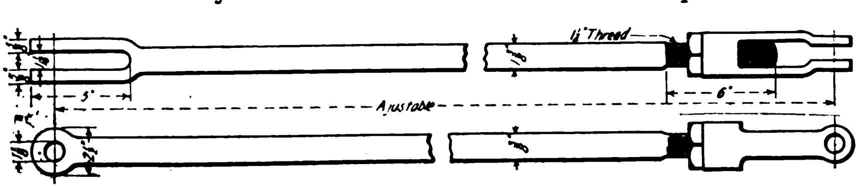

Fig. 153.—Adjustable Connecting Rod.

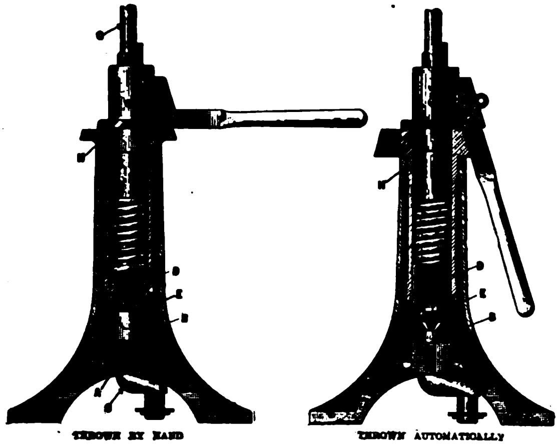

Fig. 154.—Axel Automatic Switch Stand.

clutch. The shaft C is one piece from crank to target. The spider A and the clutch jaw B are essentially one piece, the spider being cast with, or made fast to, the frame of the stand. The upper jaw E, of the clutch, forms one piece with the shank D, which is square in cross-section and held against turning by the head H. The handle is rigidly attached to the shaft and folds downward into a notch in the head H, so that the points must be closed home before the handle can be put to place. In the automatic action of the stand the head is turned, disengaging the clutch against the compression of the spring. This stand is used on the Burlington, Cedar Rapids & Northern and some other roads.

The Wharton automatic stand (Suffern and Kidd's patent), shown in Fig. 155, is similar to the Weir stand in action, but quite dissimilar in appearance and in detail of construction. The cast iron frame is made in two parts, A and A^1. The shaft B is of rolled steel and square in cross-section. The crank B^1 is at the extreme end of the shaft, as ordinarily, and

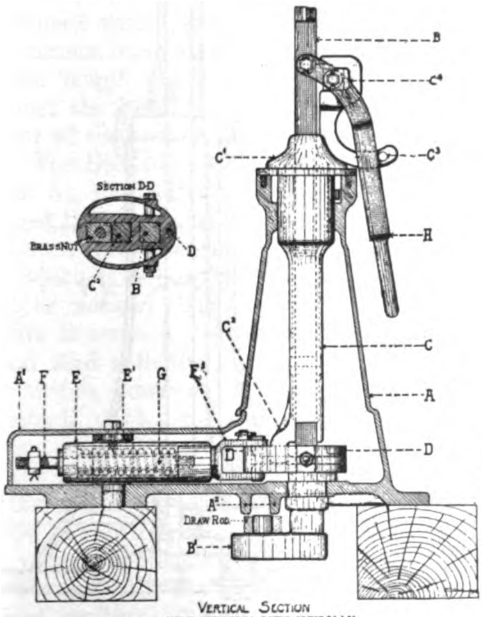

Fig. 155.—Wharton Automatic Switch Stand.

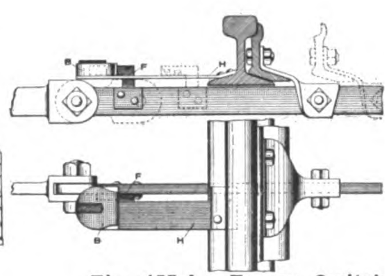

Fig. 155 A.—Emery Switch Point Lock.

a locking plunger C extends from top to bottom of the stand, turning with the shaft B and resting on the top of the frame by the collar C^1. At the lower end of the plunger C there is a locking finger C^2, which fits into a slot in the upper crank D when the lever is lowered. The extending arm C^3 C^4 is provided with a hole at C^3 to receive the lock, and with a slot at C^4, in which slides a brass nut pivoted to the hand lever H, by which means the plunger C is raised and lowered with the hand lever. Parts C, C^1, C^2, C^3 and C^4 are in one piece of malleable iron. The malleable iron Crank D, rigidly fastened to the main shaft, is provided with a slot to receive the locking finger and a brass nut pivoted to the jaw F^1. Part E is a cylinder serving for a spring casing and E^1 are trunnions upon which the spring casing swings. The rod F extends through cylinder E, one end being rigidly fastened to jaw F^1, to which the brass nut sliding in slotted crank D is pivoted. The spiral spring G is coiled around the rod F and confined between the end of jaw F^1 and the end of the spring casing. In the figure the stand is shown as it would appear when half thrown automatically. The locking finger C^2 is in the slot in crank D and prevents the brass nut pivoted to jaw F^1 from sliding inward toward the shaft. The spring is therefore compressed and the jaw F^1 and rod F are forced into the spring casing. As soon as the central position (dead center) is passed the spring expands and forces the shaft and handle around to the opposite position, thereby throwing the switch points over against the stock rail. In throwing the stand by hand the plunger and locking finger are raised, the brass nut pivoted to jaw F^1 slides inward in its slot in crank D and the spring is not compressed. Unlike the Weir stand, the spring is not compressed except during the automatic operation of the stand. The throw of the crank is adjusted by the nut on the rod F, the length of this rod limiting the turning of the crank D and hence the throw of the crank B^1. As the locking finger C^2 cannot be lowered into its slot until the points have been thrown their full distance, the handle of the stand cannot be lowered and locked if there is an obstruction to the movement of the points. In or-

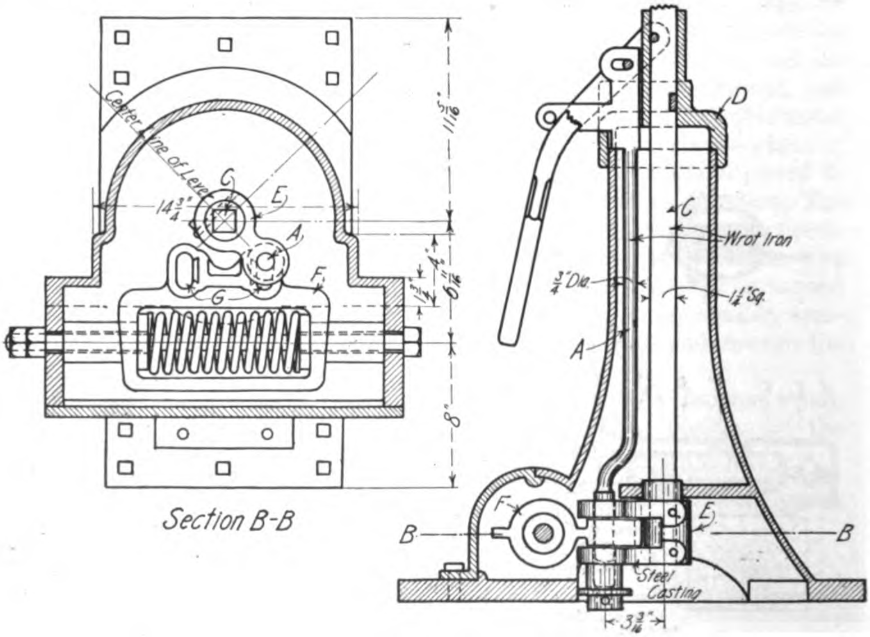

Fig. 156.—Standard Switch Stand, Southern Pacific Co.

der to engage or disengage the connecting rod it is necessary to remove lid A^1 and the spring casing and turn the shaft so that the crank passes beyond the embrace of the cast arc A^2. A stand with the same spring application is made in a yard pattern only about 10 ins. high, to top of the lever.

The standard switch stand of the Southern Pacific road is designed with a spring action to return the points to their original position in case they should be trailed through by a car or engine, when set in the wrong position, and by means of a locking device the switch-stand lever cannot be dropped into its normal position without first throwing the switch point fully up against the stock rail. This stand (Fig. 156), designed by Mr. J. H. Wallace, engineer maintenance of way of the company, consists of the ordinary vertical cast iron shell, with a rotary head or cap (*D*) fitted over the top of the shell and rigidly attached to a crank shaft (*C*) of square cross section. The crank (*E*) which throws the switch is a steel casting slotted to straddle the horizontal projection of a cast steel locking frame (*F*) which encloses a spiral spring on a bolt passing through the spring box, at the foot of the stand. This spring exerts its tension against the collared ends of sleeves passing through disks which form two sides of the frame. Thus the locking frame, by compressing the spring, is capable of movement in either direction. This frame has slotted openings (*G*) which register with a circular opening in the end of the crank when the switch stand is set in either the open or closed position. Attached to the switch-stand lever there is a vertical rod (*A*) formed into a pin at the lower end, which fits into the opening at the end of the crank and into the slot in the locking frame. This rod is connected with the lever at such a distance from the fulcrum of the latter that when the lever is raised from its normal position it withdraws the pin from the slot, permitting the stand to be thrown without engaging the spring mechanism. The lever cannot then be dropped to its normal position until the switch points have been thrown fully home, permitting the locking rod to enter the crank opening and the slot in the locking frame. When this connection is made the crank, the main shaft (*C*) and the revolving head (*D*) are locked into an engagement with the spring, and any ordinary force applied to the switch rail cannot move it from its position. A car or train trailing through the switch points placed in the wrong position will, however, set them over against the tension of the spring, and after the wheels have passed, the power of the spring will move the switch back to its original position.

The Steelton switch stand, the standard of the Nashville, Chattanooga & St. Louis Ry., is designed for use with a Lorenz spring and so arranged that the lever cannot be latched to lock the stand unless the switch has been thrown entirely home. The spring is in full use for all purposes for which it is intended, and works both ways. Referring to Fig. 157, it will be noticed that the stand has a spring connection with the switch points through a Lorenz spring, in the same manner as with any plain stand used with this spring. When the handle or lever is raised to throw the switch, however, the shaft is put in rigid connection with the switch points, through a rod connecting rigidly with the head tie bar of the points at one end and curved over at its other end so as to lie between jaws keyed to the shaft. Projecting through these jaws is the lock rod *F*, attached to the end of the lever or handle *D*, at *C*. When the handle *D* is raised to throw the switch the rod *F* is shoved downward through a hole in the curved rod connecting with the head rod, thereby placing the stand in rigid connection with the switch points so long as the lever *D* remains in the raised position. As this lever cannot be dropped until it is thrown far enough around to meet the notch in the table of the stand, it is clear that

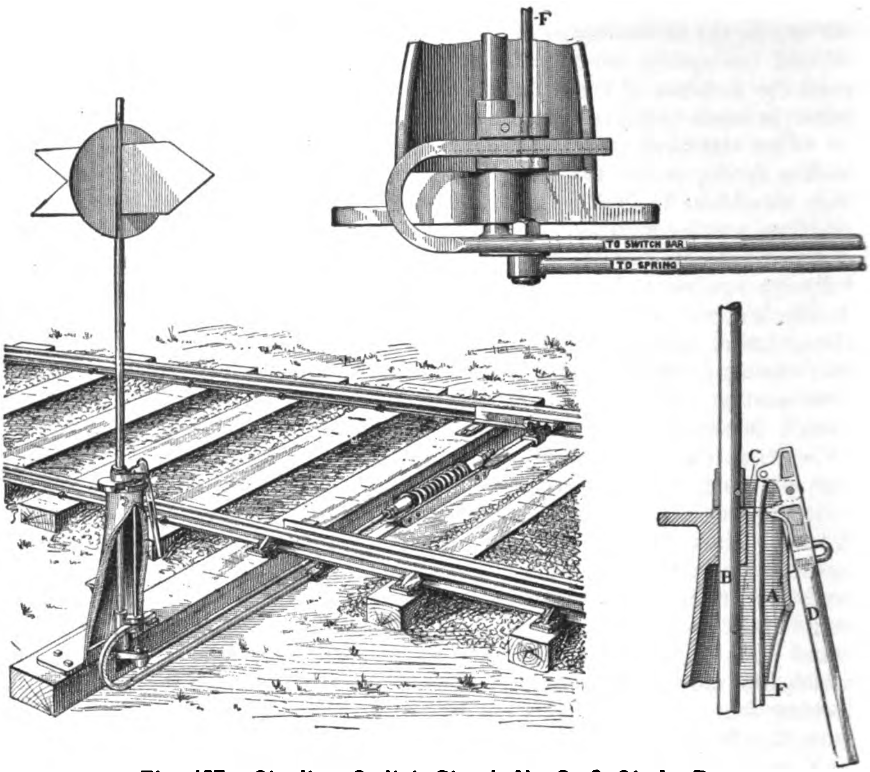

Fig. 157.—Steelton Switch Stand, N., C. & St. L. Ry.

the rigid connection to the switch cannot be broken until the points are thrown fully up to the stock rail. As soon as they have been thrown thus far, however, the lever is folded into the notch, the lock rod *F* is drawn upward, the rigid connection is broken and the stand remains spring-connected to the switch points through the Lorenz spring; so that in whatever position the stand is set or locked a train trailing the points set the wrong way will throw them automatically against the spring connection. An important advantage which the N., C. & St. L. people have found with this type of stand is that spreading of the gage at the stock rails or loosening of the stand is promptly made known by the refusal of the stand to work. If the lock bar *F* fails to fit into the hole in the head rod connection it is impossible to operate the stand, as the lever cannot be raised out of its notch. Hence a loose condition of things at the switch cannot exist very long, even if it should occur, for in order that the stand may be used the section foremen are required to keep the track at the switch to the proper gage and the stand securely fastened. The automatic switch stand of the Burlington & Missouri River R. R. (Fig. 134B) is described in connection with lever-lock switch stands.

There is reasonable distrust in the general use of automatic switch stands or other automatic switch devices. In the first place, it is not to be denied that the use of automatic switches and automatic stands, by switching crews, begets carelessness. For this reason many think it is not worth while to provide automatic devices with the sole object of permitting trains to trail from side-tracks through wrongly set switches without damaging the switch or being derailed. As such trains usually move at slow speed no great damage can result from derailment, and it would undoubtedly conduce to better discipline if the results of the negligent use of the switch were visibly indicated by injured point rails or by derailment, in case the switch is provided with a point lock. It is highly desirable, however, that a switch should operate automatically when wrongly set and trailed by a main-line train, since in forcing the points over against rigid connections there is some risk of derailment, and in any case the injury to the points or their rigid connections leaves the switch in dangerous condition for facing trains. On double track, therefore, it would seem desirable that trailing switches should work automatically, at least one way; that is, when wrongly set for main-track trains. For single track greatest safety can be had only by the use of a switch point lock for the main-track position of the switch. This arrangement renders unserviceable any automatic device for trains trailing out of the side-track when the switch is set for main track; but it is no hindrance to the automatic throwing of the switch when wrongly set for trains trailing through it on main track. Hence there is some utility in using a Lorenz spring, spring connecting rod or automatic stand with a switch point lock. Next best to this arrangement is a Lorenz spring or automatic stand rigidly connected for the main-track position; that is, adjustable only for the side-track position. For double-track trailing switches some form of automatic stand which has positive or rigid engagement of the hand lever with the point rails in hand operation is undoubtedly preferable. This form of automatic stand is preferable to the automatic switch spring connected both ways, because it does not permit of being locked until the point has been thrown entirely home against the stock rail.

The argument against the use of a spring connection or automatic arrangement for the main-track position of the switch, on single track, is not entirely one sided, for if an engine is run out of a side-track through a rigidly-connected switch set in the wrong position the injury to the points or the connections may leave the switch in dangerous condition for facing trains; and the fear is that an engine crew might do this and depart without stopping to examine the condition of the switch; in fact such cases are on record. But in the use of the automatic stand or a spring connection for facing-point switches there is (whether justly founded or not) widespread distrust in the integrity of any clutch or spring device to hold the points firmly to their place. Should the spring break or become weakened through service, it is thought, and actually asserted as having occurred, that the points after having been automatically thrown may chance to remain partly open, which, under some circumstances, would be the most dangerous position possible; it is also possible for the same condition to result from excessive wear of clutches. At any rate the use of automatic stands for facing-point switches is considered among trackmen a debatable question. For facing-point switches on double track a switch-point lock is undoubtedly a desirable arrangement, whether an automatic stand or spring connection is used with it or not.

Where a car or train has trailed through a non-automatic or rigidly-connected point switch set the wrong way, the switch should be looked after immediately, because the points, or the connection with them, will usually be found loosened to an extent which leaves the switch in a dangerous condition for facing trains. The tie rod clips should be closely examined to see whether they are bent, as if they are they will permit the point rails to cant out of their proper position against the stock rails. The switch stand also should be carefully inspected, and particularly with reference to the crank of the main shaft, as any bending of the same out of its proper shape necessarily changes the throw of the stand. The connecting rod should also be carefully inspected with reference to any bending from the original shape. The bending of a straight rod shortens the distance between its end connections, and the straightening of a rod crooked at some part (as connecting rods frequently are) lengthens the distance between its end connections, in either of which cases the throw of the switch may be considerably changed. The extent of such damage may, of course, be ascertained by throwing the switch.

On some roads automatic switches or stands are used in yards but not on main track. Such practice is explained by a fear concerning the entire reliability of such devices in high-speed tracks, but with a view to avoid damage to switch points where a great deal of switching is being done at slow speed, and where trainmen are frequently more or less careless. It is no uncommon occurrence for trainmen working on yard tracks to trail a train against rigidly connected point switches wrongly set. Of course such is bad discipline, but these matters are not under the control of the track department, and for this reason some roadmasters find that they can avoid a good deal of trouble by using spring devices with their split

switches in yards. As an instance, I have official information of a Ramapo switch stand used in a yard on a switch that is trailed in the wrong position habitually. The engines or cars throw the points automatically, and the switch has been used in this manner for more than five years, without any trouble.

69. Laying Point-Switch Turnouts.—For laying point switches originally—that is, when they are not being laid to replace stub switches—a little calculation will enable one to fix upon a standard frog angle or length of frog which will give the proper lead without cutting any rail. In this respect the point switch has many advantages over the stub switch, since there are no joints to calculate upon meeting exactly. The only difficulty to be guarded against is that of meeting a joint the inside splice bar of which might interfere with the throwing of the point rails, or possibly of having a joint come too near the bend in the stock rail. Usually, a frog numbered somewhere between 9 and 10—depending upon the length of the frog, the length of the points and the spread at the heel—will require a lead such that, in either square or broken-jointed track, by taking out three 30-ft. rails on the frog side, the frog, two 30-ft. rails and the points may be connected and put down to bring no joint to interfere with the point rails or the bent rail. More attention is being given to the matter of avoiding the cutting of rails than was formerly the case. On the Chicago & Northwestern Ry. the angles of the frogs or the lengths of the same are so calculated that closure rails of convenient length will fit into the leads without cutting—in ordinary cases 30-ft. rails are used. The data of these frogs and the lead measurements are contained in Fig. 157A. It will be noticed that no two frogs of different number are of the same length. Sometimes by using a fish plate inside at the joint, instead of an angle bar, or by cutting off the lower leg of the angle bar, a joint otherwise too close becomes not bothersome. To trim off the horizontal part of an angle bar, notch the bar along the angle with a track chisel, as in preparing to cut a rail, lay the angle bar over a rail, angle up, and strike the vertex with a sledge hammer. Whenever it is feasible to do so it is well to have the point rails break joints with the through rail and stock rail. The roadmaster who starts out laying his turnouts to some standard, will save himself much trouble in later years.

The rails on the side opposite the frog need not be disturbed at all. After the location of the frog has been determined upon and the switch ties have been put in, the guard rail in main track opposite the frog may be laid. Next, the frog, point rails already connected, the intervening lead rails and the bent or stock rail must all go in at the same time. By taking measurement the bent rail can be made ready beforehand. A sure and accurate way of taking these measurements is to place the frog, the point rails and the intervening rails end to end at the side of the main rails, in the order they are to come when the turnout is completed, and mark the desired points on the track rails with a chisel. The bend in the stock rail is best made sharply, with a jim-crow, and it should correspond to the angle of the point rails. This completes the order of the main-track part of the work. The turnout rails may be laid when it comes most convenient. Until the stand is connected no train should be allowed to pass the points without first spiking them to place, and to make secure for trains that come facing they should be braced temporarily with angle bars or blocks of wood spiked to the ties. The headblock may be put in either before or after the point rails, but it is usually placed along with the switch ties. Regarding the remainder of the work the same rules and practice apply as when laying a stub-switch turnout.

70. Changing Stub Switch to Point Switch.—Before doing anything at all toward substituting a point switch for a stub switch it should first be ascertained whether the old switch stand is going to throw right for the point rails; if not, a stand of proper throw should be provided. Up to and including a No. 10 frog, the toe of the stub switch may be used for the heel of the point switch with the same frog, by changing slightly the curvature of the turnout rails. All that need be done, then, besides altering the curvature, is to change the headblock to its proper place under the point rails and to connect the point rails to the old stub lead rails. The point rail on the frog side is spliced to the main-track lead rail and the other point rail to the turnout lead rail. The old moving rail on the side opposite the frog is spliced at the old toe joint, forming the through rail, while the other moving rail is made the bent rail, or is replaced by a bent rail, which is then spliced to the turnout rail. The ties which were used under the old moving rails may have to be adzed in order to let the slide plates under the point rails, or they may have to be rearranged to suit the switch rods, or new ones be placed in their stead.

71. Three-Throw Switches.—A "three-way" or "three-throw" switch is one which can be thrown for three tracks. The combination where such a switch is used is sometimes called a double turnout. It affords convenience in switching, besides a saving in space, labor and material. There are two kinds: one having turnouts to opposite sides of the main track and the other having both turnouts to the same side of main track. Where the main track is straight and the turnouts lead to opposite sides they are usually made the same degree of curve, and consequently frogs of the same number are used in both, in order that they may be placed directly opposite each other. The inside wing rail of each frog then acts as guard rail for the other frog. Where two frogs would come near each other in opposite sides of the same track it is always desirable to place them directly opposite, rather than nearly so, because if they are not opposite, a guard rail must be provided for each, which, for lack of room, must necessarily be short and insecure. The guard rail opposite the frog which is farther from the headblock may, by using a special filler block, be bolted on to form an extension of the inside wing rail of the other frog, and be made secure; but a guard rail for the frog nearest the headblock would in that case come within or near the mouth of the opposite frog, where it would be either impracticable or especially undesirable. In all respects regarding distances both turnouts are the same as a single turnout having a frog of the given number; the length of switch rail is the same and the lead distance is the same.

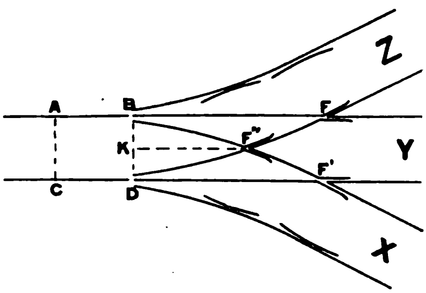

Fig. 158.

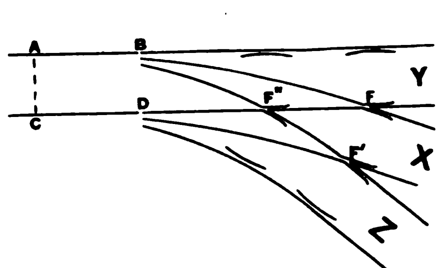

Fig. 159.

Where the two outside rails of both turnouts cross each other a third frog (F'', Fig. 158) is needed. It is called the "middle" or "crotch" frog, and its legs should be curved to fit the two turnouts. Its number is always approximately .707 times the number of the main-track frog. Its point is located in the middle of the track a distance ($K\ F''$) from the toe of the (stub) switch which is found by multiplying the gage by 1.414 times the main-track frog number, and subtracting from this product (1.414 gn) the length of switch rail for the same frog number. It is thus seen that the distance from heel of switch to point of crotch frog is 7 tenths of the total lead, and the distance from crotch frog to main frog is 3 tenths of the total lead, or 2.82 × frog number. The crotch frog may therefore be spiked to place at any time, by measurement, and the lead rails can be cut to fit in with it afterward. Where no frog of a number equal to .707 times the number of F or F' can be had, a frog of nearly that number may be used and the turnout curve made compound, the point of the crotch frog being made the P. C. C. Any frog having an angle not greater than twice the angle of the main-track frog will answer, but the lead distances to both the middle and main-track frogs will in that case not be the same as with a proper middle frog; the problem becomes more complicated and the formulas for simple-curve turnouts cannot be applied. In the practice of some roads the standard angle or number for yard frogs is such that these frogs may be used as crotch frogs for the standard frogs for main track; as, for instance, No. 7 and No. 10 frogs and No. 6½ and No. 9 frogs go well together for this purpose. On the Atchison, Topeka & Santa Fe Ry. three sizes of frogs are standard; namely, No. 9, No. $6\frac{1}{2}$ and No. $4\frac{1}{2}$. No. $6\frac{1}{2}$ is the crotch frog for main-line double turnouts, where the main frogs are No. 9. Where No. $6\frac{1}{2}$ frogs are used in double turnouts the crotch frog is No. $4\frac{1}{2}$.

Where both turnouts lead from the same side of straight track the frogs (F, F' and F'', Fig. 159) remain the same as with turnouts leading from opposite sides: F' should equal F in angle and be placed directly opposite to it. It is very undesirable to have it unlike F, as in that event it could not be placed opposite to it, the objection to which practice has already been stated. The number of F'', the crotch frog, remains .707 times the number of the main frog F or F' and, instead of being found in the middle of the main track, as before, it is now on the frog rail of the main track. The turnout Z may then be considered without reference to turnout X, the same as any ordinary turnout from the main track, having a frog angle F'' and a throw twice the ordinary. The length of switch rail for Z may be found by the ordinary formula and is almost identical with the switch rail for X; for, while the radius for Z is practically only half ($\frac{1}{2}\ R - \frac{1}{4}\ g$) that for X, the throw is twice that for X and the switch rails for the two turnouts are practically equal in length. The greatest objection to a three-throw switch of this kind is that while the switch rail for the second turnout is required to be no longer than for the first, it must be thrown a distance great in proportion to its length. The lead distance ($D\ F''$) of the crotch frog F'', from the headblock, is found by the same formula that would be used for any turnout; viz., 2 gn'' minus length of switch rail. By substitution, 2 gn'' will be found equal to 1.414 gn, as given above. The location of the point of F'' may be found also by trial. Put in the two main frogs and line the lead rails to them. The point F'' is found on the main track gage line at such a point that the distance between the far rail of the main track and the far rail of the turnout is twice the track gage. In measuring, the tape line must, of course, be held squarely across both tracks at the same time; which means that it must change direction at the middle. All such fussing, however, gives more trouble than to find the location by computing and measuring off the proper distance from the headblock.

The consideration of X and Z as turnouts from the same side is only conventional, for if we consider X the main track we may consider Y and Z as turnouts from the opposite sides of a curve, they really being such. The frog F being of such number as will require from straight track a turnout of curvature equal to that of the main curve, as heretofore explained for turnouts from curves, the turnout Y, being *against* the curve, has its curvature decreased by the main curvature and becomes straight track; while the turnout Z, having a frog of the same number and turning *with* the curve, has its curvature increased by the main curvature, or doubled. So the problem of turnouts from opposite sides of a curve is identical with that of turnouts from opposite sides of straight track, at least so far as regards the relation between middle and main frog numbers and lead distances.

In case the number of F'' is not .707 times the number of F, and the curve for turnout Z is compounded at F'', the lead distance for F'' and the curvature as far as F'' would be found in the same way as for a single turnout. The determination of the curvature from F'' to F', as well as the location of F', depends upon the angle of F'' and leads to problems too lengthy and too complicated to be taken up here. An expert trackman could, after lining the lead rails BF and BF'', locate the frog F' very well by trial by keeping its point at proper gage distance from rail *BF* and swinging it with reference to *F″* until the relative position of the two would seem to admit of a suitable curve. But such problems rarely occur and ordinarily their solution should be left to the engineer.

By going a little farther and providing a double set of moving rails, a third turnout (*W*, Fig. 160), turning either to the right or to the left, may be put in facing the other way, the rails *EF* and *GH* serving as its moving rails and all being thrown by one switch stand. The moving rails *EF* and *GH* may have their own switch rods independently of the rods for *AB* and *CD*, ordinary rods being used. In order to throw both sets of moving rails together they may be fitted, on one side, near the headblock, with a filler block of wood or iron and bolted together; or a double head rod, like the one shown in the figure, may serve both sets of moving rails. The two sets combined are not so stiff that they cannot be thrown by an

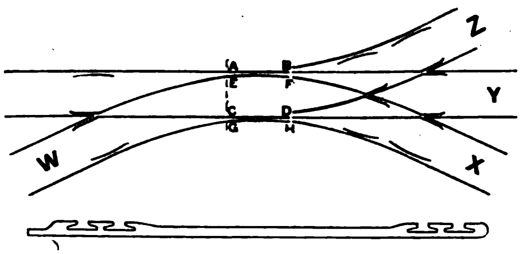

Fig. 160.—Double-Ended Turnout.

ordinary switch stand; but to add another pair to serve an additional turnout opposite to *W*, facing the same way, would probably make a switch too hard to throw in the ordinary manner. A three-throw stand will not throw the rails *EF* and *GH* to the track *Z*. Ordinary three-throw headshoes with the lugs knocked off answer for this switch. In case turnout *Z* was omitted the same arrangement of moving rails would still serve the tracks *W*, *X* and *Y*; that is, two turnouts from the same side facing in opposite directions; or if *X* was omitted there would be two turnouts facing in opposite directions and turning from opposite sides. The figure thus serves to show in how many different ways two sets of moving rails may be made to do service, as where space is wanting or where convenience may be gained, and by using nothing more than ordinary stub switch material. The ends *F* and *H* of the moving rails when thrown for turnout *W* are at the point of curve. In order to save room a switch like the one shown in Fig. 160 was laid by the writer several years ago, and was successfully operated, being in main track, at the entrance to a yard, where it was used many times each day.

Three-Throw Point Switches.—There are various arrangements for operating three-throw point switches. Figure 161 shows one operated by two stands on the same headblock. There are two sets of point rails, *CY*

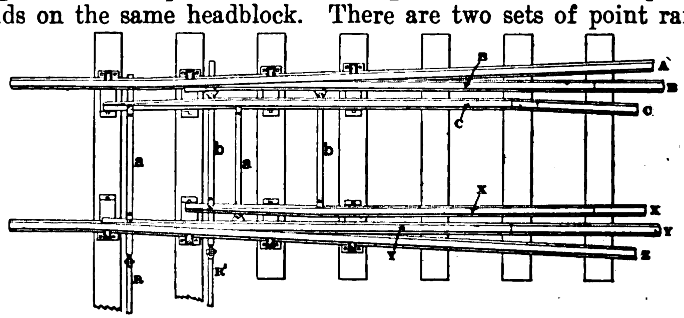

Fig. 161.—Three-Throw Point Switch.

and BX, each held together by rods independently of the other. The rods for the set BX are marked b, b, etc., and those for CY, a, a, etc. The set CY is operated by the rod R, and the set BX by the rod R'. The stock rails A and Z are both bent, when the turnouts lead to opposite sides; but when they lead to the same side only one of them is bent. By sighting along the plane of the paper, either facing or trailing the switch, the illustrations will appear much clearer to the reader. The switch is now set for the main track BY. By pushing on the rod R, the points CY only will be moved, placing C against B and setting the points for the turnout CZ. To set the switch for the track AX the points BX are pulled over by the rod R', so that point X is against Y when Y is set for main track. It will be seen, then, that before either set of points can be thrown for its turnout, the other set must be placed in the position which it would have for the main or middle track; and that when set for main track, use is made of one point rail of each set. The action is like that of the three-throw stub switch, in that, while throwing from one outside track to the other outside track, the switch must first be thrown to or by the position for the middle track—except that in this case it must be done with two stands instead of one. Both rods R and R' may be operated from the same side, or each may be operated by its own stand placed on either side of the track. It avoids confusion, however, and it is considered better in many ways, to have two headblocks, with the switch points widely removed from each

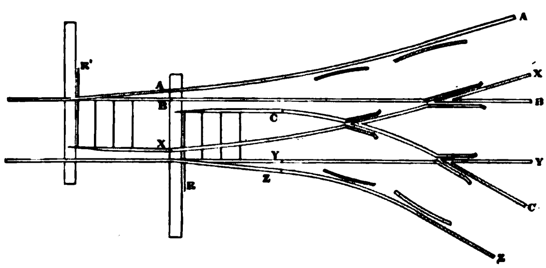

Fig. 162.—Tandem Point Switches.

other, arranged in tandem, as shown in outline in Fig. 162. The point of switch for track CZ is just in rear of the heel of the points BX, so that the ends of the points CY nicely clear the splices. In order that the frogs in the main or middle track may be placed opposite each other their angles must be such that their proper lead distances shall vary by the distance heel to heel of switch points. This scheme, like the other, is a combination of single turnouts, the arrangement serving the purpose of a three-throw switch only as regards saving of room and material. The switch points cannot be made to interfere with each other, as in the case of two stands operating on the same headblock. Should it be desired to use the turnout AX, it matters not what is the position of the points for the turnout CZ, but in order to use the turnout CZ, the switch for turnout AX must first be set in the normal position. In tandem split switches the front set of points is sometimes 15 ft. in length, with a rear set 10 ft. long. As with stub switches, so with split switches, both turnouts may lead to the same side of main track, the crotch frog then coming on the main rail, as in Fig. 159.

The true three-throw point switch is that where both sets of points are operated by one stand, those previously mentioned being really two switches separately operated. The Weir three-throw switch stand and the way it is connected to the switch points is shown in Fig. 163. The connecting rods have projecting pins which follow in a groove cut in a cylindrical shell or barrel turned by the hand lever. The groove is so arranged on the cylinder that, as the lever is thrown either way from the central or upright position, one rod is held still while the other is moved, and vice versa. The lever has a spring locking bar which fits into notches on the semi-circular locking plate, the same being part of the housing of the stand. The Hasty three-throw switch stand is shown in Figs. 164 and 165. The levers which throw the two connecting rods are operated by a cam arrangement which, through a certain range of the motion of the lever, can throw one of the rods without moving the other; while through the remainder of its range of motion, it throws the other without moving the first. Spring connection may be had with three-throw point switches the same as with ordinary switch points. If a switch rod or bridle plate is not used to hold the stock rails to gage at the point of switch the stock rails should be well braced on several ties, to take the pull of the two connecting rods. In order to facilitate the adjustment of the point rails some switch manufacturers are now making three-throw point switches with all tie rods adjustable.

In these point-switch double turnouts the lead distance for main-track frogs, and other measurements, are those heretofore given for point switches, according to the number of the frog used, the same as in single turnouts. The number of the middle or crotch frog, where the two points are thrown on one headblock, is always greater than .707 times the main-track frog number, and is given in Tables XIII and XIV. The angle of this middle frog (F'') is found by the formula

$$\cos \tfrac{1}{2}F'' = \cos F + \frac{\tfrac{1}{2}g}{R + \tfrac{1}{2}g},$$

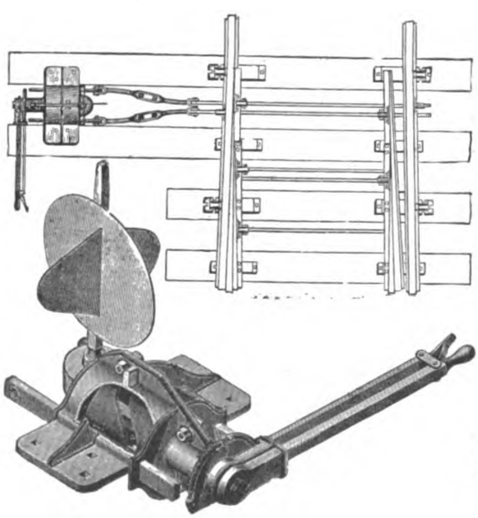
where R is the radius of the center line of the turnout curve. The number corresponding to the angle is found by the well-known formula

$$n'' = \tfrac{1}{2} \cot \tfrac{1}{2}F''$$

The lead distance from headblock to point of middle frog is not the same as it is with three-throw stub switches, but is equal to

$$p + (\tfrac{1}{2}g - h) \cot \tfrac{1}{2} (\tfrac{1}{2}F'' + P),$$

where g is the gage of the track; h, the spread at the heel; F'', the middle frog angle; P, the switch angle; and p, the length of the switch point.



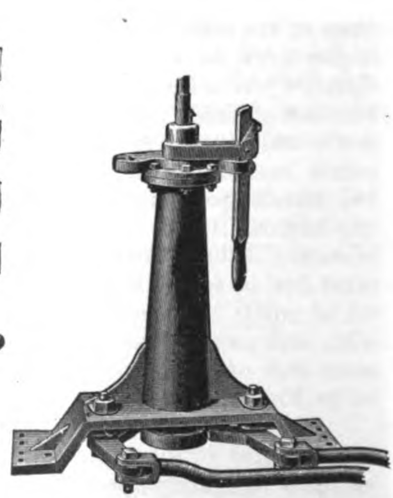


Fig. 163.—Weir 3-Throw Point Switch and Stand. Fig. 164.—Hasty Triple Stand.

Fig. 165.—Three-Throw Split Switch with Hasty Stand.

Where two points are thrown from different headblocks, as in Fig. 162, the angle of the middle frog and its position can be computed by coordinate geometry. Obviously it will not be placed in the middle of the main track, but a few inches from the middle and toward that side of the track which has the frog of lesser angle. The most rapid and most satisfactory method of determining the location of these points and the crotch frog angle is to lay out the turnouts on the draughting board to as large scale as is convenient. Measurements scaled off such a drawing will be accurate enough. Lengths of switch ties also can most conveniently be had from this drawing, and also the position of the mark on each tie which corresponds to the center of the main track. Mr. A. Torrey's book, "Switch Layouts," gives data for a large number of pieces of special work of this kind and affords a convenient and valuable reference.

Three Tracks on Four Rails.—There is a special arrangement of tracks used to some extent on ore and coal docks which requires a three-throw switch. In order to spot cars to best advantage for dumping into the pockets, four rails are laid over the dock about 4 ft. 11 ins. apart c. to c. or 4 ft. 8½ ins. apart in the clear, between heads, as shown in Fig. 166. The four rails thus stand to gage for three tracks, and the arrangement for shifting cars from the middle track to the track at either side, or vice versa, consists of a special double turnout with a three-throw switch and small-angle frogs in the middle track. The turnout shown, which is in service on the Duluth & Iron Range R. R., has two No. 25 spring-rail frogs and a No. 4½ crotch frog. The right and left leads from the three-throw switch turn out by 14-deg. curves, which are reversed at the heel of the crotch frog, into 15½-deg. curves as far as the heel of the spring frog in the main or middle track. The frogs (Fig. 167) have been styled "single-pointed," which term has reference to the construction of the point piece of the frog, by planing a single piece of rail to a point instead of joining two pieces of rail together, as in ordinary practice.

72. The Lap Switch.—Figure 169 shows the Elliot lap switch. In a general way it differs from the stub switch only in having the ends of the moving and stub rails beveled so as to lap a few inches by each other on the headshoe. For strength, the ends of the stub rails are flared and the web is retained on the beveled portion, the bevel being formed by planing off one side of the head and base. The ends of the fixed rails are bolted together through filling blocks which restrict the creeping of the moving rails to a safe limit. The switch was designed to overcome one of the objections raised to the stub switch due to the running of the rails from expansion, contraction or creeping of the steel. The switch rails are sometimes rendered immovable from running tight together, and sometimes the joint is too wide from contraction in a cold day. The lap switch provides a continuous-bearing rail regardless of a moderate amount of running, and saves a good deal of work at tamping headblocks, especially in yard tracks that are not well ballasted. In yards, where the tracks are much cut up by switches and excessive contraction cannot occur it would be well to use

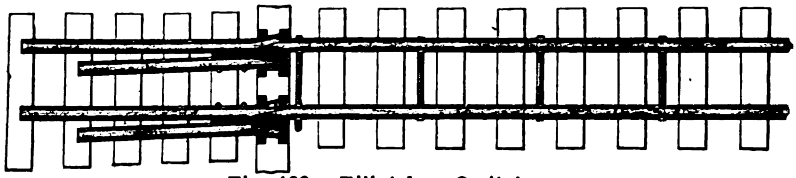

Fig. 169.—Elliot Lap Switch.

a spring connecting rod with this switch, to keep the beveled ends of the rails in contact and prevent strain on the connecting rod when the rails expand.

73. The Wharton Switch.—The only switch wherein both main-track rails remain unbroken is the Wharton or "lifting" switch. Except when thrown for the siding it stands entirely clear of main track. In Fig. 170, which shows diagrammatically the old form of Wharton switch, *A* and *B* represent two moving rails connected together like the split rails of a point switch, the rods connecting them being bent to pass under the main-track rail *H*. The rail *B* was formerly a grooved rail, but is now usually made a split or point rail. The outside switch rail *A* is an ordinary T-rail bent in a vertical plane. Both switch rails rest on a series of graduated iron blocks, called "elevation castings," which rise gradually from the point of switch so that about 3½ ft. therefrom they are 1¾ or 2 ins. higher than the main rails. In passing through the switch the wheels are thus lifted so that their flanges clear the rail *H* in passing across it. The elevation castings are continued behind the heel of the switch to gradually slope the turnout rails down to a direct bearing on the ties. In one form of this switch the shaft *D*, which operates the rails *B* and *A*, extends back and operates also the automatic trip rail *C*. This device is an ordinary guard rail with one end pivoted to an iron chair at *K*, while the other end is moved in against the main rail *H* when the switch is thrown for the turnout. By this arrangement the switch, if wrongly set for a train trailing it on main track, is thrown automatically by the crowding of the wheel flanges against the guard rail which, through its connection with the shaft

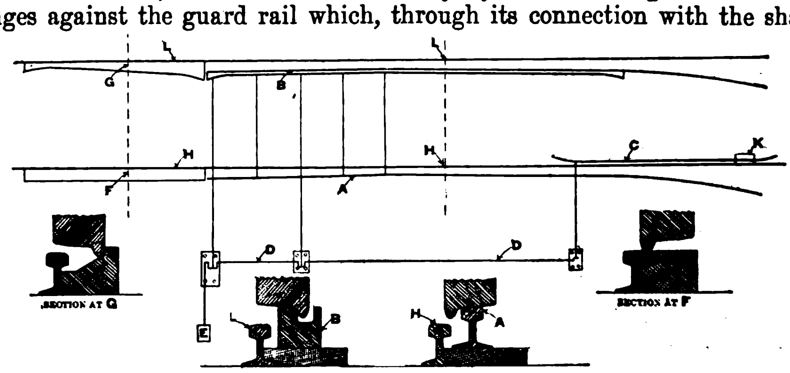

Fig. 170.—Diagram of Old Wharton Switch.

D, throws the moving rails. In yards the shaft need only be held by a weighted lever *E.* For a main track switch the lever, if set wrongly for main track, would not in all probability be locked; in case it was, however, a train trailing through the switch would break or bend the elevated rail *A* or its connection to *D,* but would not be derailed. In case the switch (old style) was wrongly set for a train coming out of the turnout the wheels, after leaving the switch rails, were caught by the safety guard rails *F* and *G* and so guided that they dropped to place on the main rails. Sections of these guard rails are shown in the figure. The guard *F* is the same hight as the main track rail throughout its whole length, except for a few inches near the end next to switch rail *A,* where it is sloped down about 1¼ ins. The inner side of *G* has a rib which, as it leaves the rail *B,* gradually approaches nearer the main-track rail *L.* This rib and the

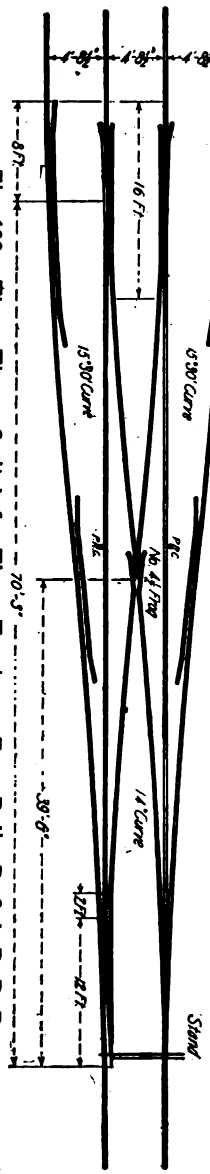

Fig. 166.—Three-Throw Switch for Three Tracks on Four Rails, D. & I. R. R. R.

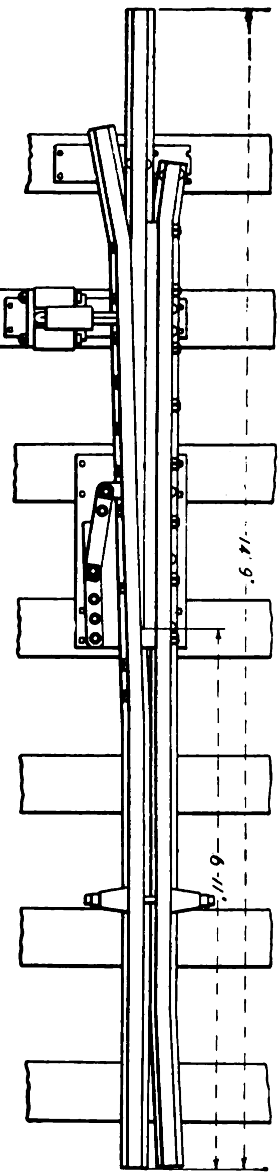

Fig. 167.—No. 25 "Single-Pointed" Weir Spring-Rail Frog.

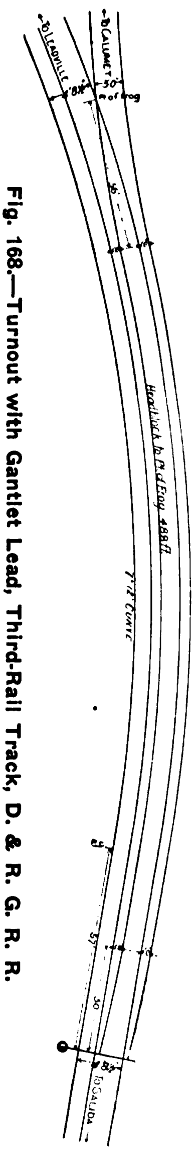

Fig. 168.—Turnout with Gantlet Lead, Third-Rail Track, D. & R. G. R. R.

sloping side easily move the wheel over to place, which of course acts to pull over the opposite wheel. The guard G should be well braced.

The improved Wharton switch is made entirely of T-rail and is usually about 18 ft. long. Figure 171 shows the form used on the Cleveland, Cincinnati, Chicago & St. Louis ("Big Four") Ry. Instead of the grooved rail a guarded point rail forms that side of the switch. This serves to prevent the wheel flanges on the opposite side from riding the main rail. In place of the catch guards (F and G), described in connection with the previous figure, two plain guard rails are employed. That at the end of the point rail is intended to form a continuation of the guard bolted to the point rail; that on the opposite, or frog, side makes it certain that when a train is entering the turnout the wheel treads overlap the main rail far enough to catch the outside switch rail. It also guards wheels trailing out of the switch while they are coming down off the high rail and relieves the

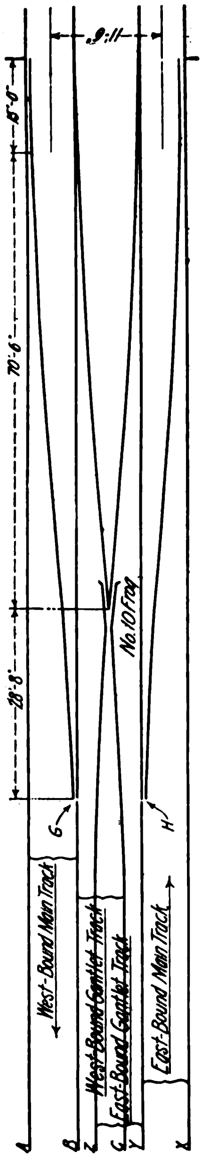

Fig. 171 A.—Gantlet Track for Temporary Use in Musconetcong Tunnel, Lehigh Valley R. R.

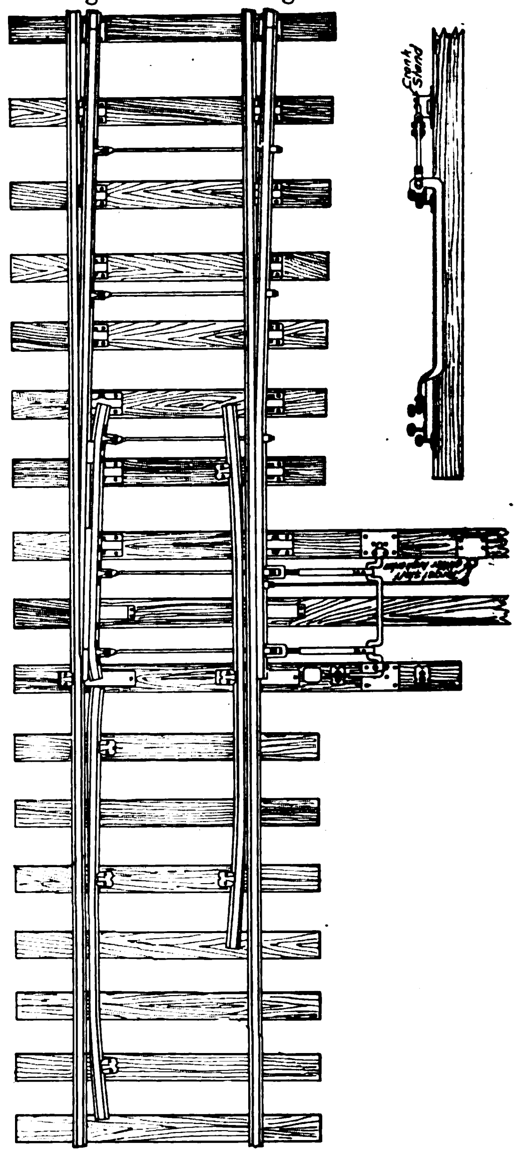

Fig. 171.—Improved Wharton Switch, C., C., C. & St. L. Ry.

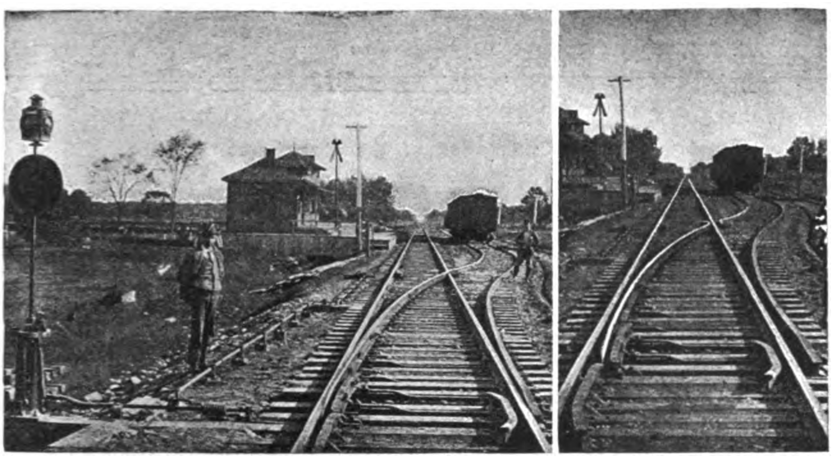
main rail on the opposite side from side pressure. It is evident that this arrangement, unlike the catch guards, will not prevent the derailment of a train running out of the siding through an open switch. The movable guard or automatic trip rail is not always used. As used in Austria, the point rail is made shorter than the outside switch rail, and the latter extends farther ahead on the track. When a wheel is coming out of the switch the guard rail at the end of the point rail is thus enabled to hold it (the wheel) before it leaves the outside switch rail. By duplicating the parts for opposite rails the Wharton switch is made three-throw.

Owing to its bulkiness and its cost the Wharton switch has never come into what may be termed general use. For shunting or flying in cars rapidly it is not as satisfactory as the point or the stub switch; and in fact derailments have happened to trains coming out of the switch at speed which would have been safe over a point or stub switch. It has, however, long been in use on a few roads, and there can be no question as to its superiority to all others in point of safety to trains on main line. For outlying turnouts infrequently used, especially at high-speed points, it is unquestionably the best. As the switch has no contact with the main line when not in use it is subject to but very litle wear, and the main-track rails are free to expand in either direction without fouling the switch rails or shoving the switch rods against the ties. It is therefore an economical



Set for Siding. Set for Main Line.

Fig. 172—Mac Pherson Switch, Canadian Pacific Ry.

switch to maintain, so far as attention and cost of repairs are considered. For turnouts from the outside of curves, where it is particularly undesirable to break the rail, the Wharton switch is the remedy, and is frequently recommended for such locations. For many years previous to 1901 this was the standard switch of the Chicago & Alton Ry., and was used on the whole length of the road. It is now in use to at least some extent on a goodly number of roads, being the standard switch on the Mexican Central Ry., the standard switch for main track on the Plant System, and one of the standard switches of the Cleveland, Cincinnati, Chicago & St. Louis, the Delaware, Lackawanna & Western, the Pennsylvania Lines West and other roads.

The underlying principle of the Wharton switch is so sound that several modifications of the device have been adopted in the practice of late years. An interesting example of this kind is the MacPherson switch, designed by Mr. Duncan MacPherson, division engineer with the Canadian Pacific Ry.

Figure 172 shows the switch in both the open and closed positions, as used on this road. In this particular instance the switch is used with a MacPherson frog (Fig. 94), the two being interlocked. As may be seen, the switch is constructed on the Wharton principle, having a point rail on one side of the track and a raised switch rail sloped at the end, for lifting the wheels over the main rail at the other side of the track. As used on this road the connecting rod is rigidly attached to the switch in ordinary use, but in case the switch is set the wrong way for a trailing train the forcing of the points will shear a split pin and bring a spring into play, so that the points are not damaged by being forced open, and a record is left showing that the switch has been improperly used. Referring to Fig. 173, it will be seen that there is an adjustable spiral spring coiled about the connecting rod, one end of the spring being attached to a lug held to the connecting rod by jam-nuts and the other end to a turned-up end of the head switch rod. The end of the connecting rod projects through the turned-up end of switch rod No. 1 and terminates in a flat piece ½x⅞x3 ins. long. Through this flat terminal there is a ⅜-in. pin which, in the ordinary condition of affairs, holds the connecting rod and the head switch rod in rigid connection, and the spring does not come into service. When, however, the points are forced aside by trailing wheels the pin is sheared and the points are forced open against

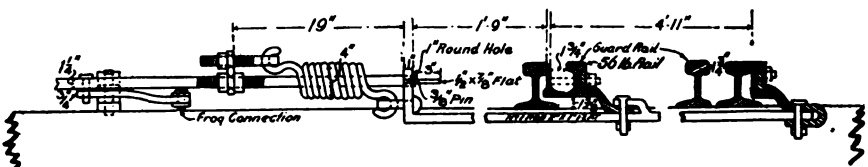


Fig. 173.—Spring Connection of the MacPherson Switch.

the tension of the spring, which then serves to return the points to their original position after the wheels have passed. The engraving also shows a section of the switch rails opposite the switch stand. The two inner rails are guard rails, the 56-lb. rail being attached to the point rail and the other guard rail being set so as to hold the wheels well over toward the sloping switch rail (see also Fig. 172). This sloped rail, which serves to elevate the wheels opposite the point rail, is reinforced by a ¾-in. strap, as shown. As used on the Canadian Pacific Ry., these switches are laid in ordinary main-line turnouts but not at junction points or in turnouts where the siding is used as frequently as main line. They are also in service on numerous other roads, among which are the Boston & Maine, the St. Lawrence & Adirondack, the Southern Pacific, and the Canada Atlantic.

74. Derailing Switches.—Where the grade of a side-track descends toward the switch it is unsafe to leave cars standing upon it without some reliable means to prevent them from running out and fouling main-line trains, in case they break loose. Under favorable conditions cars might be expected to start unaided on a grade of about four-tenths of one per cent, but wind will start cars down an easier grade, and heavy wind might start them on the level. The setting of brakes should not be depended upon to hold cars that are left alone; and so, wherever there is likelihood that cars on side-track may start from gravity or be blown or easily pushed, the only safe policy is to provide for derailing them before they can get far enough to obstruct main track. If the side-track is used exclusively as a passing siding the rule does not apply.

A derailing switch may consist of a single moving rail connected with a switch stand, on a headblock; although it is better, if it is much used, to put in a headshoe. Sometimes two moving rails are used, the same as in a stub switch. One moving rail is all that is required to derail the car, but the use of two facilitates hauling the car back again. The lower engraving of Fig. 174 shows the derailing switch with a single moving rail set for derailing. A single moving rail should heel toward the frog and the rail should be thrown inward, as shown in the figure, so as to guide the wheels away from main track. In side-tracks it is placed in the outer rail, or the one farthest from main line. In the derailing position it should be backed by a few rail braces near the end, as at *A* in the figure. When two moving rails are used they may heel either toward the frog or in the opposite direction, as suits convenience. When they heel toward the frog they should throw inward, but when they heel the other way they obviously should throw outward.

A single switch point with a bent stock rail, the switch point heeling toward the frog and throwing inward for derailment, is the device most extensively used for a derailing switch, being the usual standard for main-track derails near interlocked crossings. The point rail, in its position for derailment, should be backed by two or three rail braces. If a spring connecting rod or Lorenz spring be used with the point rail, as appears in the upper engraving of Fig. 174, a car entering the side-track may pass over the point in the open position without breaking it or the connection. Switch points for derails may be made more blunt (of larger angle) than those commonly in service in turnouts, but for derails in side-tracks old point rails too badly worn for further service in main track may be used. The throw of the stand should be such that a derailed wheel may pass between the point and stock rails without spreading them apart. At the heel

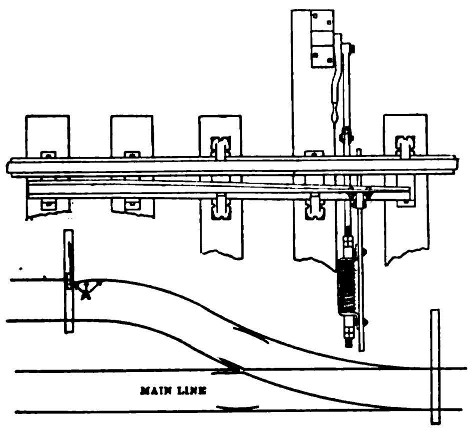

Fig. 174.—Derailing Switches.

of the point rail the nuts of the splice bolts should come on the gage side, There have been numerous instances where the leading derailed wheels have sheared the nuts outside the splice, thus permitting the wheels following to force in the point rail, mount the main rail and proceed thereon. One objection to the use of a switch point derail in main line is that the rail is broken on one side of the track, and where rails creep badly the derail may frequently be thrown out of adjustment. A remedy for trouble of this kind is a heavy anti-creeping casting bolted rigidly in between the main rail and the bent stock rail behind the heel of the point rail.

The derailing switch stand need be only a ground lever. When cars are standing in the side-track unattended it should always be set for derailing, and by all means it should be kept locked. In side-tracks much used, however, the only proper arrangement is to connect the derail with the main-line switch or stand. The derail is closed when the main switch is opened and, vice versa, it is opened when the main switch is closed. This

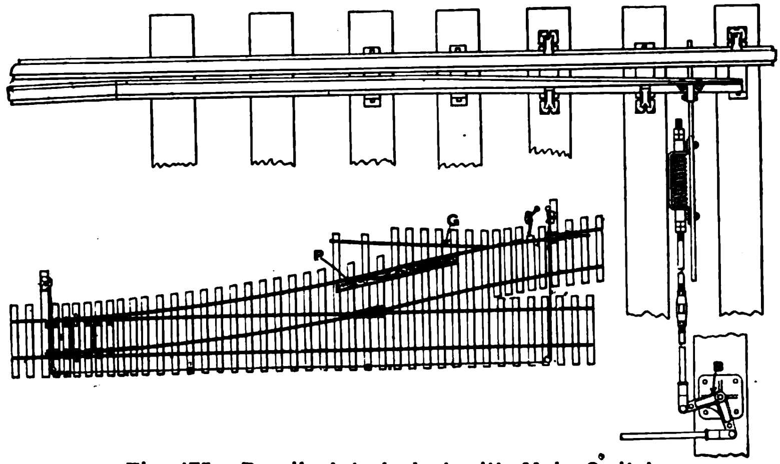

Fig. 175.—Derails Interlocked with Main Switch.

method assures that the derail will be always properly set, and it avoids the inconvenience which otherwise would result from having to throw the extra stand each time the side-track is used. The connection is usually by means of throw rods and bell crank (*B*, Fig. 175). The lower engraving of this figure shows an Elliot lap switch derail connected with the main switch by a cable. When the main switch is closed this cable pulls open the derail, and when the main switch is opened the derail is closed by a weighted lever arranged as shown. The same derail is also installed with a pipe-line connection, which gives positive action both ways. On the Southern Pacific road derails are put in all sidings which descend toward the switch on grades of 21 ft. per mile or over, and the derail is thrown independently of the main switch. To remind the man who opens or closes the switch, of the derail, there is a derailing switch notice sign attached to the target shaft of the main-line switch stand, with the sign facing the throw lever. This sign is a cast iron plate 8x10 ins. x $\frac{1}{2}$ in. thick, with a rim $\frac{3}{8}$ in. thick, painted white, with black letters reading: "Attend to Derailing Switch."

Among other derailing devices the Wharton switch, shortened in length and simplified in construction, is used a good deal in main track

Fig. 176.—Wharton Throw-Off, Philadelphia & Reading Ry.

in connection with interlocking. It is known as the Wharton "throw-off" and is shown in Fig. 176. When set for clear running if affords the important advantage of an unbroken track, thus insuring safety, smooth running and no wear from traffic. As it is operated with a 6-in. throw, it is, when open, well out of the way of passing wheels, with no chance for the traffic to run afoul of a slightly opened point. For use on curves, where it is usually undesirable to break the rail and put in a switch point, the Wharton throw-off is particularly well adapted. There are some conditions, however, under which the Wharton derail is liable to give trouble. Derails of this type which turn to the inside of curves will not always act where the outer rail of the curve is badly flange worn. Where the side and top corner of the rail head was much worn the wheel flanges, which tend to crowd the rail, have been known to pass behind the switch point and not follow the derail. To overcome such difficulties as this it has been the practice on some roads to renew the outside running rail of the curve every six months.

The Dailey automatic "cut-out" switch (Engr. *T*, Fig. 177), designed by Mr. A. G. Dailey, superintendent of tracks with the Michigan Central R. R., where it is in extensive use for derails in side-tracks, consists of a

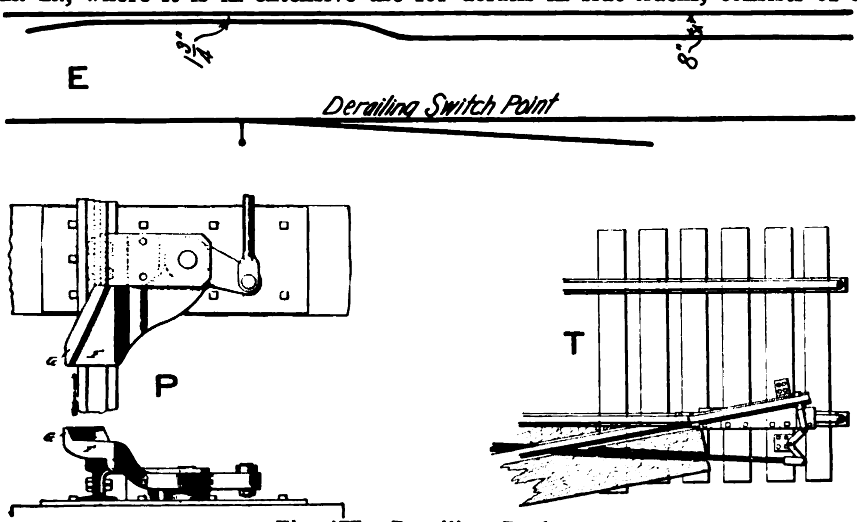

Fig. 177.—Derailing Devices.

swing rail about 5 ft. long heeling toward the frog and throwing inward in the track. It is connected with the main switch by means of pipe line and bell cranks, which open the derail when the main switch is closed and set it for passage when the main switch is opened for the side-track. The piece of swing rail is hinged to a heavy base plate, which extends between and under the ends of the fixed rails, there being a shoulder at each connection to prevent the fixed rails from closing in on the swing section when expansion or creeping occurs. At the heel of the derail, on the outside of the track, an old switch point is laid to deflect derailed wheels from the ties and away from main line. The web of this deflecting point rail is cut out for the pipe line and the latter is protected from being cut by derailed wheels by planking. This device is also in service on the Grand Trunk Western, Pere Marquette and other roads.

In connection with derails mention may be made of the scotch block, two forms of which are shown in Fig. 178. This device is used in connection with interlocking apparatus and is often substituted for a derailing switch, on side-track, where it is desirable that cars shall stand as near the fouling point as possible and still be prevented from running out upon main track. In case the car should strike the block at good speed it would, of course, be derailed. The chock is pivoted to a bearing piece securely bolted to the rail, and the manner in which it is thrown back or moved into the "reverse" position to permit the passing of a train is made clear by the appearance of the pipe-line throw rods. At the right-hand side of the illustration the chock is shown in connection with a detector bar, which will not permit it to be thrown under a car or train or immediately in front of a car or locomotive. The Travis derail (Fig. 177, Engraving *P*) consists of a scotch block pivoted to a plate outside the track and swung over the rail for the derailing position, as it appears in the figure. The front *F* is beveled down and there is a rib *G* running diagonally, so as to catch the flange and carry the wheel athwart the rail. It is used in interlocking work, and is especially serviceable on curves too sharp for the convenient use of a point rail or where a guard rail inside the outer rail of the curve will not permit of a point rail being used. Like the Wharton throw-off, it overcomes all the objections which stand against the use of the point or split rail in such places. The main or movable part is a heavy malleable iron casting weighing 61 lbs.; the whole apparatus weighs 170 lbs. The Smythe derailer consists of a steel casting hinged to a base piece at the side of the rail, in a manner to flop over and rest upon the rail for the derailing position. The top of the casting has a diagonal groove which carries the wheel flange across and off the rail.

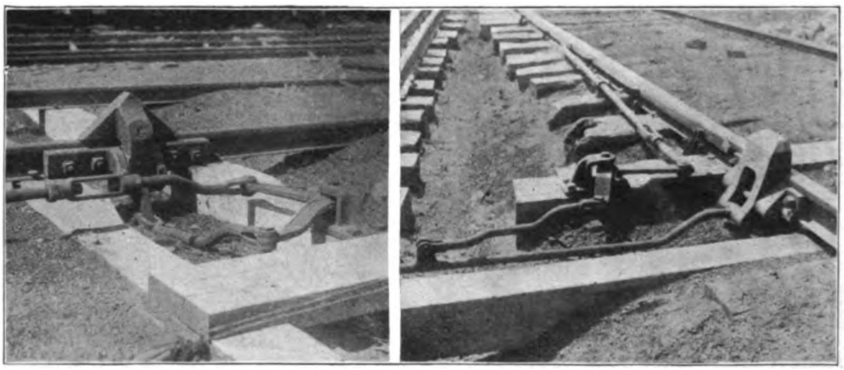

Fig. 178.—Scotch Blocks.

Wherever a derail is used in main track it is desirable to prevent, as far as possible, the ditching of derailed trains. In order to hold the wheels to the ties a long guard rail should be laid in the track about 8 ins. from the opposite rail, extending from a point in advance of that where the wheels are derailed. Figure 176 shows two guard rails for this purpose. In side-tracks, the object of the derail being to prevent obstruction to main line, the derailed car must be diverted, and it is not desirable, therefore, to use a guard rail for holding the wheels to the ties. In such places, however, it may save damage to derailed rolling stock, and facilitate the work of hauling it on the track again, if a short stretch of smooth, unobstructed ground is provided in the vicinity of the derail. In case the derail comes on a fill the embankment should be shouldered out to a respectable distance from the ends of the ties. To place a derail in track where the embankment slopes rapidly from the ties, as one may sometimes see, has the appearance of "looking for trouble."

On some roads point derails in main track are protected in the closed position by a guard rail placed opposite and set to the ordinary distance

(4 ft. 6½ ins.), as in laying a guard rail opposite a frog. This guard rail (Sketch *E*, Fig. 177) extends from a point a few feet in advance of the derail, and the flangeway holds to standard width (1¾ or 1⅞ ins.) some 3 or 4 ft. in rear of the point rail end, where the guard rail flares rapidly, so as not to interfere with the function of the derail when set for derailing. Usually this guard rail is continued, at a distance of about 8 ins. inside the running rail, in position to hold derailed wheels to the ties, as above noted. Although point-switch derails in main track are usually, if not always, secured in the closed position by a point lock, the purpose of a guard rail opposite is, of course, to prevent wheel flanges from crowding the end of the point rail when it is closed. On double track, derails are placed in an outer rail, so as to avoid obstructing the other track in case of derailment. This arrangement sometimes brings the derail on the inside rail of a curve.

Where a side-track derail is interconnected with the main-line switch or switch stand a brakeman will quite frequently forget about the derail when a car or train is entering the turnout, and close or attempt to close the switch immediately the last car passes over it. If he succeeds in latching the stand before all the wheels have passed the derail the latter will usually be set over by the trailing wheels at the cost of broken or bent throw rods, in case the connection is rigid; but if he is not quick enough, in the interval between the passing of the wheels, to get the derail fully

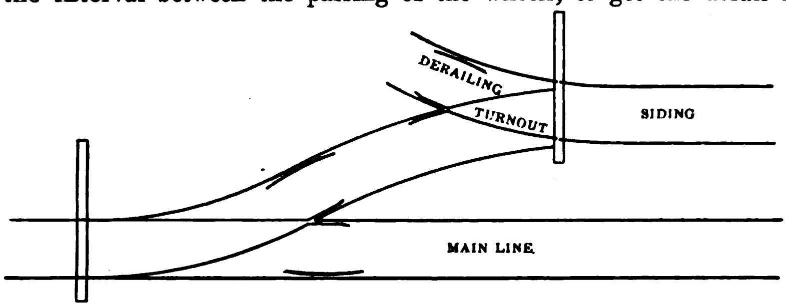

Fig. 179.—Derailing Turnout.

open and the stand latched, he is quite liable to suddenly meet with rough handling at the end of the throw lever; in fact persons attempting to close a switch under circumstances of this kind are sometimes injured more or less seriously. Damage to the throw rods may be prevented in cases of this kind by a spring connection with the derail, as by a Lorenz spring (Fig. 175), but trouble for the brakeman can be avoided only by the use of a detector bar (Fig. 224, described further along), which should be placed between the main switch and the derail, and which will not permit the latter to be thrown until all the wheels have passed. As, however, the installation of a detector bar is a matter of considerable expense it is not usually provided in side-tracks. Such being the case it is pertinent to observe a danger in the way of connecting a derail with a main switch or stand working on the automatic "set-over" plan. In case such a stand should be latched before a car entering the turnout has passed the derail the wheels trailing the derail would automatically throw the switch and stand and leave the switch set in the wrong position. Instances are also conceivable where trouble might arise with automatic "fly-back" stands operated in the same manner. The safest stand for such work is, therefore, a rigid one.

Where considerable headway may be attained cars might, unless derailed a good distance back, run over the ties far enough to foul the main track. So where the grade of the siding is a long one, or steep, like a siding for coal chutes, for example, something more than simple derailment is necessary. Figure 175 shows an arrangement whereby the derail may be located near the main line switch and still throw cars a good distance clear. There is a deflecting guard rail *G*, and a plank *P* placed so as to run the wheels over the rail. The surest and best way of accomplishing the purpose is to lay a derailing turnout or stub track, as shown in Fig. 179. As the arrangement is intended for use only in emergency cases, old material can be worked up in this way to good advantage. When the track is extended beyond such a turnout the contrivance is known as a "diverting track" or "catch siding." Such are sometimes used in main track, for purposes explained presently.

Catch Sidings.—For stopping runaway cars or trains on heavy grades, without derailing, resort is sometimes had to catch sidings. A notable example of such provision is to be found on the Canadian Pacific road, between Hector and Field, B. C., near the summit in the Rocky Mountains, where there is a nine-mile grade of 4.4 per cent. Along this grade there are spur tracks or "blind sidings" one mile apart, each tended by a switchman. Each spur track runs up into the mountain side several hundred feet on a very steep grade which rises in the direction in which the grade of the main track falls. Normally the switches are all set for the side-track and are not closed for main track unless called for by whistle. Hence if a train or detached cars get beyond control and come down the grade they are diverted to a heavy up grade at the first switch, without giving any signal. As the speed at which runaway cars are liable to enter such a siding is high the curvature of the turnout should be easy and the angle of the switch points small. Wherever it is feasible to do so, it would be well to have the

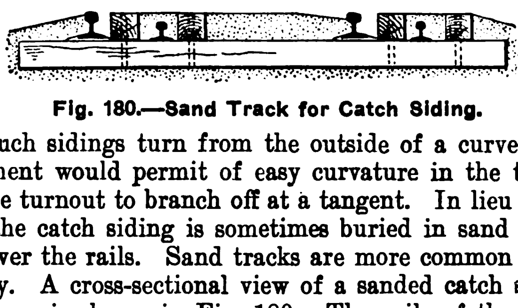

Fig. 180.—Sand Track for Catch Siding.

switches for such sidings turn from the outside of a curve in main track. This arrangement would permit of easy curvature in the turnout, or perhaps enable the turnout to branch off at a tangent. In lieu of the up-grade arrangement the catch siding is sometimes buried in sand to the depth of a few inches over the rails. Sand tracks are more common in Europe than in this country. A cross-sectional view of a sanded catch siding in use at Dresden, Saxony, is shown in Fig. 180. The rails of the diverting track are laid gantlet fashion, on the same ties with the main rails, and the stretch of diverting track is provided at both ends with a switch for connecting with the main line. Guard timbers or angle irons for retaining the sand are placed at both sides of each rail of the siding, which gradually dips deeper until it is covered by 2 or 3 ins. of sand. The arrangement is considered very efficient for the purpose. In this particular instance the catch siding is 1640 ft. long and 1148 ft. of the same is covered with sand. In very dry weather the sand is kept damp. The braking effect of sand sidings is discussed in "Engineering" (London, England) for Dec. 10, 1897, and in the Bulletin of the International Railway Congress for July, 1899.

75. Side-Tracks.—A side-track means, of course, any track not used as main track. By the term "spur" or "stub track" is usually meant a side-track which is connected to another track with only one switch. If the freight traffic from a side-track is small, or if it is moved principally in one direction a spur track answers quite well. To suit convenience in switching, a spur track should open out into the main track in the direction in which most of the cars are moved when outward bound. On single-track roads where much traffic is moved from a side-track in both directions, especially if the main track be level at the place, it ought to open out into the main track both ways; such is usually called a "siding." On double track, where considerable traffic is moved in both directions, a spur for each track is preferable to a siding, with its two switches, on one track; and all such spurs are, for both convenience and safety, laid trailing to the movement of the trains.

Wherever it is practicable spurs and sidings used for loading or storing cars should turn out from the main track at a slightly descending grade for a distance beyond the frog sufficient to give clearance from the main line, as under ordinary conditions a derailing switch may then not be needed. The remainder of the length should preferably be level, so that cars may be moved readily with pinch bars. Sidings used for passing tracks should, if possible, be level with the main track or on the same grade with it. To have them lower or higher than the main track often results in a loss of time getting out of or into them with heavy freight trains. Where there is little or no filling to be done, side-tracks may just as well be laid as much as 15 ft. c. to c. from main track, for at least that much space is needed where loading is being done or to give safe room for trainmen working at repairs or attending to hot boxes, between the tracks.

Whenever it can be done side-tracks should be located where a good view may be had both ways along the track. If there is a curve in main track the side-track should be on the outside, as then the view around the curve will not be obstructed by standing cars. Switches should not be located near bridges, ravines, high embankments, etc., when they can well be avoided, as derailment at such points is usually hard on rolling stock. As far as the service will permit, switches from curves should be avoided. In some instances where it is necessary to have the turnout leave the main track on a sharp curve the frog is located at the required point, but a long lead is run back around the curve to bring the switch on tangent. This arrangement is illustrated and more fully described under the subject "Gantlet Tracks," § 77, of this chapter.

Regarding the alignment of the piece of track immediately beyond the frog where a turnout is laid to a parallel track, room and material may be saved by continuing the turnout curve beyond the frog and reversing to bring it parallel at the proper distance. While for spur tracks where but little shifting is done a decreased first cost in this manner might be justifiable, not to consider the room saved, the saving in cost effected by reversing the curve at the entrance of sidings much used for loading or for passing tracks will hardly compensate for the trouble which these reverse curves will give. Where the main line is straight and a No. 9 frog is used, for instance, by continuing the turnout curve beyond the frog and reversing between it and a parallel side-track distant 15 ft. between centers, clearance of 12 ft. between centers may be had in 61.2 ft. from the point of frog, measured along main track; while by continuing the turnout straight beyond the frog for 50.7 ft. and connecting with the side-track by a curve of same degree as the turnout curve (as in the other case), the distance required to give the same clearance is 67 ft.; hence a saving of only 6 ft. of track is effected. It is hardly worth while, then, to attempt to save anything by continuing the turnout curve beyond a frog of number no larger than 9 if the distance between track centers does not exceed 15 ft. Clearance may be had in less distance by making the track straight for some distance beyond the frog than by reversing the curvature at that point. But where the distance between main line and side-track is small the curvature must be reversed at the heel of frog, sometimes, to avoid a curve of too great degree leading into the parallel side-track. It is, perhaps, not advisable to lay the track straight beyond the frog any further than will allow room between it and the parallel side-track for a curve not greater in degree than the turnout curve. This rule might sometimes cut the piece of tangent off pretty short, or cut it out altogether, and thus require the curve to spring from the heel of the frog. As the subject of clearance is again touched upon it may be remarked in this particular connection, that on some roads the clearance point or clearance post is established at the end of the connecting curve which is farthest from the frog; in other words, at the nearest point where the siding becomes parallel to main track. Such practice is defended by the argument that the clearance point, as so understood, is readily and conspicuously definable, even in the absence of a post or other sign of special character; that to designate it at any point nearer the frog is only tolerating encroachment on dangerous ground. When a car "shoved in just to clear" stands at an angle with main track there is no latitude for backward movement, and thoughtless shifting of the car, as with a pinch bar, by some non-railroader, in order to gain a more advantageous position for loading, might lead to trouble. Of course, the question of room and the distance between track centers cuts some figure in the matter, but a derail at the proper point will insure safety without wasting legitimate siding room.

Side-tracks may be laid with culled ties, but they should be full spiked, because they are generally allowed to become further decayed before renewing than are ties in main track. Except under pretty light rail the space between ties in side-track may be increased considerably beyond that required for main line. For passing sidings 12 ties of average size, and for loading tracks 10 ties of ordinary size, per rail length of 30 ft., do well enough on straight line. Old rails can be used with economy, but if the ends are badly battered the battered portions should be cut off before laying. On tracks occupied most of the time by standing cars, rails in almost any condition of wear (so long as pieces of the head are not broken out) are serviceable. On passing sidings a somewhat better class of rail, generally speaking, is required, but rails with heads only moderately slivered or roughened by wear are not objectionable. Side-tracks subject to constant use by locomotives, as the ladder tracks and the main thoroughfares of yards, should be laid with smooth steel not inferior to second-class rails of fair quality; that is, worn rails which would still do in main track but which are sometimes removed in stretches to make room for laying new rails continuously: rails with heads too badly roughened for main-track service should not be used on such tracks as these (A classification of rails is given under "Reports and Correspondence," § 194, Chap. XII). If bolts are scarce and must be used sparingly the two holes nearest the middle of the splice are the proper ones to use. If arranged differently it might so happen that a failure of one of the bolts would leave the remaining one too far from the middle to be of any service. When old spikes are used they should be straightened before redriving, and if the head is greasy time and trouble may be saved by sticking it into the sand or dust before attempting to drive it.

Where old steel is being utilized in laying side-tracks rails of different sections and shapes are quite likely to be found, and quite frequently rails in side-track must be spliced with rails of heavier section, such as are used in main track and laid through the turnout. In order to bring the tops of such rails to the same level and the heads to the same gage at the joints where they meet, step chairs or compromise splices must be provided. Such splices for main track are elsewhere referred to. For use in unimportant side-tracks a cast step chair supported upon a tie is good enough. As the tops of switch ties are supposed to lie in the same plane it is not considered good practice to use compromise splices or chairs on the same. Where the rails in main line and side-track are of different section it is well, therefore, to lay one length of side-track beyond the frog with rails of the pattern used in main track, as above intimated. The same rule would also apply to a change of rail section at a switch in main track. As it is possible for side-tracks to get too rough or uneven, they should be put in good surface and line at the time they are laid and then surfaced occasionally thereafter, particularly when ties are renewed.

Lap Sidings.—On single-track roads it commonly occurs that two trains moving in opposite directions must take side-track at the same place to let a third train pass, and at points where the meeting in this manner is frequent or habitual it is desirable that both trains may enter the siding and leave it without backing up and without interference, such as one of the trains waiting for the other to pull by. One arrangement to permit simultaneous independent movements of this kind is a double siding, the two tracks of which may lie either on opposite sides or on the same side of main line. In the latter case they are connected in ladder style at each end with the turnout from main track. An example of such construction generally followed is to be seen on the relocated portion of the Wyoming division of the Union Pacific R .R. Passing tracks are located at average intervals of 3 miles, and some of these sidings are 8000 ft. long. In almost all cases the sidings consist of two tracks side by side, on the same side of main line, the first one being laid 14 ft. c. to c. from main line, with a view to use for main track in case the road should be double-tracked. These sidings are of sufficient length to permit two long freight trains running in opposite directions to pass a train of superior class, without interference, and if the road should be double-tracked there would still be the outside siding remaining.

From an operating standpoint, however, this arrangement of sidings is not always the most advantageous. Where a train is waiting on side-track time is saved by having the engine stand near the telegraph office, as orders can then be delivered quickly, and as soon as the track is clear the train can pull out without delay. It is also the practice on some roads to place interlocking levers in the telegraph offices or towers for throwing the switches of passing sidings in the vicinity thereof, so that trains may enter or leave the same at good speed without being delayed in stopping to open or close the switch. In order that such methods of operation may apply to waiting trains which are oppositely headed, it is necessary to arrange the sidings on opposite sides of main track and overlapping each other at one end, where the telegraph office may be located conveniently to both switches. Referring to Sketch A, Fig. 181, it will be seen that the arrangement is equivalent to a stretch of double track between the distant extremities of the two sidings (A and D), with a crossover half way between them.

As a general proposition long sidings for single track should be located with a view to future incorporation into main line in case the road should be double-tracked, and for such a scheme the arrangement of lap sidings will usually afford the best economy in grading. When a road is double-tracked most of the sidings previously used for passing tracks are abandoned, or relaid with steel and connected in to be used as one of the main tracks. In the case of lap sidings it usually requires but little extra grading to shift the two side-tracks into line for the double main track; or, if it is desired to maintain a middle siding between the main tracks, the old single track becomes the siding and the old lap sidings are converted into the outside double track, without disturbing the alignment.

A brief reference will be made to some of the plans for locating lap sidings with a view to later change them into main track use without extensive shifting of the alignment. Where the sidings are made to lap each other without changing the original alignment of the main track, as in Sketches "A" and "B," Fig. 181, the arrangement is known as a "plain lap." The distance C to B is called "the lap," and obviously the frogs for the two turnouts should be far enough apart to allow clearance distance between leads throughout the lap, thus permitting trains to pass through both turnouts at the same time. When $C\ B$ is much longer than is required for this purpose it is called a "long lap." Sketch "B" shows the sidings arranged to lap on a curve. So far as the ultimate purpose of the arrangement is concerned it is a much more desirable form than the foregoing, since to double-track the line it would suffice to reline the curve to conform to the broken lines, the outer one of which, as will be seen, is a simple curve between the original line $A\ E$ and the new tangent $G\ K$; and the inner one a similar curve between the east-bound siding and the old main

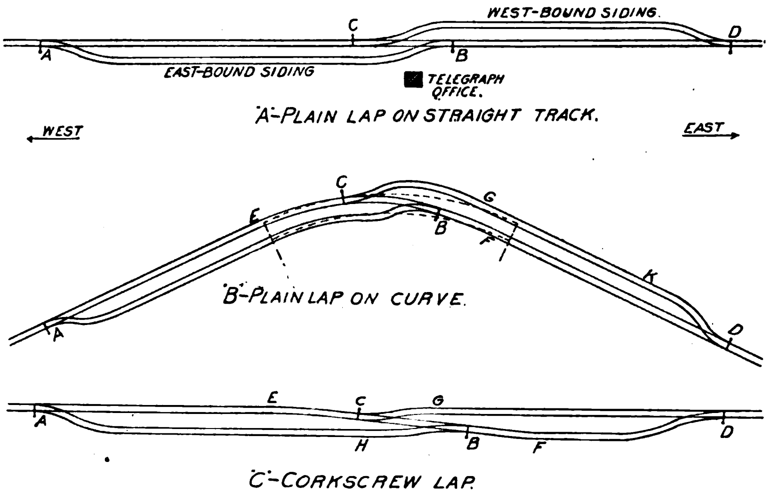

Fig. 181.—Lap Sidings.

line $F\ D$. The new curve could be kept within the tangent limits of the old curve $E\ C\ B\ F$, and practically on the same roadbed, by compounding or spiraling. In the case of double-tracking in Sketch "A" it is evident that one siding must be thrown to the opposite side of main track or else the main track for some distance must take the form of a reverse curve; or the whole stretch of straight track must be relined and thrown to a new location throughout—any one of which is an objectionable plan. To obviate these difficulties the "corkscrew" lap, shown as Sketch "C," is sometimes resorted to. The line $A\ E\ C\ G\ D$ is the original main track simply thrown over at C. The new track $C\ B\ F\ D$ is constructed for the main track in the new position, while $C\ G\ D$ becomes a siding. The curves at E and F are made of small degree with a piece of tangent between them, from which the sidings take their lead. The turnout at D is given a long lead, so as to form an easy curve for the main line. If, however, there be a curve at D, the main track should be lined into the curve and the siding connected in the usual manner. While this arrangement presents rather an odd-looking main-track alignment, it nevertheless requires a minimum of alteration in changing to double track. As the tracks between F and D and between H and A are, throughout most of their length, parallel to the general direction between A and D, it becomes necessary only to cut the crossover and throw the comparatively short portions of curved track at C and B into the alignment of the straight track on either side. In case it was required that the distance between main and side-tracks should exceed the standard distance between double tracks, in order to advance the clearance point of both sidings, it would, in double-tracking, be necessary, of course, to throw nearly the whole stretch $A\ H\ F\ D$ toward $A\ D$ the amount of the excess; but such a change would involve no great amount of trouble with tracks on the same bed. Sidings specially arranged for the convenience of traffic on double-track roads are referred to in the chapter on "Double-Tracking."

76. Crossovers.—A crossover is a double-ended turnout connecting two tracks, and consists of two turnouts facing in opposite directions, connected between frogs by a short piece of diagonal track. If the two tracks are straight and parallel and near together, the piece of track between the frogs should be straight, and consequently the frogs in both turnouts should be of the same number or angle; where the frogs are of different angles the track connecting the two must be curved in an awkward manner, or else one of the parallel tracks must be thrown into a double reverse curve, which is sometimes done in the case of a side-track the alignment of which is unimportant. A condition essential to the satisfactory laying and operation of a crossover between two tracks that are near together is that they shall both be on the same level. If they are not at the same level they should be so placed at the crossover, and for convenience of tamping and tie renewing

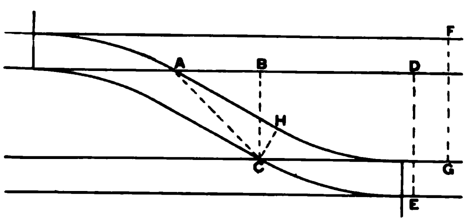

Fig. 182.

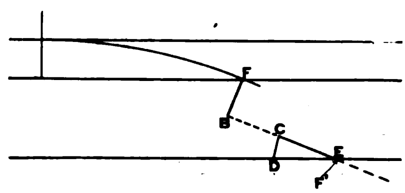

Fig. 183.

the track between the frogs should be laid with long switch ties extending through and under both outside tracks. For tracks at 13 ft. centers this arrangement requires ties 21 ft. long which, however, are not as long as ties sometimes used behind the frogs in turnouts from three-throw switches. The usual arrangement is to lay both turnouts of the cross-over with switch ties of ordinary lengths and use short ties (8 ft. long) under the track connecting the frogs, interlaid with the ends of the ties in the outside tracks.

The method of laying a crossover is, after determining the starting point, simply that of laying a single turnout. This starting point is the point of frog on either track, after the location of the point of frog on the other track has been decided upon. The first point of frog is chosen arbitrarily, but the second must be located at a definite distance from it, depending on the frog angles and the distance between the tracks. After the second point of frog has been located the measurements for that turnout must be taken with reference to that point. On straight parallel tracks the distance between frog points in a crossover may be measured in two ways; either along the parallel tracks, as $A\ B$ in Fig. 182, the line from B to C being perpendicular to the tracks; or by a direct measurement between the two frog points, called the "diagonal distance," represented by $A\ C$ in the figure. The diagonal distance is the simplest to use, since it is direct; whereas, when using the other measurement, $A\ B$, the point C must be established directly or squarely across from B—a method requiring two operations. A rule sometimes used for the parallel distance $A\ B$ is the product of the frog number by the difference between the distance center to center of the two tracks and twice the track gage—

$$A\,B = n\,(F\,G - 2\,g),$$

where n equals the frog number, $F\,G$ the distance center to center of the two tracks, and g the gage of the track. This rule is only approximate, and always gives a distance too long. The correct distance may be found very nearly (within an inch) by decreasing the distance found by the above rule by the quotient of 36 ins. divided by the frog number. It is certainly a near enough rule for business purposes. An approximate rule for the parallel distance where the frogs are not of the same number is to multiply the distance between track centers minus twice the gage, by half the sum of the two frog numbers, or $AB = \frac{1}{2}(n+n')\ (F\,G-2g)$.

The correct parallel distance is the difference between two quotients: one of which is the distance center to center of the two tracks less the track gage, divided by the tangent of the frog angle; the other is the gage of the track divided by the sine of the frog angle; that is,

$$A\,B = \frac{B\,C}{\text{tang}\,F} - \frac{g}{\sin F}$$

The length of the tangent $A\,H$ is found by dividing the distance center to center minus the track gage, by the sine of the frog angle, and decreasing this quotient by the gage of the track divided by the tangent of the frog angle; that is,

$$A\,H = \frac{B\,C}{\sin F} - \frac{g}{\text{tang}\,F}$$

This formula is of use in determining the length of tangent to lay at the heel of the frog before reversing with a curve of the same degree as the turnout curve to bring the side-track parallel with the main line.

The diagonal distance $A\,C$ is the square root of the sum of the squares of the parallel distance, and the distance center to center minus the gage; or

$$AC = \sqrt{[(AB)^2 + (BC)^2]} = \text{also}\ \sqrt{[(AH)^2 + g^2]}$$

Table XV (see index) gives the correct "parallel" and "diagonal" distances, and length of tangent between points of frogs, for different gages center to center of tracks varying by 6 ins., and for frogs of different numbers. For gages c. to c. of tracks intermediate between those given in the table the corresponding frog distances and tangent lengths may be found by interpolation.

Before starting to lay a crossover both the tracks in the vicinity of the crossover should be put in good alignment. The distance center to center of the two tracks is most conveniently and expeditiously found by measuring between the gage lines of rails on the same (right or left) side of each track; that is, either $D\,E$ or $F\,G$, in Fig. 182. A convenient way to find the second point of frog by trial, is to lay the first frog and put down temporarily a straight rail at its heel to line properly with the frog. Then slide a track gage along it, keeping the tool perpendicular to the rail until it meets the gage line of the near rail of the other track. The point where the track gage just reaches is the point of frog. A device called a frog board is also used to some extent. It consists of a triangular piece of board 7 or 8 ft. long, the edges of the board meeting at an angle corresponding to the angle of the frog to be used. After the first frog is laid a track gage is placed across the turnout at the frog point, perpendicular to the line of the frog. The position of the point of the second frog, on the rail of the other track, is estimated roughly, and the frog board is moved along near this point until a string stretched from the end of the gage to the point of the frog board is in line with the edge of the board. With the board in this position the point of the same is at the point of the second frog. The use of the frog board is shown in Fig. 183. *F* is the point of the first frog, or the one put in arbitrarily; *F B* is the track gage; *C D E* is the frog board; *B E* is the string. Slide the board along the rail until the string *B E* can be made to line with the edge *C E* of the board. The point *F′*, or the position of *E*, the end of the board, is then the point of the second frog.

Where the two parallel tracks are on a curve the track between the two frog points of the crossover cannot be straight if the two frogs are of the same number. For slight degrees of curvature and frogs of small number, say No. 7 or less, and the tracks near together, the connecting track may be made straight between the frog heels by using the same parallel or diagonal distances as for straight tracks; but this piece of track will be slightly out of line with the two frogs. But for ordinary frogs of the same number the connecting track between the two frogs on parallel curved tracks (using the same parallel or diagonal distance as for straight tracks) should be curved to a radius which is longer than that of the main line in the proportion of the length of tangent (*A H*) to the parallel distance (*A B*). This curve must then be compounded with the turnout curve at the point of the outer frog and reversed to the turnout curve at the point of the inner frog. Such is better practice than that of extending both turnout curves to a point of reversal somewhere between the frogs. Where, however, there is considerable distance between parallel tracks, room may be saved by reversing the curves between the frogs. For this purpose both frogs may be of the same or of different angle. But by using frogs of different angle the connecting track between them may be made straight, the frog of greater angle being placed in the outer track. In selecting the frog for the outer track it should be borne in mind that it goes in on the inner side of the curve in that track, in which case turnout curvature runs up fast as the angle of the frog increases. There is no simple rule for finding the proper distance between frogs in crossovers between parallel curved tracks, and the problems are so diversified that they will not be taken up here. A practical way of laying such crossovers is to use such a frog in the outer track as will answer to a turnout of suitable curvature. Then tie two strings of equal and sufficient length to the ends of two sticks, each of which is equal in length to the gage of the track. Stretch out the two strings, keeping the parallelogram rectangular and holding it so that the outer string lines straight with the frog already laid or with a frog board placed at the point chosen for that frog. The point where the other string crosses the gage line of the near rail of the inner track will be the point of the second frog. Such measurements can then be taken from string to rail as will determine the angle of this frog. Plotting the crossover to large scale is the readiest method of getting the measurements in the office.

On double-track roads, crossovers are laid trailing to the movements of the trains. This arrangement requires the trains to "back over," but in using the crossover to clear the track for a following train it really effects a saving in time, since it gives the flagman who goes out ahead a start equal to the train length before the train can back over; and after the train following has passed, the train which has backed over can pull straight ahead. But aside from these advantages, the element of safety is with the trailing switch. The two switches of crossovers are sometimes connected with one stand placed midway the crossover. In other instances a stand is sometimes used at only one switch of the crossover, the other switch being operated by a pipe line and bell crank connection between the two. Either arrangement is especially useful in busy yards where the switches are thrown by hand, as it saves the time that would be required for the switchman to run from one end of the crossover to the other if a stand was used at each switch.

77. **Crossings.**—At the crossing of two tracks four frogs are required. The manner of constructing these frogs depends largely upon the angle at which the tracks meet. Crossing frogs are sometimes referred to as single or double-pointed; but unless these terms "single" and "double" are understood they are liable to lead to confusion in other connections. A frog can have but one point, which, real or imaginary, must be the intersection of the two gage lines. Figure 184 shows the outline of a crossing of two straight tracks. There are four frog points: F, F', F'', and F'''. The angles at F and F'' are acute and equal and those at F' and F''' are obtuse and equal. The frog angle at F is the angle $A\ F\ B$ and the point pieces are $A\ F$ and $B\ F$. The frog angle at F' is $A'\ F'\ B'$ and the point pieces are $A'\ F'$ and $F'B'$. The wing rails of the first-mentioned frog are $G\ E$ and $C\ D$; those of the second-named are $G'\ E'$ and $C'\ D'$. The two frogs shown as F and F' are each ordinary frogs, in no way different except in their angles, the same being supplements of each other. Now when a wheel approaches in the facing direction a frog of ordinary angle, the wing rails forming the mouth of the frog

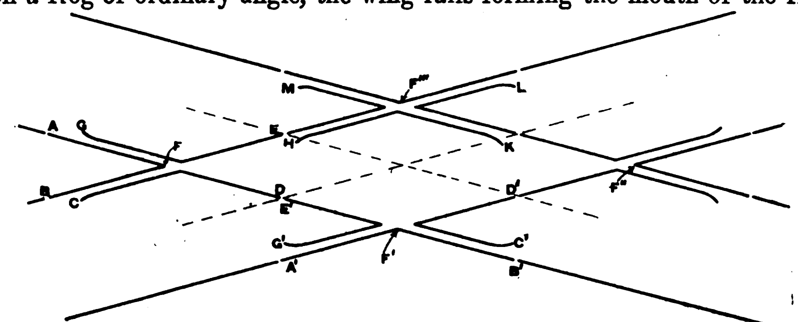

Fig. 184.

guard the flange before it reaches the throat; but if the frog angle be large, as at F', the wing ($C'\ D'$) will not guard a wheel flange (approaching from E') until after it has passed the throat; and the same with the wing $G'\ E'$ for a wheel approaching from D'. Hence in frogs of such large angle there must be two guard rails or wings not required by frogs of ordinary angle in order to guard the wheel flanges in advance of the throat. These guards are placed in the mouth of the frog, like the piece $H\ K$ for the frog F'''. They belong also with the frog F', but have been omitted in the figure for sake of clearness of description. It is this piece $H\ K$ which gives rise to the name "double-pointed," but it constitutes two guard wings, and, using the conventional names for frog parts, the frog is double-guarded or double-winged, rather than double-pointed; the double points referred to being the sharp angles in the wing rails. With this understanding, however, and in deference to common practice, we call it double-pointed. As names denoting the positions of the frogs in the crossing, it is quite largely in vogue to call the frogs F and F'' the "end" frogs and F' and F''' the "middle" frogs. At a crossing of straight tracks the angles about all the four frog points are the same as those about the intersection of the center lines of the tracks; but if one or both of the tracks be curved at this point the angles at the corners will all be different. The angle at each point is, of course, the angle made with the tangent of the curve at that point, and, as previously noted for other special problems of like nature, the readiest method of solution is to plot the tracks to large scale and take the angles off the drawing. Crossings on curved track are usually avoided, if possible. On foreign roads it is quite customary to introduce a piece of tangent at the crossing.

Construction.—In a general way, four styles of crossing construction are recognized. For crossings of small angles—15 deg. and less—the usual arrangement is that of "disconnected frogs." The end frogs are of ordinary construction and ordinary length, and there are connecting rails between these and the middle frogs. For angles of 8 deg. and above, the middle frogs are usually double-pointed, but for smaller angles use is made of movable-point frogs referred to more in detail further along. For angles between 15 and 35 or 40 deg. the crossing is usually made in four sections, the end and middle frogs meeting at joints all around, as in Engraving *A*, Fig. 185 (Weir Frog Company's crossing patterns). This style of crossing is known as "long-angle construction." The fourth style is known as "short-angle construction." In this style, which is usually employed for angles of 35 or 40 deg. and higher, the rails of one track are continuous over the frogs, or throughout the length of the crossing, with the rails of the other track butted against them as arms. If the crossing is made as a single section, known as a "through rail" crossing there are no joints between the corners, as in Fig. 186 (Elliot Frog & Switch Company's pattern); if it is made in two sections, for convenience of shipment, the crossing is cut in two at

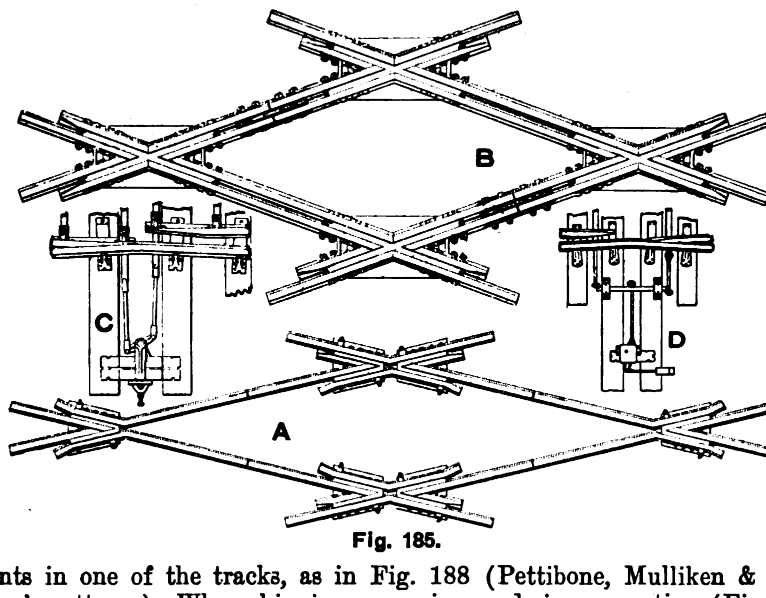

Fig. 185.

joints in one of the tracks, as in Fig. 188 (Pettibone, Mulliken & Company's patterns). When shipping a crossing made in one section (Figs. 186 and 191) either two or four arms are usually taken off. It should, of course, be understood that in designating types and styles of construction the relation of the angles to the various conventional terms and to the range of application of certain details should be taken broadly. Each manufacturer has his own standards in these respects, and among the railways there are no generally recognized standards for frog and switch construction.

For short-angle construction the end frogs are usually double-pointed, and such is also frequently the case with long-angle crossings. The guard rails are then extended from the four corners and joined, or are made continuous, forming what is called a "double-rail" crossing, illustrated by Engraving B, Fig. 185, and by both engravings in Fig. 188. Figure 192 (Ramapo Iron Works patterns) shows the double-pointed end frog for a double-rail crossing at an angle as small as 20 deg. Engraving *A*, Fig. 185, shows a "single-rail" crossing. If the inside guards of a double-rail cross-

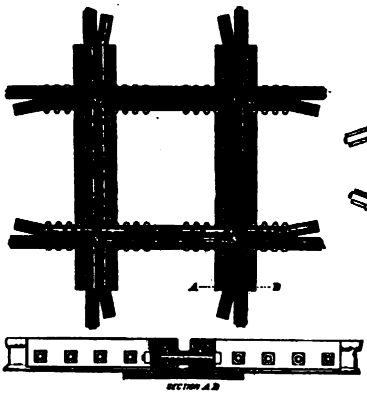

Fig. 186.

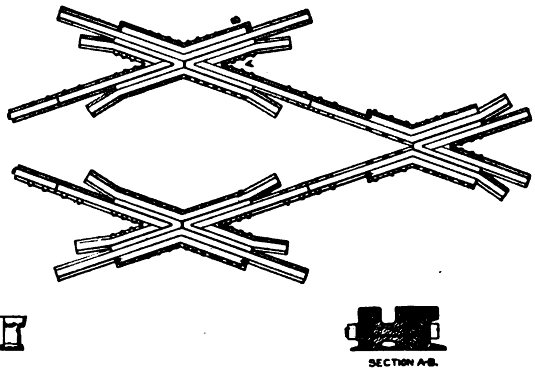

Fig. 187.

ing are not continuous they should preferably break joints with the running rails, as in Fig. 189 (Paige Iron Works pattern), and the filler blocking should break joints with both. In a short-angle crossing with double track the arms between the tracks should be made of proper length to fit without connecting pieces, and preferably without a joint in either guard or running rails. An important modern improvement in crossing construction is the use of reinforcing rails with easer ends, to carry the outer flange of worn wheels. Figure 187 shows the application of this feature to the obtuse corners of a long-angle crossing, and Fig. 189 shows a crossing with reinforcing rails throughout. In this case the easing rails in the outer corners break joints with the main rails, thus affording very rigid construction.

As the flanges of street-car wheels are usually smaller than those of steam cars, the flangeways in a street railway track crossing a steam road may be narrowed accordingly, and much to the benefit of the crossing for the steam cars. The situation is also improved by narrowing the gage of the street car track over the crossing about $\frac{1}{4}$ in., as such steadies the motion of the street cars and reduces the flangeway otherwise required. The crossing of a steam road with a street railroad is sometimes made by leaving the rails of the steam road undisturbed, except to cut notches across them just deep enough and wide enough to let the street car flanges through. The street railway rails are then butted against the steam-road rails and

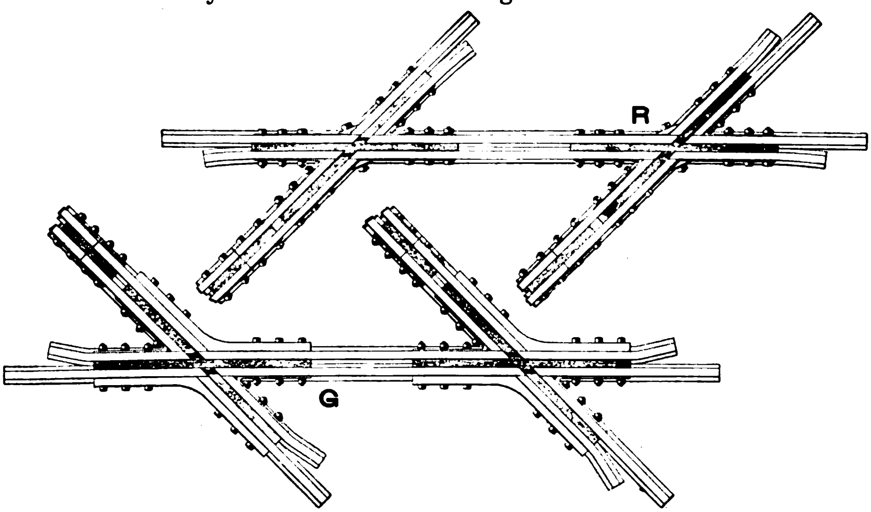

Fig. 188.

bolted to them by splices fitting the angle. The street railway rails must be broken for sufficient distances to make room for the steam road flangeways and guard rails. When the rails of the steam road become battered at the notches they can be removed and new ones substituted without tearing up the crossing. The best form of crossing for steam roads and street railways, however, is one wherein the rails of the steam road are reinforced throughout the length of the crossing, as such reduces the battering at the notches. Such a crossing is shown as Fig. 191. The sectional view shows how the flangeway along each street-car rail is made by planing out a groove in the head of the guard rail for the same, which is laid touching the head of the main rail and solidly bolted to the same through filler pieces. A flangeway for the street railway 1 in. to $1\frac{1}{4}$ ins. wide and $\frac{3}{4}$ to $\frac{7}{8}$ in. deep is usually ample. Such crossings are preferably built entirely with T-rails of the section used on the steam road. The compromise splices necessary to connect with the rails of the street railway, which are usually of the girder type, then come outside of the crossing, and such construction is more satisfactory than that of joining the two kinds of rail together in the crossing. By careful measurements the bolt holes in the rails of the steam road may

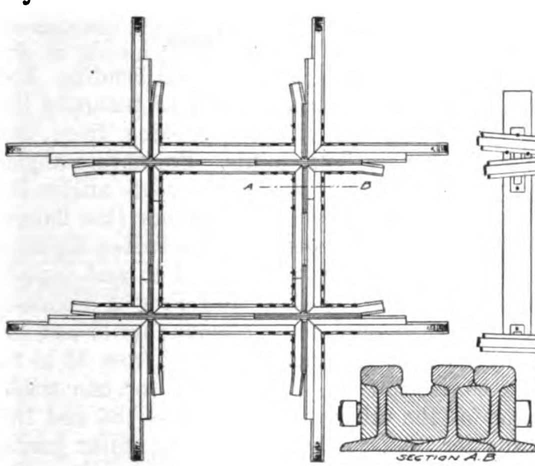

Fig. 189.

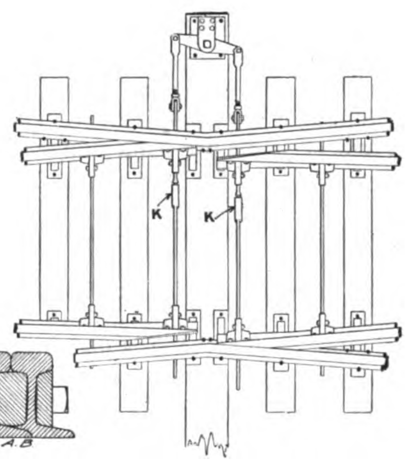

Fig. 190.

be drilled in the rail in place and the crossing then laid without tearing up or obstructing the steam road. The notches are readily cut out of the rail head with hack saw and cold chisel. The rails in the steam road should be continuous over the crossing, even in the case of a double-track street railway. If a joint happens to come within the crossing as located, the rails may readily be cut and moved along to bring the joint off the crossing. When renewal of the crossing becomes necessary the rails for the steam road may be drilled and notched beforehand, ready for laying in place as soon as the time comes for the change.

In long-angle construction it is largely the practice to bend the wing and guard rails to the obtuse angles. Rails for crossings are frequently bent 25 deg. and sometimes 35 deg., and perhaps even more than this in a few instances, but objections are raised to heavy bending, for two reasons: First, a rail cannot be bent to a well-defined angle, and, secondly, the heating of the rail, which is necessary for heavy bending, softens the metal right at the point where the wear is heaviest. Aside from the angle, the necessity for heating rails when bending depends upon the hardness of the metal and the size of the section. Under average conditions in these respects a rail can be bent cold to an angle of about 15 deg. as the maximum. The observation of some authorities is to the effect that the bending of rails for

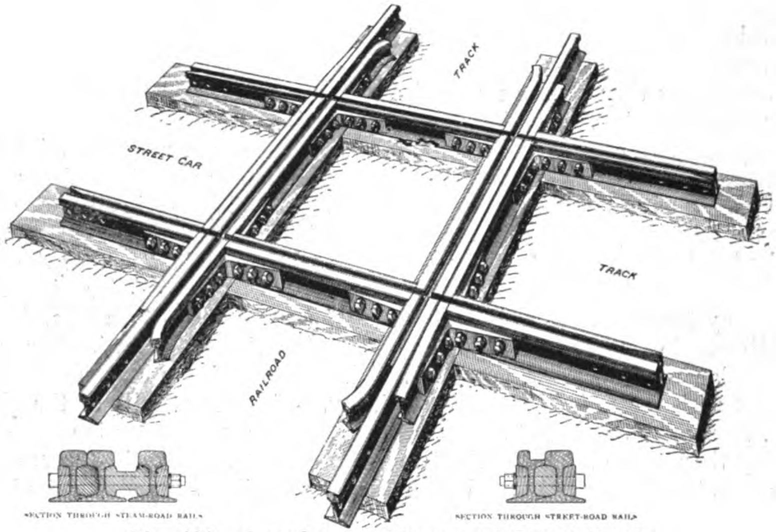

Fig. 191.—Crossing for Steam and Street Roads.

crossing frogs should be restricted to the limitations of cold bending. For angles higher than this they consider a well spliced joint as generally the preferable arrangement. In assembling the arms of crossing frogs two kinds of joints are made, namely miter and butt joints. For obtuse angles the miter joint is perhaps the most common style and for acute angles the butt joint, but when the rails in one of the tracks are continuous (the flangeway being cut through the head only) the pieces must be butted together all around, as in Fig. 188. For angles above 25 deg. and to and including 35 deg. it is the standard practice of the Cleveland Frog & Crossing Co. to use miter joints in both the obtuse and acute corners; up to and including 25 deg. the rails forming the obtuse corners are bent; from 35 to 90 deg. the standard construction consists of continuous rails for one track, with arms abutted against them for the other track. Figures 186 and 189 show both butt and miter joints for 90-deg. angles. In long miter joints, as, for instance, in the acute corners of crossings at 45 deg. and less, the web should support the rail head to the extreme end of the joint or apex, as in the 40-deg. frog, Fig. 192. In order to carry the full web support in this manner the end of the rail is bent before the planing for the miter is begun. The engraving for the 20-deg. end frog, in the same figure, shows

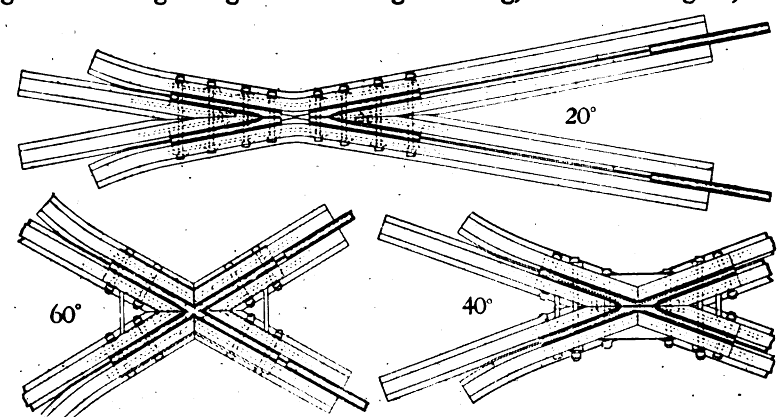

Fig. 192.—End Crossing Frogs.

how the web is carried out to the end of each piece when "main point and side point" construction is employed, as in ordinary single-pointed frogs.

Rolled iron or steel makes the strongest filling, but such must, of course, be used in separate pieces. The crossing frogs shown in Engraving *B*, Fig. 185 and in Fig. 189 are "cross filled" with rolled pieces halved together, so as to be continuous both ways. The filling of the 40-deg. end frog in Fig. 192 is in two pieces planed to fit together along the axis of the frog. The angle splices for crossing frogs should fit accurately and they should be heavy. In order to get the proper strength they should fill all the space between the head and flange of the rail. Engraving *G*, Fig. 188, and Figs. 186, 191, and 194 show examples of extra heavy angle splice construction. The type of stout splice shown sectionally in Figs. 186 and 194 affords the maximum sectional area for the thickness. Cast angle splices of this style —that is, extending flush with top of rail—as thick (horizontally) as 6 ins. have been used on the Grand Trunk Western Ry. The Cleveland Frog & Crossing Co. makes a heavy, solid cast steel angle bar which has the angle filled up and extended flush with top of rail, to form a triangular "easer block" outside the rail head, as shown in Fig. 193. Another stiffening device used a good deal is an angle brace, most frequently across acute corners, as shown in Fig. 192 and by Engraving *B*, Figs. 185 and 194. In

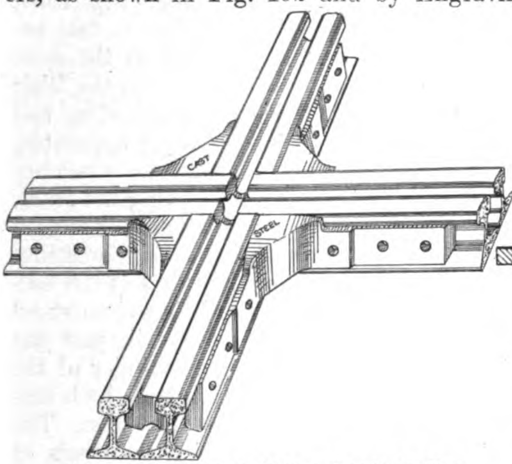

Fig. 193.—Easer Block Angle Splice.

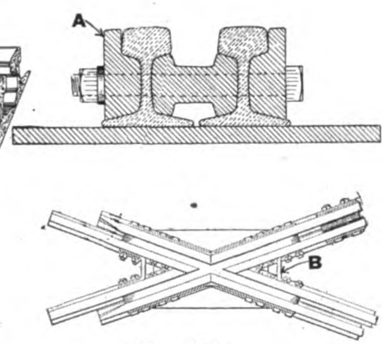

Fig. 194.

one style this brace consists of a heavy strap with the ends bent up against the arms of the frog, but on the 60-deg. frog shown in Fig. 192 the brace strap and angle splice are welded together, forming a solid A-shaped splice. In some instances these brace straps are placed farther out from the apex than in the positions shown, being sometimes as long as 18 ins. Aside from their general utility these corner braces are of good service to prevent bending of the crossing arms in handling during shipment. A bolt across the mouth of the frog (*R*, Fig. 188), with large beveled washers, is a good arrangement for securing the joints in the wing rails. The 40-deg. frog in Fig. 192 is shown with the large washers and two bolts, the latter passing through the webs of the point pieces. Still another stiffening arrangement is a base plate. In the largest practice plates are used only at the corners (*B*, Fig. 185), but in short-angle work continuous plates the full length of the crossing, under one of the tracks (Fig. 186), are used to some extent.

Movable-Point Frogs.—In small-angle crossings the guard rail of each middle frog (*HK*, Fig. 184) is sometimes set to shade the two points by about ⅛ in.; that is to say, the channels between *H* and *F'''* and *K* and *F'''*

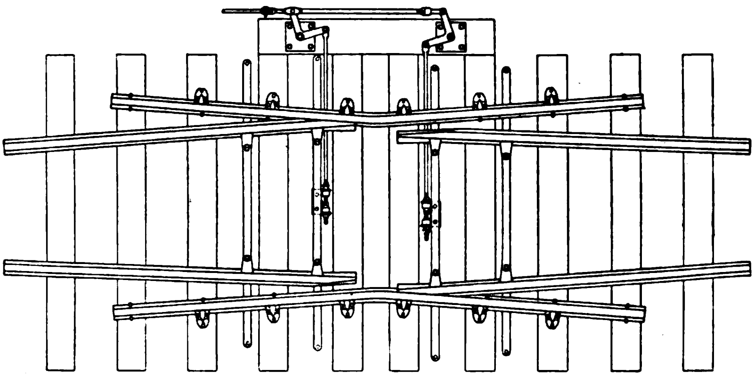

Fig. 195.—Movable-Point Frog.

are each made $\frac{1}{8}$ in. narrower than the channels between M and F''' and L and F'''. This arrangement affords some degree of security, but as the angle gets smaller it cannot insure safety. For crossing angles of less than 8 deg. the throats of two middle or double-pointed frogs would come so nearly opposite that it would be impossible to guard the points, in which case the point-rail crossing, otherwise known as the movable-point frog (Fig. 195), is used. It consists of two sets of short switch points placed face to face between two bent rails. They are moved in opposite directions at the same time, either by direct connection with a double-throwing stand on the Weir or Hasty idea (Figs. 163 and 164); or by a "T" or oppositely-acting bell cranks connecting with an ordinary stand or with interlocking apparatus, as appears in the figure; or by connecting both pairs of points to a balance bar, as in Fig. 190—the throwing of one set of points then moving the other. This arrangement also causes the points to operate automatically if trailed when wrongly set. The Weir automatic stand for movable point-rail crossings (Eng.C, Fig.185) has an adjustable spring working on a tail piece of the balance bar, on the principle of the action of the Weir automatic switch stand (Fig. 151). As soon as a trailing wheel throws the point rails past the half-way position the spring assists in throwing them the remainder of the distance and closes them tightly against the opposite stock rail, both sets of points being operated simultaneously and in opposite directions. The Elliot Frog & Switch Company's arrangement for throwing both sets of points at the same time, and which is also automatic, is shown by Engraving D, same figure. Figure 196 shows a stand for movable-point frogs used on the Pittsburg, Ft. Wayne & Chicago Ry. There is a parallel-throw ground lever turning a shaft and beveled pinion, the latter being engaged with a sector gear on the arm of a balanced lever connected to the two sets of points.

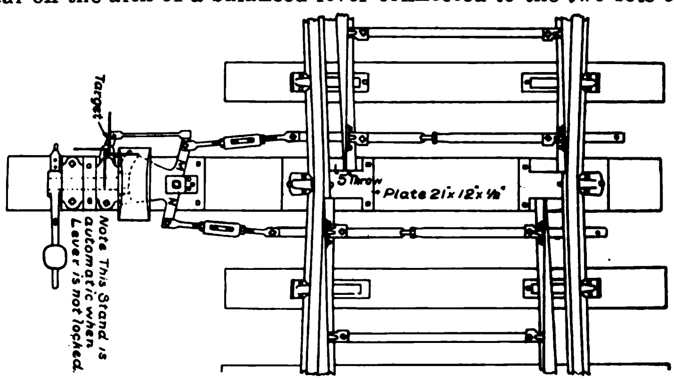

Fig. 196.—Stand for Movable-Point Frog, P., Ft. W. & C. Ry.

Other details in connection with the operation of the stand are made clear in the illustration. Another advantage in the use of the movable-point frog that is worthy of mention is that it provides a continuous-bearing rail; and another condition under which the use of the frog becomes desirable is where one or both of the tracks are on a curve.

All parts of a crossing should be made with rails of exactly the same form and size, and if the tracks be laid with rails of different weight the heavier or deeper section should be used throughout. If the difference in section be such that compromise splices are required in one of the tracks, a length of rail of the same section as that used in the crossing should connect with each frog, so as to remove from the proximity of the crossing any diversity of conditions in the joints. In loading or unloading crossings or sections of the same, as during shipment, considerable care is

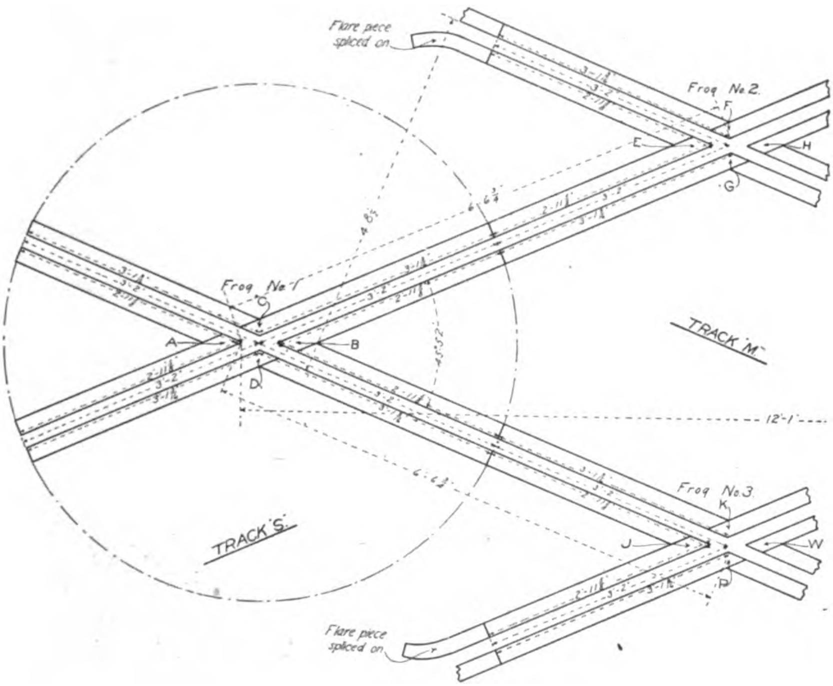

Fig. 197.—Mansfield Reversible and Interchangeable Crossing Frogs.

necessary to avoid knocking the legs out of line. At crossings on double track two joints in each track, not far from the crossing, in the direction from which the creeping takes place, should constantly be kept open, so that the running of the rails in the two tracks, in different directions, will not throw the crossing frogs into bad alignment.

Reversible and Interchangeable Crossing Frogs.—As all the parts of a double-rail crossing are not subject to wear from the traffic it would appear that if the frogs were made reversible or interchangeable the wear could be distributed more uniformly over the parts and thus increase the service of the frogs. Mr. M. W. Mansfield, engineer maintenance of way for the Indianapolis Union Ry., has put this idea into practice to some extent. The diagram of a set of frogs designed for the Erie R. R. according to Mr. Mansfield's plan is shown as Fig. 197. The two tracks cross each other at an angle of 45 deg. 52 min. and each frog is made symmetrical with respect to the point of intersection of the center lines of the filler blocks. All legs symmetrical with either axis of the frog have the same length, and these lengths are not arbitrary. Having the gage of the track and width of flangeway the angle of the crossing then determines the length of the legs. The flare of the guard rails is made by curved pieces spliced on, as shown. As both ends of each frog are the same, and all four frogs exactly alike, any or all of the frogs may be reversed in place, or any one will fit in the place of any other. The utility of the design for the purpose intended may, for example, be considered with reference to Frog. No. 2. Under traffic the wear upon this frog comes upon the points *H, F* and *E*; that is, wheels rolling along the track "S" pass over *E* and *F* and wheels rolling along track "M" pass over *H* and *F*. The part *F* is then subject to wear from the wheels on both tracks, while the part *G*, being on the guard rail, undergoes no wear at all. Now if the frog be reversed in the same position the guard rails change places with the running rails and the wear will come upon parts *H, G* and *E*, the part *G* then being subject to "double wear" and the part *F* relieved of wear. Thus by reversing the frog in its place all parts of the frog are brought into service and the service upon all of the parts is equalized, inasmuch as the parts in double wear are

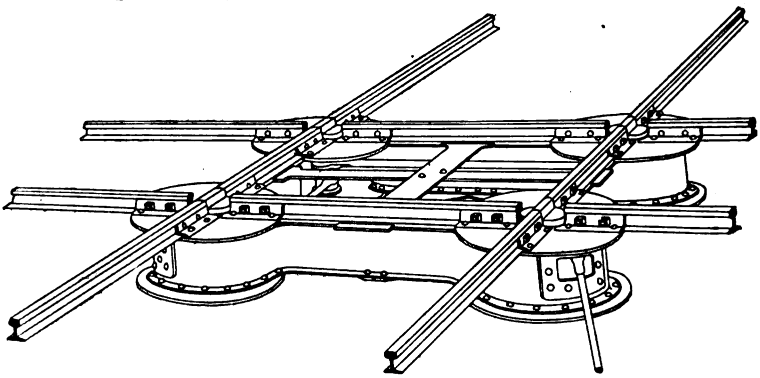

Fig. 198.—The Fontaine Crossing.

in service only half of the time. Or suppose that Frog No. 2 be interchanged with No. 1. The wearing parts then become *F, E* and *G*, corresponding to the parts *C, A* and *D* respectively, the part *E* (corresponding to part *A*) coming into double service. Next suppose the frog be interchanged with No. 6. The wearing parts then become *E, G* and *H*, corresponding to parts *J, P* and *W*, respectively, the part *G* (corresponding to part *P*) then coming into double service. By interchanging the frog with No. 4, not shown, the parts *F, H* and *G* become the wearing parts, with part *H* in double service. Thus by interchanging each frog with the frogs at all of the four corners of the crossing, each of the four points about the throat of the frog is in turn brought into double service and the wear upon all the parts of the frog is equalized.

With frogs of this kind in a crossing of two tracks one of which is much used and the other but little used, as, for instance, the crossing of a main track by a siding or branch line handling but a small amount of traffic, the economy of wear is equally, if not more, apparent. Suppose track "M" be a main track or a track much used and the track "S" a side-track or track but little used. It is evident that in a case of this kind the wear on frog No. 2 would come principally upon the parts *H* and *F*, while the part *E* would come but little into service; and on frog No. 1 the same applies to the parts *A* and *D* in the main track, and part *C* in the side-track. If now frogs No. 2 and 1 be reversed in place or interchanged, the parts *H* and *F* and *A* and *D* will be relieved of wear from the traffic in the main track and the parts *G* and *E* of frog No. 2 and *B* and *C* of frog No. 1 will come into main-line service. The life of the frog should therefore be practically doubled. Two sets of these frogs in service at the crossing of the Belt Ry. with the Cleveland division of the Cleveland, Cincinnati, Chicago & St. Louis Ry., in Indianapolis, Ind., after being reversed and changed four times, had given between two and three times the amount of service previously obtainable from frogs of ordinary pattern used in the same crossing. Interchangeable crossing frogs of the same design are also in service on the Chicago, Indianapolis & Louisville Ry.

Crossing Support.—Crossing ties should be long switch ties, placed diagonally to the two tracks rather than squarely across one of them, the preference being to place the ties at right angles to the longer diagonal of the crossing, and thus symmetrical to both tracks. In some situations, however, it is considered good practice to lay the ties at right angles to the line of heavier traffic. On a few roads ordinary ties are used, the ties of the two tracks being interlaid so as to come as nearly as may be at right angles in each track. Large sleepers placed longitudinally under the rails, halved together where they cross under the frogs (Fig. 191), are sometimes used, in place of ties. For square crossings the Buffalo & Susquehanna R. R. uses sleepers 12x16 ins. in size. Mr. Jerry Sullivan described, in the Railway Review for Apr. 9, 1892, a substantial foundation for crossings where the intersection angle is 90 deg. or nearly so. He excavates to a depth of 19 ins. under the rail base and lays 7x9-in.x9-ft. sawed ties side by side in the bottom of the trench, over a length of 9 ft. of track. On top of these, and crosswise, three pieces of 12x12-in.x9-ft. timber are laid, two being used as sleepers for the rails of one track and the other lying in the middle of the same track, all three pieces then acting as cross ties for the other track. The idea seems a good one and no doubt a further improvement would be had by using bed ties of 12 ft. length and two extra 12x12-in. timbers properly spaced outside the three, as per his arrangement.

The drainage of crossings is very important. Unless the ground under the crossing can be kept reasonably dry it cannot be expected to maintain the crossing in good surface. The best practice seems to favor the use of a good depth of broken stone ballast, with drain tile for foundations that are shut in, or from which the water cannot readily escape. A committee report to the Roadmasters' Association of America, in 1896, recommends a pit 4 ft. deep framed with timbers and filled with crushed rock, with a drain from the bottom of the pit. When tile is laid under track at a crossing the foundation should be excavated to slopes which will give drainage to the tile.

Continuous-Rail Devices.—As the angle between the two tracks approaches 90 deg. it becomes more difficult for crossing frogs to give satisfaction, owing to the open channel space lying more nearly square across the rails and allowing the wheels to drop. Numerous devices have been contrived and tested for overcoming this objectionable feature, but without any permanent success. The result of a noteworthy attempt at solving the difficulty is the Fontaine crossing (Fig. 198), tried some years ago on the Baltimore & Ohio; Vandalia; Pittsburg, Ft. Wayne & Chicago and other roads. It consisted of four vertical turrets connected together by heavy rods and enclosed within a strong frame of channel iron. At each corner there was a short piece of rail mounted upon a small turntable arrangement rotated by connection with an interlocking tower. It is said to have preserved a smooth riding crossing and to have shown durability to a marked degree, but the unavoidable accumulation of rust and grit caused revolving parts and locking bars to work so hard that their operation became unreliable. Four of these devices used in the crossing of the Chicago Terminal Transfer and the Chicago & Grand Trunk roads at 49th Street, in Chicago, from 1892 to 1897 were finally condemned and sold for scrap. During the five years they were once rebuilt at an expense of about $800, and they were a source of annoyance the whole time. It required the services of an extra man practically day and night to keep the crossings oiled and in proper adjustment. Every little while one of the revolving posts would break, requiring one of the tracks to be abandoned until repairs were made. The reason for relating this much of experience with the Fontaine crossing is that it was an exceptionally well built device, and the information concerning the same may be of value to persons inclined to experiment with crossings got up on the same idea, which seems to be a favorite one with inventors.

Gantlet Tracks.—It sometimes becomes necessary for the trains of two (usually parallel) tracks to traverse the same space for a short distance where there is not room enough for two tracks at clearing distance apart: such, for instance, as the passing of a double-track road through a narrow street; or over a bridge or through a tunnel built for single track. In such cases no switch is needed, as the rails of both tracks may be laid side by side on the same ties, as near each other as may be convenient—say 8 ins. apart. The crossing of the two inner rails is made by ordinary frogs, as shown in Fig. 199. This arrangement of two tracks on the same ties is known as a "gantlet track." The weighing track over track scales is usually gantleted with another, so that cars which are not to be weighed may pass without bringing load upon the scales.

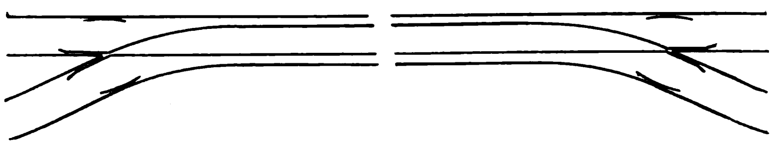

Fig. 199.—Gantlet Track.

An interesting application of gantlet tracks was put into temporary service in the Musconetcong tunnel of the Lehigh Valley R. R. in 1899 while a portion of the same was being lined. There was a double track through the tunnel, and during hours when the work of lining was being carried on it was found desirable to divert all traffic to the center of the tunnel, so as to get room at the sides for tram cars which were used to carry out the excavated rock. A rail was laid outside each main track and used with the outer rail of the latter for a tram track of 2 ft. gage. As the traffic was heavy (an engine or train passing through the tunnel every 10 minutes, on the average) it was found expedient to use the regular tracks at such times as the tunnel work did not interfere. No work was done nights and Sundays, and at other times the work did not obstruct the regular tracks all of the while. To make room for the side supports of the arch centering the main tracks were thrown in to 11½ ft. centers, as shown in Fig. 199A. The arrangement for single-track operation consisted in laying two rails in the space between the tracks, to gage with the inner rails of the main tracks, thus forming a second track alongside each main track. The outside of the inner rail of the main track in this case was the gage side for the "second" track, and the two so-called "second" tracks were gantleted together in the space between the two main tracks. In other words, for east-bound movements there were two tracks on three rails, or two tracks using one rail in common; for west-bound movements there was a like arrangement independent of the other; and the inner of the two tracks for movements in each direction were gantleted. The illustration shows the arrangement of the ties laid for the support of the extra rails, including the rails of the tram tracks, laid outside the main tracks for running the excavated rock out of the tunnel while traffic was being operated over the gantlet tracks. The rails for the gantlet tracks were laid on the ends of the ties of the two main tracks, but too near the ends to permit them to be securely spiked. In order to hold these rails to gage it was necessary to interlay ties between the ends of the ties of the main tracks, as shown. As the ties in the main tracks did not everywhere stand opposite each other, it was not practicable to lay ties for the gantlet track between each pair of ties in the main tracks. It was feasible, however, to lay 10 or 12 ties per rail length for holding the gantlet tracks to gage.

The switch connections for the gantlet operation are shown in Fig. 171A. For west-bound main-track movements the rails A and B were used, while for west-bound movements through the gantlet the rails B and C were used. For east-bound main-track movements the rails X and Y were used, and for east-bound movements through the gantlet the rails Y and Z were used. The switching of trains from each main track to the gantlet was by an ordinary point switch operated from an interlocking tower and telegraph office outside and near one end of the tunnel. All train movements over the gantlet were controlled from towers at either end of the tunnel. The turnout lead from each main track into the gantlet was a 5-deg. curve, and as the arrangement was only temporary there was no frog

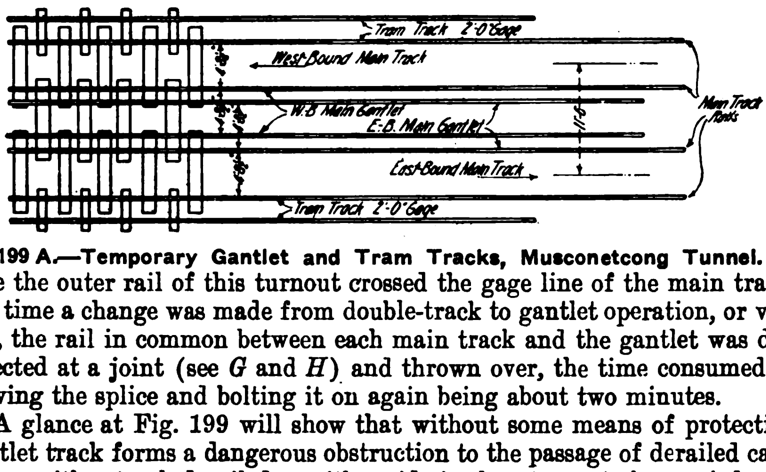

Fig. 199 A.—Temporary Gantlet and Tram Tracks, Musconetcong Tunnel.

where the outer rail of this turnout crossed the gage line of the main track. Each time a change was made from double-track to gantlet operation, or vice versa, the rail in common between each main track and the gantlet was disconnected at a joint (see G and H) and thrown over, the time consumed in removing the splice and bolting it on again being about two minutes.

A glance at Fig. 199 will show that without some means of protection a gantlet track forms a dangerous obstruction to the passage of derailed cars. A car on either track derailed on either side is almost sure to be carried over and break the train, after passing the frog at one end or the other of the gantlet. To avoid trouble of this kind as far as possible a bridge guard, consisting of two rails gradually drawn in to meet in the center of the track, is laid at the heel of the trailing frog in each track.

How to Avoid Switches on Curves.—The elements of danger always present with switches leading from the outside of curved track make it desirable, as heretofore stated, to avoid such arrangements wherever the situation will permit. In some instances, however, it is found to be necessary to lead a side-track or branch line from the outside of a sharp curve. Under such a condition the frog must be placed on the curve, but by going to some expense the switch may be placed back on straight line and the lead gantleted around the curve to the frog placed at the desired point of departure. In one application of the arrangement which I have seen a side-track branches from a sharp curve the P. C. of which comes at the end of a swing bridge. For lack of room the opportunity for laying a switch and desirable lead on that side of the bridge was otherwise not good, and so to solve the difficulty the switch was put in on tangent, in advance of the bridge, and the lead gantleted across the bridge to the frog leading out of the curve just beyond.

Gantlet leads are in use at several places on the Denver & Rio Grande R. R., for the purpose here in view, and the operation of the same is quite satisfactory. An illustration of a layout of the kind is shown in Fig. 168, some pages back. The particular turnout is from third-rail track (4 ft. 8½-in. and 3-ft. gages) at Hecla Junction, a few miles west of Salida, Colo., where a narrow-gage branch line leaves a 7° 30′ curve in the main track and extends to some iron ore mines at Calumet. (It may prove interesting to state that the grades on this branch line reach a maximum of 7½ per cent.) In the illustration it will be noticed that the headblock of the stub switch is located on straight track 57 ft. from the point of curve. In a distance of 30 ft. from the headblock the lead rails of the narrow-gage turnout separate from the rails of the main-line narrow-gage track a distance of 1 ft., from which point onward they are carried the same distance apart. The throw of the switch in this case is 5 ins. The point of frog is 488 ft. from the headblock, the rails for the narrow-gage tracks being gantleted 1 ft. apart to a point within 36 ft. of the point of frog, where the curvature of the long lead is reversed to turn out through the No. 10 frog. The ties in the gantleted lead are of ordinary length, or 8 ft. long.

78. Slip Switches.—At a crossing of two tracks traffic may be switched from one track to the other by a set of switch points in each track, the two facing in opposite directions and connected by a curve—all contained between the two end frogs of the crossing. Such an arrangement is very convenient for crossover work, or where economy of space is necessary. It is called a "slip switch" or "combination crossing." No frogs are used in passing through it from one track to the other. These switches are used mostly in yards for connecting a leader with the parallel tracks which it crosses. For this purpose it accomplishes not only a great saving of track room longitudinally of the yard, as compared with a series of crossovers with frogs of the same angle as are used in the leader, but it also affords a much better alignment for a train movement across all or a number of the parallel tracks. Consider, for illustration, six parallel straight tracks at 13 ft. centers. A series of crossovers using No. 6 frogs, with headblocks 10 ft. apart on the intermediate tracks, will extend about 725 ft. lengthwise the yard; and a train moved from Track No. 1 to Track No. 6 will pass through ten turnouts and meet with nine reversals of curvature. A leader across the same yard, with No. 6 frogs at the crossings and slip switches connecting with all the intermediate tracks will extend only about 445 ft. in longitudinal yard space, thus saving 280 ft. in length of yard; and a train moved from the first to the sixth track will traverse only two turnouts and one reversal of curvature.

A slip switch is single or double according as it gives access from either track to the other in one or both directions. It is evident that with the "single slip" (Fig. 200) the movement of trains in one direction on each track is trailing to the slip points, in which case the train must back, in passing to the other track. With the "double slip" (Fig. 201) a train may pull straight ahead from one track to the other when approaching the crossing in either direction on either track, slip-switch connection being made across both obtuse angles of the crossing. As already stated, two kinds of middle frogs (rigid and movable-point) are used at crossings, and of course either may be used in connection with slip switches, whether the latter be single or double. With crossing frogs of the larger angles, however, the movable-point frog permits the laying of a more suitable curve, the inside guard rails of the rigid frogs being somewhat in the way, when such are used.

Figure 202 shows a device employed by the Morden Frog & Crossing

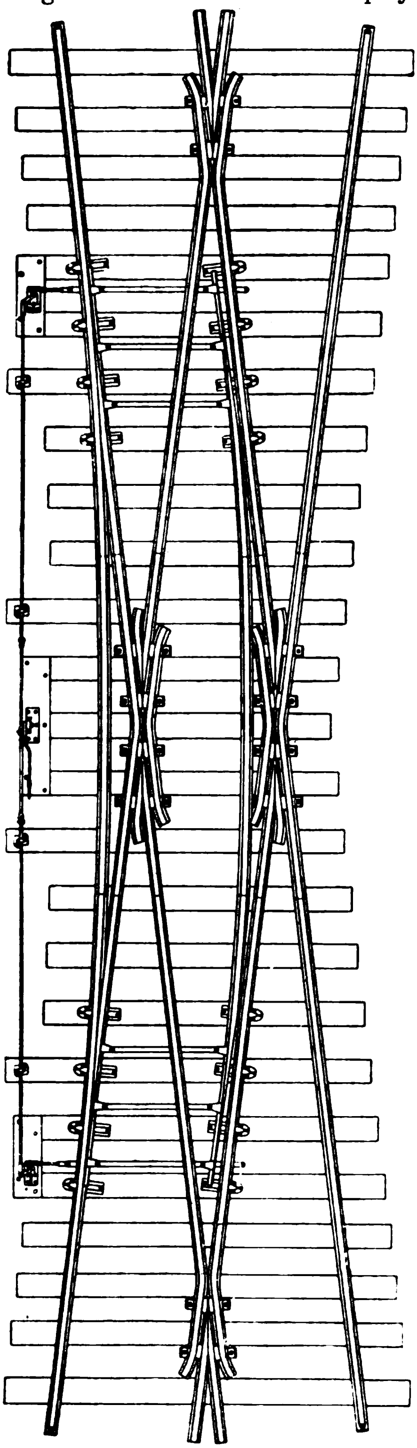

Fig. 200.—Single Slip Switch with Rigid Middle Frogs.

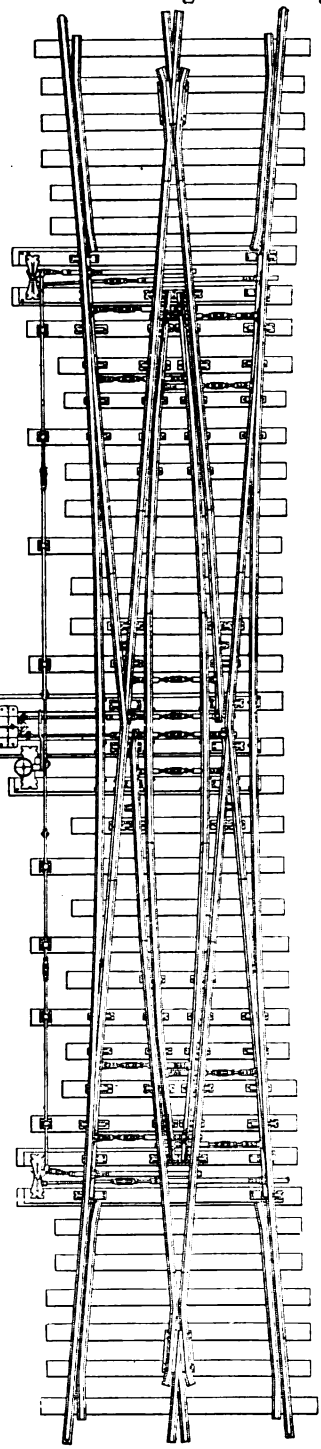

Fig. 201.—Double Slip Switch with Movable-Point Frog.

Works to secure the outer rail of the slip curve, where there are rigid middle frogs, by bolting it to the guard wing of the frog. The connection is by means of channel or U-bars, as shown in the sectional view *A-B*. The idea is to assure that all parts of the combination will be laid in exactly their proper relative positions and secure them against being changed from such. In the yard tracks of the Southern Union Station (Boston Terminal Co.) in Boston a similar device is used at the heel joint of each point rail in slip switches, including the point rails for the movable-point frogs. It consists of a channel bar 10 ins. long and 3 ins. deep with two bolt holes in each flange—one for a bolt each side of the joint. This channel is bolted against the splice bar on one side and against the web of the stock rail on the other side. The rails are of 100-lb. section, the slip points being 13 ft. long and the movable points of the middle frogs 10 ft. 10 ins. long, and in order to obtain free working of the same it is found necessary to leave the heel splices slightly loose. In order to do this without permitting slack nuts the splice bars are tightened up against 1-in. pipe thimbles or spools on two of the bolts just long enough to prevent the splice bars from pinching the rails when the bolts are tightened. In order to receive this spool the bolt holes in the rails are reamed out to a diameter of 1$\frac{3}{8}$ ins. Another device used for the same purpose as the two channel fastenings just mentioned is a cast filling block of short length through-bolted with the webs of the rails.

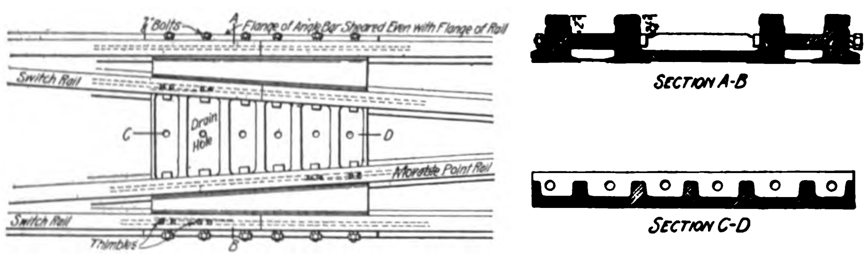

Fig. 201 A.—Anti-Creeping Heel Castings for Movable-Point Frogs and Slip Switches.

The angle or number by which a slip switch is designated is the angle or number of the crossing in which it is located. There is a limit to the room available for a slip switch as the number of the crossing frog gets smaller. With frogs lower than No. 6 the curve that must be laid to connect the heels of the two sets of switch points becomes so sharp as to be impracticable of operation. A No. 6 slip is about the lower limit for switch engines; and No. 8 for passenger trains, when used in connection with a movable point frog; Number 15 is about the upper limit. As usually laid, the point rails of slip switches are evenly matched, but the Weir Frog Co. uses long and short points, as is shown in Fig. 201. The longer point is placed on the inner side of the slip curve, for the purpose of effecting an increase of gage in the curve without having to increase it at the bend of the stock rail or introduce a kink in the inner rail of the curve after it leaves the point rail. The manner in which this is accomplished becomes entirely clear if it is considered that the long point extends past, and the bend in the stock rail lies beyond, the real point of switch. If, therefore, the gage be correct at the bend of the stock rail, it must be somewhat wider at the point of switch. It will be further noticed that this slip switch has long tie plates or steel bridle plates, 8 ins. wide by ½ in. thick, extending under the slip point and stock rails and continuous beyond the T-crank housings, and also under the movable frog points and bases of the two stands operating the slip points and frog points. This arrangement is intended to decrease the tendency to lost motion or change of relative position between operating and moving parts.

The standard No. 8 double slip switch of the Chicago & Western Indiana R. R., adapted for interlocking, is curved through the slip 11 deg. 22 min., and the actual distance between the frog points at the ends of the crossing "diamond" is 76 ft. The length of the slip switch points is 18 ft. and the slip curve begins at the heel of the planing, which runs out 7 ft. 9 ins. from the point end. The throw is 4 ins. The gage of the track on the slip curve is 4 ft. 8¾ ins. The movable frog points are 8 ft. 8⅜ ins. long and the throw 4 ins. The slip switch points have a reinforcing bar ⅜ in. x 2½ ins. x 10 ft. long on the gage side and another ¼ in. x 2½ ins. x 9 ft. 2 ins. long on the back side, ending 10 ins. in rear of the switch point. The movable frog points have reinforcing bars ⅜ in. x 2½ ins. in section on both sides, that on the gage side being 4 ft. long and that on the back side being 3 ft. 2 ins. long, ending 10 ins. in rear of the point. The rail is of 80-lb. section, and the slip and crossing points and connecting rails are well supported upon tie plates and securely braced. Both rail braces and braced tie plates are used, the latter being formed by splitting the end of the plate along the center line and turning up half of the end for a stop, the other half, which remains flat, being punched for the outside spike. At the points where the thrust of the switch rails is received by the main

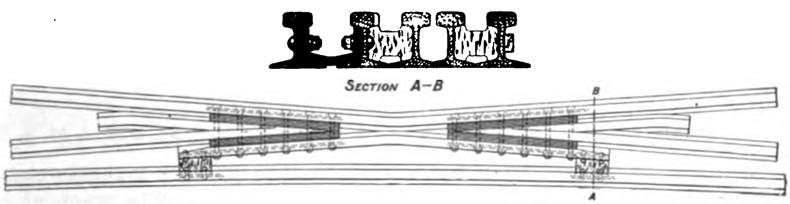

Fig. 202.

rails, through plates 6 ins. wide and ½ in. thick are used, with rail braces. Both the movable frog points and the slip switch rails heel at a common point, and as a means of securely splicing them, as well as to avert derangement of the interlocking and other troubles from creeping rails, the joints are bolted through and through with heavy cast filler blocks of anti-creeping pattern, the details of which are shown in Fig. 201A. The castings at each heeling point are three in number and 33 ins. long. The castings are made to fit the rails snugly, and to allow free movement of the point rails the casting is tapered off at the point where movement is necessary. To provide for tightly bolting up the splice bars the bolts have pipe thimbles which take the pressure between the outer splice bar and the casting, thus permitting the necessary lateral movement for the switch rail, which, being short, would either work very stiff or fail to throw at all if room was not provided in this manner.

There are various throwing arrangements for slip switches. The simplest is, of course, to place a switch stand opposite each end of the slip and another opposite the center to throw the movable-point frog, in case such is used. This arrangement for throwing each set of points independently of the others is in vogue to some extent, ground levers being the type of stand usually employed, but it makes a good deal of work for the switchmen. Except in interlocking, the points of slip switches are usually operated by one switch stand placed opposite the middle of the crossing. In double slips all four sets of points have connection with the same stand and are operated together. In most instances connection is made from stand to points by means of "tumbling rods" (pipe lines) and bell or T-cranks.

To keep the adjustment of the tumbling rod correct it is necessary to prevent relative movement of the end and middle ties, and this is sometimes done by spiking a plank (usually 2x6 ins.) to the tops of the ties just inside the tumbling rod, or by a long iron plate running the entire length of the slip beneath the tumbling rod and spiked to the ties. The Elliot throwing arrangement consists of a rocker shaft extending the length of the slip in the usual place, outside the track, with suitable connection to the points and to an operating stand midway of the crossing. The intention of this form of connection is to eliminate the effect of expansion and contraction as a disturbing influence on the switch adjustments.

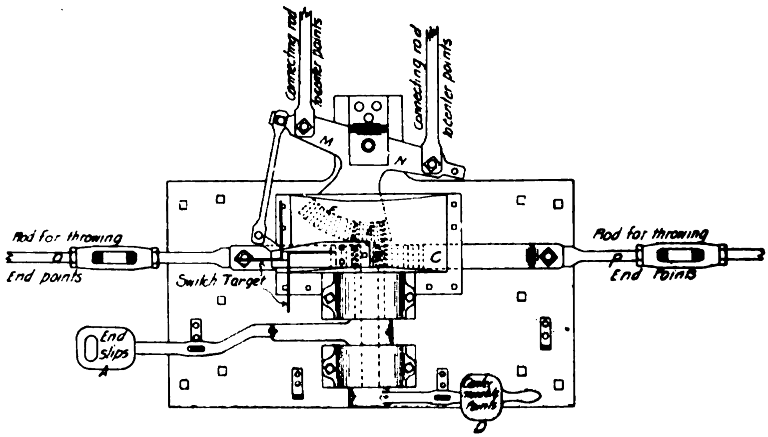

Fig. 203.—Double Stand for Slip Points and Movable-Point Frog, L. S. & M. S. Ry.

Where movable-point frogs are used with slip switches separate stands are usually employed to operate each, one being placed within reach of the other; that is, one stand operates the frog points and another the slip points, as in Fig. 201. As the frog points cannot properly be used while the slip is thrown for service (not at all in case of double slips) it matters not what their position may be in such event. It is also clear that, with the slip points set in their normal position, only one stand at a time need be thrown for any train movement whatsoever about the crossing. With the slip points open to the crossing tracks, however, it might be necessary to throw both stands in order to permit a movement over the crossing, and some think that both of these operations should be controlled by the same stand. By a mistake on the part of the switchman in throwing the wrong stand, or in not throwing both, or even in throwing the lever to the wrong position in the case of a single stand, it is possible, evidently, to run the wheels against a pair of points wrongly set for the intended movement. When both frog and slip points are thrown together six sets of points must be operated by one stand, in the case of double slips. While such must be a hard-throwing arrangement, still its use avoids the possibility of some mistakes which might result from confusion in the use of two stands.

A single stand for operating both middle and end points must be a triple or three-throw device, one movement being requisite for setting the slip points and two movements for setting the movable-frog points. The Elliot arrangement (Fig. 104A) for this purpose consists of two rocker-shafts, each connected to a pair of points at both ends of the slip and to a pair of movable-frog points, but working reversely; the rocker-shafts are operated by a Hasty stand (Fig. 164). When the switch stand lever is in the middle notch, as shown, it gives both slips; but in throwing the lever from the middle to either of the extreme notches, only one pair of points in each slip is moved; and this pair gives that track for which the frog points are set. The other pair of points in each slip remains unchanged from the position held when the lever is in the middle notch. With the lever in either extreme notch, then, the situation is just this: one of the tracks through the crossing is clear, while in the other track through the crossing a pair of points in each slip is set to give the slip. A train attempting to pass through the crossing in either direction on this latter track would, therefore, be turned into one of the slips and would force the points at the far end of the same, but could not run against the center or movable frog points. It is therefore impossible for a switchman to make a mistake on the center points and they cannot be run against in any event. In throwing the lever from one extreme notch to the other extreme notch all slip and center points change position and way is given over the other track through the crossing. When desired, the switch points are connected to the shafts with spring connecting rods, so that the split rails cannot be damaged in event the switch is forced when wrongly set for a trailing train, as just explained.

The Cleveland Frog & Crossing Co. at one time produced a three-throw stand operating directly on a lever pivoted at the center, for throwing the movable center frog points, and on a large bell crank for throwing the switches at both ends of the slip. Some of these stands were used on the Vandalia Line (Terre Haute & Indianapolis R. R.), and although the working principle was evidently correct, the stands were made too light for the service. The double stand shown as Fig. 203 was then designed as a substitute. It combines a compact arrangement of two handles, one for throwing the center or movable-frog points and the other for throwing the end or slip points. The handle *A*, lettered as shown, to prevent mistake, turns the plain pinion *B*, which actuates the rack bar *C* to the left or right. The rack bar works underneath the pinion and is connected by turnbuckles to the rods *O* and *P*, for throwing the end points. Handle *D* for throwing the center points turns the beveled pinion *E* by a shaft passing within the shaft to which pinion *B* is keyed. Pinion *E* moves the sector gear *F*, swinging underneath, *F* being one piece with the arms *M* and *N*, which are connected with the center points by rods. The bottom plate of the stand is of iron, 1 in. thick, and the stand weighs 300 lbs. The sector gear *F* and the rack bar *C* are made of cast steel. The switch target, being in this case a low one, is revolved by a rod connecting with the arm *M*. The gears (shown in broken lines) are enclosed under a cast iron box, as a means of protection against snow and dirt. This type of stand is in service on the Lake Shore & Michigan Southern Ry. The Chicago Junction Ry. has in use for slip switches a stand performing similar functions, on which the two levers are interlocked in such a way that the movable frog points cannot be set contrary to the position of the slip points. This stand was designed and made by the Ajax Forge Co.

79. Y-Tracks.—A "Y" consists of three tracks called "legs" arranged in the form of a triangle, each track connecting with the other two by switches. When locomotives or cars are run around it they come back to the first track turned about from the way they started. If not too long, and land is cheap, it is less expensive than a turntable and more convenient, especially where there are cars to be turned with the locomotives. In order to save room, the legs of a Y are usually made curved track their whole length. Where the main track is used for one leg it is usually straight and the other two legs curved. The "Y" enclosing the least possible ground is one having the three legs equally curved and of as sharp degree of curvature as the rolling stock will stand with guard rails. The three switch points of such a "Y" lie at the vertices of an equilateral triangle having sides the same length as the radius of the curves. That is to say, if each of the three legs be 20-deg. curves, the equilateral triangle whose vertices lie at the three points of switch has sides 287.9 ft. in length, or the same length as the radius of the curves. The length of track required beyond the switch points of the "Y" depends on how many cars are to be turned with the locomotive. On a "Y" of the Peoria & Pekin Union Ry., at Peoria, Ill., 12 to 15 passenger trains are turned daily, without uncoupling from the locomotives. Before this means of turning was put into service combination and certain other cars, which it was desired to run with the same end always forward, had to be turned singly on a turntable, consuming a good deal of time.

A turnout connecting two tracks at a crossing, with switches outside the end frogs of the crossing, is known as a "transfer"; the same term is also applied to a connecting track between two roads which cross on separated grades. Wherever a transfer track is maintained between two roads at a crossing it requires only an additional transfer to make a "Y." Unless the crossing is at a large angle, however, say between 70 and 90 deg., the room required for this second connection (on desirable curvature) is rather excessive. If the two tracks cross at right angles, or nearly so, there is opportunity for putting in a "Y" by leading two turnouts from one of the tracks to the other in opposite directions from a three-throw switch.

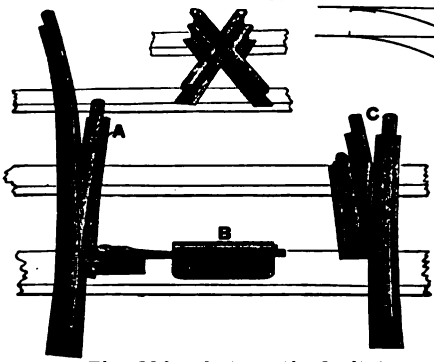

Fig. 204.—Automatic Switch.

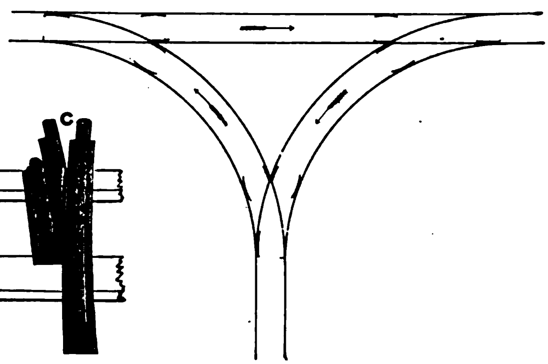

Fig. 205.

For light steam or dummy roads, electric roads, or wherever the rolling stock can use heavy curves, automatic switches can be arranged at the three turnout points of a "Y" to be thrown by the locomotive itself. In Fig. 204 there is shown an automatic switch, and in Fig. 205, a "Y" laid with these switches. The point rail *A* is held by a housed spring *B* which closes it after each wheel flange passes by, the action being similar to that of the hinge rail of a spring rail frog. The device *C*, placed opposite the point rail, is called a "mate;" its true point (the intersection of the two gage lines) is placed about opposite the end of the point rail, or slightly in rear of it. The locomotive trails around the "Y" in the direction of the arrow points, and the operation of the switches is apparent.

80. Turntable and Drawbridge Joints.—Where but one track extends both ways from a turntable, considerable trouble is often experienced with the joints at the ends of the table. A common arrangement for latching turntables is a flat bar or bolt working in guides and fitting between stop lugs or into a socket, being usually operated by a lever; and another arrangement extensively used is a hinged bar thrown over into a cast-iron jaw or between stop lugs. In either case the parts of the latch are usually attached to the track ties, both on the turntable and on the abutment or pit wall. Careless hostlers are much in the habit of bringing the table to rest by shoving out or dropping the latch bar, instead of first stopping the table. Unless firmly held by masonry, or braced by heavy coping timbers extending around the pit, the abutment track is in this way thrown out of line and at the other end of the turntable there is formed an ugly lip which, in the dark, is likely to be unnoticed and the cause of derailing locomotives when moving off the table. It is in this way that serious damage or inconvenience is sometimes charged to defective track when the real cause is bad discipline among employees not supposed to be responsible for the condition of the track. This trouble can be avoided by latching the table to the masonry of the pit wall instead of to the abutment track; or by using a latch which cannot be put into place for locking the table until the table has been brought to rest in the right position.

One device of the type first described consists of vertical rollers pressed against the pit wall by an adjustable spring and locking into curved recesses in castings built into the pit wall. If the table is swinging too hard when the latch springs, the lock will roll out and permit the table to pass on by, thus avoiding sudden shock. A device of the other type mentioned, which is used a good deal, is a sliding cross bar with "T" ends fitting between the webs of the rails. It lies in the track, at the end of the turntable, and when the turntable has been swung into line with the fixed track this bar is shoved with the foot or by a lever to place the "T" ends across the joints in the rails. A wide flat bar is sometimes used in place of the double T-iron. A still simpler arrangement, employed on some roads, is a piece of plank used in the same way. The length of the plank corresponds to the gage of the rails, web to web. When the tracks have been brought even the plank is slid across the joints; that is, the plank lies crosswise in the track, half on the table and half on the abutment. The simplest arrangement of all is to dispense with latching devices entirely, which requires that the table must be held in place or watched when an engine is passing on or off, until the first pair of wheels has passed the joint, the rigidity of the wheel base being sufficient to hold the table in line after that. The practice of dispensing with latches is extensively in vogue. It saves trackmen a good deal of trouble, and seems to be satisfactory from every other standpoint. To prevent the rails from cutting into the ties at the ends of the table and into the timbers on the pit walls they are sometimes supported at these points on steel plates or cast iron chairs.

End Rails for Drawbridges.—A common arrangement for the rails at the ends of drawbridges is a butt joint, the rails being seated in grooved chairs or on wrought plates with riveted lugs for lateral guards, placed on solid bearings on the abutment side. The bridge rails are movable, being usually held together by switch rods and guarded laterally by the backs of parallel angle irons bolted to the ties. Some sort of lifting device is provided to lift the rails out of the seats when the bridge is about to be turned. In addition to the bridge lock and the end seats a knuckled strut between the webs of the rails is sometimes used to hold the stub ends securely in line at the joints. Any misadjustment of the end bearings of the bridge permits some springing in the ends of the rails, and, owing to temperature changes, wide open joints cannot be avoided at all times; so that, sooner or later, heavy pounding is liable to arise. One way of obviating trouble of this kind is by a "carrier rail" joint (Fig. 206). A short piece of rail, *A-B*, is bolted to the outside of each lift rail on the bridge, so that it drops down just outside the abutment rail when the bridge is closed. The ends of this short piece of rail are sloped off, "easer" fashion, to lift the outside flange of badly worn tires, and the wheel is carried over the joint without shock. With this provision it is not necessary to maintain a close joint in the rails at the ends of the bridge, and hence trouble from the expansion of the rails in hot weather can be avoided to a considerable extent. One feature of the butt joint or stub end which is counted for safety is that, with expansion or creeping of the rails there is no tendency for the rails to lip at the bridge joint.

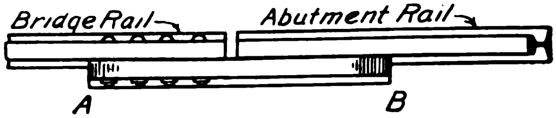

Fig. 206.—Drawbridge Joint.

Another type of drawbridge joint, widely considered the most satisfactory, is the split or skew joint, less frequently called a miter joint. Such joints are made 10 to 24 ins. long, the two sets of rails, for the fixed track and the movable span, overlapping on solid supports resting upon the abutment or wall timber. On double track the lap of the joints should be trailing to the train movements. In order to swing the bridge one set of rails, usually that on the bridge, must be lifted above the other. To maintain the gage of the movable rails they are held together by switch rods. The lifting mechanism commonly in use is a cam acting on the rail base, operated by a lever attached to a cam shaft at each end of the bridge or by a single lever at the middle of the bridge, connected with the two end cam shafts by throw rods. The movable rails are held between beveled guard blocks, so as to drop into proper alignment. To show some of the details of a joint of this type illustrations (Figs. 207-210) are presented of the joints of a plate-girder swing bridge on the Chicago, Burlington & Quincy Ry. at Ottawa, Ill. It will be noticed that the rails are lifted by a cam arrangement of the simplest form. The cams are attached to a shaft extending across the track underneath the rails, which shaft is turned by a lever thrown to the position indicated by the dotted lines when the rails are raised (Fig. 208). It will be noticed also (Fig. 209) that the webs of the rails where they are bent at their ends to form the skew joint are retained,

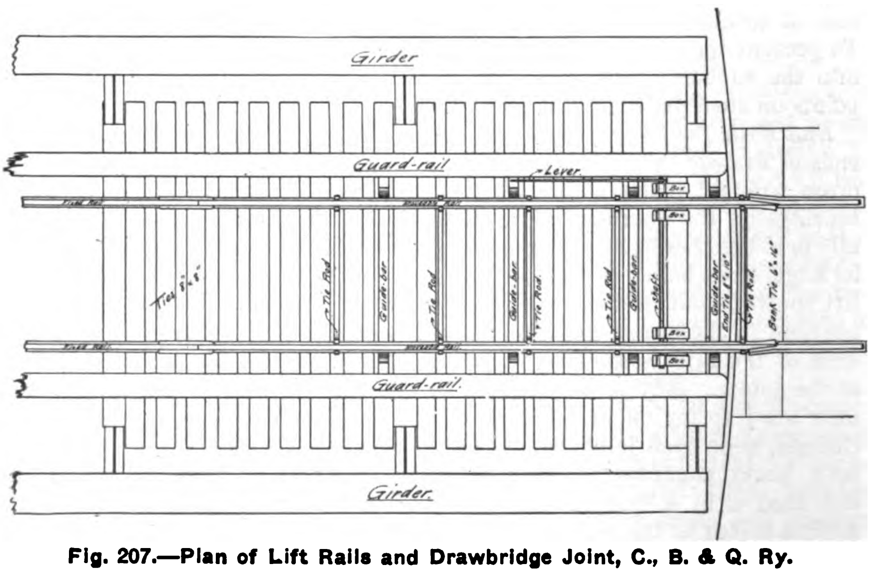

Fig. 207.—Plan of Lift Rails and Drawbridge Joint, C., B. & Q. Ry.

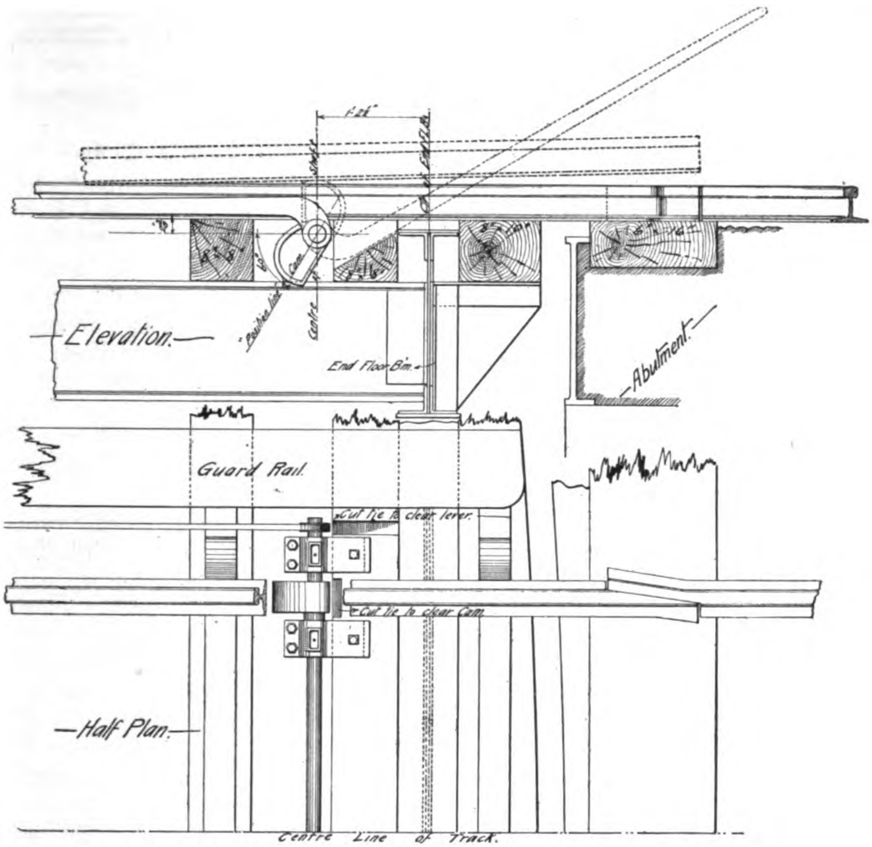

Fig. 208.—Details of Rail Lift for Drawbridge Joint, C., B. & Q. Ry.

thus very much strengthening the support for the rail head. The details of the hinge splice at the heel of each movable rail are shown in Fig. 210. The angle bars are bent in the middle enough to turn up ½ in. in 16 ins. The top is then planed down in line with the other half of the bar, so as to fit snugly under the head of the rail in its lowered position. The bottom flange of the splice bar is cut away for 8½ ins. back from the end. The bolt hole, in the rail, nearest the joint is reamed to 1 in. diam., and the second hole is slotted out to $1x1^3/_{16}$ in., as shown. Other details are made sufficiently clear in the illustrations.

To overcome the difficulty with creeping rails at the ends of drawbridges it is customary to place expansion joints in the track a short distance from the bridge. One form of joint designed for use in such cases is shown as Fig. 211. A pair of disconnected switch points is placed be-

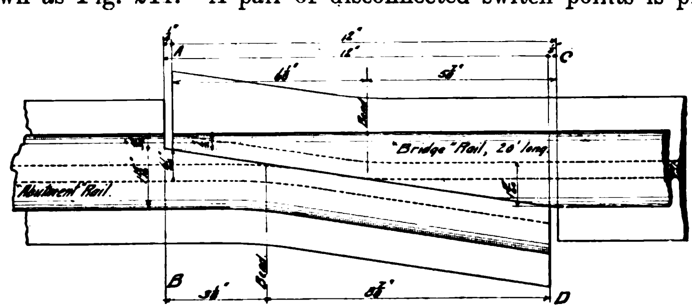

Fig. 209.—Details of Skew Joint for Drawbridge, C., B. & Q. Ry.

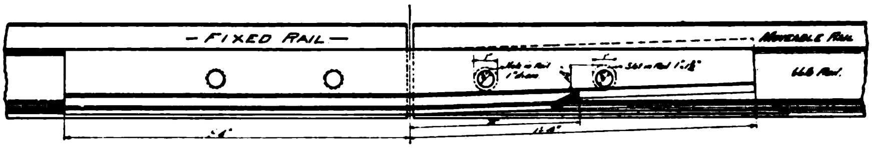

Fig. 210.—Hinge Splice for Drawbridge Lift Rails, C., B. & Q. Ry.

tween two stock rails and held tightly to place by a set of three spring clamps on each point rail. The spring clamp is adjustable and bears against the web of the point rail by the friction roller *F*, thus permitting free longitudinal movement. By setting the device with the gage a trifle wide on the start considerable expansion or creeping of the rails can be taken care of before the gage becomes too tight for safety. The arrangement can be improved upon, however, by separating the point rails on the two sides some distance instead of placing them opposite. This change would permit a guard rail to be laid opposite each split point to keep wheel flanges from contact with it. On double track the split rails would, of course, be laid trailing to the traffic, but in any event a guard rail protecting the split rail its whole length would be approvable.

81. Yard Tracks.—The matter of arranging tracks in freight yards so as to minimize the amount of switching and the amount of interference between working crews, to the end that trains may be made up with the least amount of handling and with greatest dispatch, is of great importance; yet most of the large freight yards throughout the country have been enlarged from smaller ones without keeping with any definite plan. While as to details experienced yardmen might not entirely agree as to the best arrangement of tracks for any given yard, there are, nevertheless, certain features of yard design which, in the main, meet with general approval. Of course the locality has much to do with the way a yard should be arranged, and the question of making most use of available ground is often the matter of weightiest consideration. A yard entirely satisfactory in one case might not meet the requirements of some other place where the conditions peculiar to the traffic may have special demands. The arrangement of tracks in one yard may not be a satisfactory pattern for another. By way of illustration, the yard may be at a terminal point, where its function is to distribute the traffic going to various industrial establishments, factories, grain elevators, steamship wharves, coal docks, stock yards, freight stations, team tracks etc., and to assemble into trains the outbound shipments originating at or delivered from such sources; or the business of the yard may be partly or principally that of handling the interchange of traffic with other roads. The handling of traffic between the yards of several railways

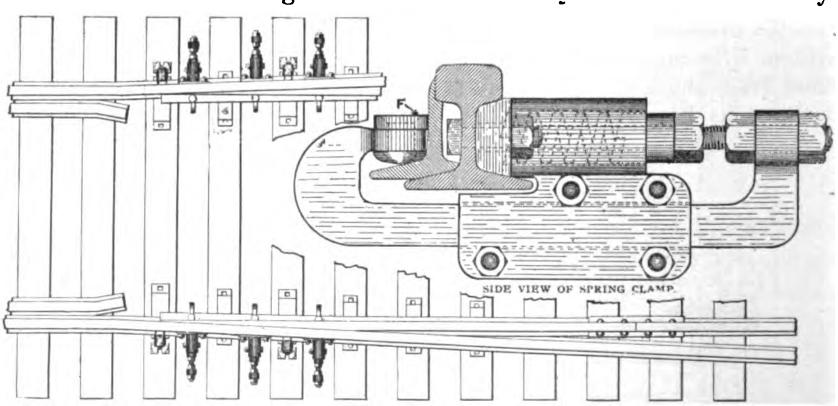

Fig. 211.—Weir Expansion Joint.

in a large city or important railway center, commonly known as "switching," is frequently carried on by a "terminal," "belt line" or "union" railway company, which may also have yard facilities of its own. The yard may be at a junction point with other roads or with branches or lines of the same road or system, where the trains are broken up and the converging traffic separated and again made up into trains for the various routes. The yard may be at a division point, where a readjustment of the make-up of some or all of the trains becomes necessary for the forward movement. The conditions requiring such a rearrangement are various. The traffic originating on the division and brought in by the local trains must be classified and distributed among other local and through trains. Some of the traffic arriving on through trains for points on the next division ahead must be shifted to local trains; and a considerable change in the maximum grades, as at the foot of a mountain division, may require a reformation of the trains on the basis of a different tonnage rating. In a yard at any point the distribution, storage or dispatch of the empty cars necessarily constitutes part of the work.

The character of the work to be done in any yard in question is thus seen to depend very largely, if not quite entirely, upon the situation respecting the traffic. The men best acquainted with yard operation are yardmasters, conductors, locomotive engineers, brakemen and switchmen; and before laying out or enlarging any yard the engineer in charge should call to his aid these different employees and with them look over the ground. As future requirements are always an important consideration, the traffic department should also be consulted. The proper laying out of yard tracks is thus seen to be a broad study, requiring time, careful investigation and to some extent the gift of prophecy.

As a first principle it may be laid down that, with roads handling any considerable amount of traffic, the yards should be so ample in capacity and so arranged that the main track need not be used in switching. In order to accomplish this, or at any rate to avoid frequent crossing of the main track, the yard should all lie on one side of it. If the road be double track the best arrangement is to have the main tracks diverge far enough to make room for the yard between them, else there must be more or less crossing at least one of the main tracks. Generally speaking, a yard should consist of at least two distinct sets of tracks or divisions: "receiving" tracks and "classification" or "distribution" tracks. The purpose of the receiving tracks is to hold trains temporarily as they arrive at the yard, permitting the main track to be cleared immediately and the release of the power and the road crew. The distribution tracks are next in order to the receiving tracks and the ones on which the cars are separated or distributed as the trains are broken up. On these tracks the cars for various routes and destinations are collected, and the different classes of freight are got together and made up into trains, and from them the trains are usually dispatched ahead. In the largest practice this division of a yard is known as the "classification" tracks, but the term "distribution" is in considerable use and more frequently expresses the purpose.

Where the traffic is so heavy that the distribution of cars must be carried on uninterruptedly a third division, known as the "advance" or "departure" tracks is made, to receive the trains as soon as they are made up on the distribution tracks and hold them while they await orders to proceed. In terminal yards such tracks would be used only by the outbound trains. The necessity for departure tracks can be dispensed with by increasing the number of distribution tracks, and at the same time shorten the total length of yard. Where, for any reasons, there may be periods in which trains in considerable numbers must be held for some time, a fourth division, known as storage tracks, is sometimes made. The necessity for still another division is sometimes recognized, but seldom provided for in this country, namely that of sorting tracks, for arranging the cars of a train in station order after being made up on the distribution tracks. Where the yard is at a division point and traffic is heavy both ways, it is convenient and customary to have receiving and distribution tracks for each direction. At terminal points the distribution tracks connect with tracks leading to the different freight stations, team tracks, elevators, docks, warehouses, etc.

Yard Design.—The tracks in the various divisions of a yard—receiving tracks, distribution tracks, etc.—are usually arranged parallel, leading off at intervals from a straight piece of track called a "ladder" or "backbone," shown in Fig. 212. All the frogs in a ladder should be of the same angle, including the frog connecting with main track or the main siding at *A*; that is, if all the tracks are to be parallel and run straight from the frogs. The frog at *A* may, however, be of different angle from that of the others, and frequently is, in which case either the ladder must leave the frog *A* by a curve or else the parallel tracks must leave the frogs on the ladder by curves, or both; also, to shorten the ladder without using frogs of undesirably large angle, curves may be introduced behind all the frogs, whether *A* be like the others or not, and such is frequently done. The arrangement of running the parallel tracks straight from the ladder is the simplest and affords the advantage of an unobstructed view from end to end of a train of cars, both sides, after it has been pushed in past the frog, thus enabling the engineer to take signals directly from brakemen coupling or uncoupling cars. In some cases where the ladder curves from the frog to make a large angle with the main track or main siding it is not possible to join consecutive parallel tracks with the same (the ladder), owing to lack of room for the turnouts. In such a case the parallel yard tracks are usually connected in sets of two or three, and only one track of the set is joined directly with the ladder. Another arrangement is to have the parallel tracks lead out from the ladder in pairs from three-throw switches, like the turnouts *X* and *Z* in Fig. 159, it not being necessary to have the frogs *F* and *F′* opposite each other, which might make the curvature of the turnout *Z* undesirably sharp. The use of three-throw split switches in this manner has been applied in the "sorting sidings" of the Midland Ry. at Wellingboro, England.

The distance between any two frogs leading from the ladder is the distance between the centers of the parallel tracks leading from them, divided by the sine of the frog angle. In the figure,

$$A\,B = \frac{B\,D}{\sin B\,A\,D}, \text{ and } B\,C = \frac{C\,G}{\sin C\,B\,G}$$

C G is, of course, equal to *E F*, the distance between track centers. This distance is sometimes assumed to be equal to the distance between track centers multiplied by the frog number. The results found by that formula are approximate. All the parallel tracks need not necessarily be the same distance apart. Table XVI (See index) gives distances between frog points or headblocks on ladders, corresponding to the number of the frog used, and for various distances between track centers.

A leader is a diagonal track crossing several parallel tracks at such an angle as to admit of connecting with each track crossed by means of a slip switch. By such an arrangement a set of receiving tracks long enough to hold two or more trains may have switch connections each train length to permit the prompt release of road engines; or the leader may be used across any set of long tracks to enable the rear portion of the cars on any track to be taken out without switching the whole string of cars, which might be longer than one engine can handle, especially under unfavorable conditions such, for instance, as through deep snow.

The switch stands on ladder tracks should be arranged on the side opposite the frogs, especially if they are to be tended by a switchman on foot, as he then has clear running space between them. Where cars are to be switched by poling, the stands between the tracks should be low enough to permit the pole to clear the stand with a lamp on. The number of the track may be painted on the target of the stand. In order to reduce the distance between the switches to a minimum, a minimum allowable distance between tracks and a maximum allowable frog angle are used. Twelve feet is about the minimum distance between track centers that is extensively employed, although yard tracks are sometimes laid as close as $11\frac{3}{4}$ or $11\frac{1}{2}$ ft., c. to c., where room is scarce. The maximum frog angle advisable is perhaps that of a No. 7 frog, giving a turnout curve of 12° 26′ for a stub switch and a curve of about 13° for a point switch. A No. 6 frog, giving a lead of about 17°, is frequently used. Where there are so many movements as there are in yards, however, much wear and tear to both rolling stock and track results from sharp turnout curves, and many think that a No. 8 frog, giving a lead curve of about 10°, should be the maximum angle to use. Where the switches on the ladder are operated from a tower, and available ground is plentiful, it is advisable to place the tracks farther apart and

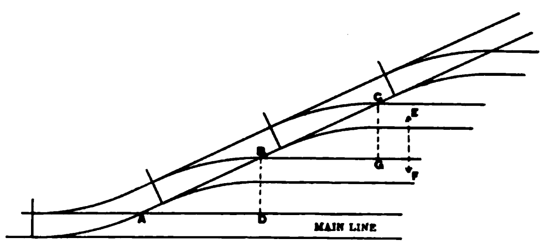

Fig. 212.—Ladder Track.

use turnout curves of still smaller degree. A spacing of 13 ft. c. to c. of tracks is quite commonly employed, even where the switches are operated by hand. Such is the spacing distance in vogue on the Michigan Central R. R. in connection with No. 9 frogs on the ladder and a No. 11 frog where the ladder connects with the main track. On the Lehigh Valley R. R. No. 10 frogs are standard for yard tracks in all new work where the available room will permit, and nothing less than No. 8 is used. Between main track and the first yard track room is usually needed for signals, water cranes, etc., and 15 ft. c. to c. is the minimum distance to be recommended. On the Michigan Central R. R. this distance is made 16 ft. So far as track work and the work of switching are concerned plenty of room between yard tracks is desirable and a convenience in many ways, and 13 ft. between centers is none too much. A liberal allowance of space between the tracks affords room for piling track material while repairs are under way and for piling snow when the tracks become obstructed in winter; it is also a measure of safety to brakemen in switching cars. It is sometimes recommended that where economy of space is important an extra width of spacing may be made at intervals of five or six tracks in order to allow for the piling of material, drainage, etc. Tracks running parallel with ladder tracks should be at least 15 ft. distant, c. to c., to allow room for trainmen to give signals, throw switches, etc., between moving trains. Although on tracks cut up as ladder tracks are there ought to be but little trouble from expansion or contraction with stub switches, still point switches are undoubtedly the better to use, since with these there is less tamping of headblocks and fewer cases of derailment.

The ruling principle in yard design is that the movements of the cars shall be forward: backward movements, at least so far as the general work of switching is concerned, interfere with orderly operation. In order to fulfill this requirement it is necessary that the switching tracks shall be open at both ends, so that traffic may enter at one end and pass out at the other, and there should be direct passage from each track in any set into any track of the set next in order. The arrangement essential to these conditions is a ladder at both ends of each set of tracks. The receiving division should be large enough to hold temporarily several trains, should they arrive at about the same time, until each may in turn be run out for the distribution of its cars according to their various destinations or the classification of the commodities. The number of tracks required in the receiving set will then depend a good deal upon the train schedule; that is, how the trains arrive—whether a large portion of them arrive within a period of a few hours or whether the service is more or less evenly distributed over the whole 24 hours.

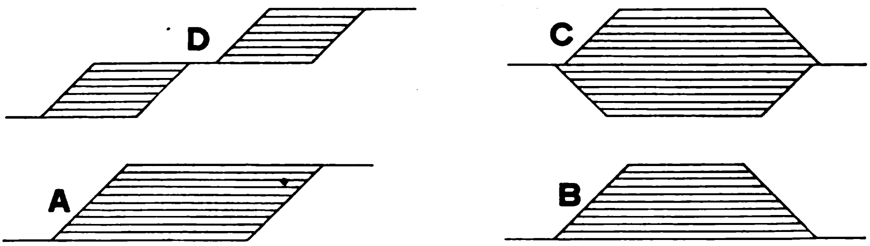

Fig. 213.—Ladder Arrangements for Sets of Tracks.

It is usually stated that each receiving track should be long enough to hold the longest train that is ordinarily hauled over the division, taking account of double headers. It is contended, however, by some careful students of practical yard design that such a length for all of the receiving tracks is seldom necessary, as trains of empty, loaded, and partly empty and partly loaded cars vary much in length, and engines of different classes are rated differently, so that it is rarely the case that a considerable number of trains entering the receiving division consecutively are of the maximum length. A committee of the American Railway Engineering and Maintenance of Way Association has recommended that when the trains of maximum length represent less than 20 per cent of the total number of trains entering the yard the average train length will then be the most practicable basis for the length of the receiving tracks, providing these tracks are all of equal length. If some of the trains are longer than the longest receiving track it then becomes necessary to cut the train and dispose of it on two tracks, and, of course, this arrangement is undesirable if it applies to a considerable portion of the traffic handled daily. Equality in the length of the tracks of a set requires that the ladders at the two ends shall be parallel (*A*, Fig. 213), but such a feature is not an essential of yard design. A set of tracks of trapezoidal outline,—that is, with ladders converging (*B*, Fig. 213)—is a flexible arrangement, and if the lengths of the tracks included cover the variation from the train of average length to that of maximum length the convenience of the scheme is apparent. In deciding upon the length of yard tracks the prospective changes in length of trains through increase in weight of locomotives and in the possibilities of grade revisions, should, of course, be considered.

The purpose of distribution tracks is to separate the cars by routes, by destinations or by commodities. Thus, in a junction yard some or all of the trains are broken up for the distribution of the cars to the lines meeting at the junction. In a terminal yard the inbound traffic must be distributed to various destinations in the locality. In a division yard the traffic destined for points on the adjoining division must be separated from the through freight, and shipments of miscellaneous products received in large quantity by local trains are usually separated and rearranged for the forward movement more or less into trains of the same class of commodities, such as coal trains; trains carrying agricultural products; general merchandise and manufactured articles; and fast freights, carrying stock, refrigerated meats and dairy products, fruits and other perishable goods. The time element in the movement of freight is a condition relevant to the distribution of cars in yards.

The number of distribution tracks required in any case is governed by the number of divisions to be made of the traffic in the regular work of the yard. The length of these tracks should be determined by the general arrangement of the yard in respect to the making up and starting of the outbound trains. In the great majority of the yards in this country the trains are made up on and start from the distribution tracks, in which case the tracks should accommodate the longest trains that are ordinarily handled; and some allowance should also be made as to the number of the tracks, so that the switching movements may proceed after some of the tracks have been filled up and the trains are awaiting orders. In this case, as in that of the receiving tracks, the trains vary in length, and it is therefore not usually necessary that all of the tracks of the set should be of equal length. By converging the ladders at the ends of the set the lengths of the tracks may be graduated from the longest required to the average length of the trains, or shorter, if desired. Where the yard includes a set of departure tracks the lengths of the distribution tracks are not so important, as in that case any congestion of cars on the distribution tracks may be relieved by running them ahead to the proper place on the departure tracks. For the inbound traffic in terminal yards the distribution tracks may usually be shorter than in division or junction yards, as the cars after being distributed are not usually handled in trains of full length. There is also another condition which has arisen during late years rendering distribution tracks of full train length unnecessary, and that is the separation of air-braked cars from those not so equipped. In making up trains the cars with air brakes are coupled together, next the engine, with the non-air cars on behind, and in order to assemble the cars in this way it is necessary to first make up these parts of the train on two tracks. Where the tracks in a yard set are more numerous than the space on one side of the ladder will provide room for, or require a ladder of undesirable length, a double or V-shaped ladder is sometimes used. By arranging the ladders at both ends of the set in the same manner, but oppositely disposed, as in Sketch *C*, Fig. 213, the longest tracks, which may be used for the heaviest business, come central, or in position most convenient to the switching movements. Tandem switches or switches entirely separated, at the point where the ladders branch from the main lead, are perhaps preferable to a three-throw switch, although the three-throw switch is sometimes used in such a place. The departure tracks should be long enough to hold the longest trains operating on the division.

Sorting tracks, for arranging the cars of a train in station order, usually consist of a series of stub tracks of short length, located conveniently to the distribution tracks, but preferably between the distribution and the departure tracks, although not necessarily in the direct line of travel. In Europe "gridiron" tracks are used to some extent for this purpose. The arrangement consists of a set of short tracks with a ladder at each end, the length of the tracks and the number of the same being arranged with reference to the capacity for holding the cars of an entire train. By shifting the cars of a train into such a set of tracks they may be pulled out at the other end in sections and in station or "industry" order. To solve the most complicated problem of sorting, the cars must be run through the grid twice or there may be a double grid, as in Sketch *D*, Fig. 213. The number of tracks should at least equal the square root of the number of cars to be switched, the car capacity of each track in that case being equal to the number of tracks. Thus, to arrange in consecutive order a train of cars numbered from 1 to 60, but promiscuously coupled, would require a grid of at least eight tracks with a capacity of eight cars each. At the first sorting the cars numbered 1 to 8 would be shifted to track No. 1, cars 9 to 16 to track No. 2, and so on; but the cars on each track would not likely be in consecutive order. At the second sorting, or on the second grid, the cars would be placed in regular order back and forth across the eight tracks. The handling of cars in this manner with an engine would require too many movements for practical switching, so that the only feasible scheme for such a system of sorting would be that of gravity operation. The most notable example of "gridiron" sorting tracks, and the one usually referred to in literature on the subject, is that of the Edge Hill yard, near Liverpool, England, where the switching is by gravity.

As a matter of practice it is not essential to any considerable saving in time or to greater convenience to have cars precisely in station or district order. The object in the regular arrangement is to avoid the handling of long strings of cars in setting out cars at sidings along the road and to reduce the number of switching movements on the road to a minimum. If the cars for each "set-out" are together and arranged with some approximation to regular order—that is, if the cars for the first few stations are next the engine, those for points at the middle of the division somewhere about the middle of the train, and so on—it is not usually worth while to rearrange them in the exact order of the stations; as under ordinary circumstances the few cars coupled in between the engine and those to be set out at some of the places will not be bothersome to handle. It is usually more important to look carefully to the order in which the cars must be placed on the side-tracks at the stations. For illustration, the coal bins at a certain side-track may be in advance of a lumber yard. In setting out cars loaded with coal and lumber, at the same time, they should obviously be arranged in proper order for unloading simultaneously; and to save the road crew the time and trouble of shifting the cars to get them in this order the necessary switching should be known to the yardmaster and be done in the yard, while the train is being made up. Cars containing explosives or inflammable substances are usually coupled in at the middle of the train, regardless of destination.

Yard Movements.—The sequence of movements in handling freight cars in yards is about as follows: After the train arrives upon one of the receiving tracks the engine is cut off and goes to the roundhouse and the train is inspected and taken in charge of a switching crew. The caboose is cut off and switched onto a track specially set apart for cabooses, and if the train is to be broken up it is run ahead to the ladder or track entering the distribution set. Here the cars are switched in accordance with classifications heretofore explained, and as the cars accumulate, upon the arrival of following trains, they are made up into newly arranged trains on the distribution tracks. Meantime the bad-order cars have been switched to the repair tracks and the "hold-for-order" cars (usually cars for which the way-bills have not been received) to the storage tracks. The cars may then be rearranged in order and sent to the departure or "starting" tracks, if the yard is so divided; if not, they remain upon the distribution tracks. The road or transfer engine is next attached, the caboose is taken on and the train is sent forward.

Methods of Switching.—In yard switching there are four methods of handling cars: namely, rear-end or tail switching, poling, shifting over a summit or "hump," and gravity switching. The relative extent to which these methods are employed in this country is about in the order named, with tail switching used in the great majority of cases. By this method the locomotive is coupled on at the rear end of the train or string of cars to be switched, and in the course of successive movements forward and back the cars are pushed or "kicked" to place on the distribution and other tracks. The track which forms the extension of a ladder or is connected with the same, and on which the movement of cars takes place in switching, is called a "drilling" track. As in this method of switching, the whole string of unswitched cars must be handled at each movement, it is necessarily slower than some other methods.

By the poling or "staking" method the train is usually run out of the receiving tracks and left standing on a track which joins with the ladder of the distribution tracks. The switch engine working on an adjoining parallel track, pushes, by means of a pole, the cars from the head end of the train, one at a time, or as many at a time as are found together belonging to the same destination or lot, commonly called a "cut." Sometimes a double cut is started in one movement. When such is done the pole is placed against a car in the first cut and the man who works the couplers rides between the last car of the first cut and the foremost car of the rear cut. As soon as the whole string of cars is got up to good speed the coupling between the two cuts is slipped and steam is crowded on to put the first cut the desired interval ahead for the two switching movements. But if the cars are to be weighed, they are passed over the weighing scales one at a time, and on down the ladder of the distribution set until switched to the proper track. As by this method the whole train or string of unswitched cars does not have to be moved each time a car is shifted, it is widely in favor, and is employed in a large number of yards.

Where the ground is level the engine must follow the car some distance and give it a flying start. As hard-running cars are liable to stop on the ladder, it is well, where it can be done, to extend the poling track alongside the ladder. In both tail switching and poling it is an advantage to have an assisting grade entering the distribution tracks, as then the cars do not have to be shoved so hard to send them to place. A descending grade as steep as 0.4 or 0.5 per cent is desirable, as then the cars have only to be given a start from the train, after which they will continue running.

To keep an engine busy at poling cars it is necessary to have quite a large crew of brakemen (seven to sixteen or more, according to the length of the yard) at the ladder to catch the cars and ride them to the proper stopping points. The method cannot be employed economically, therefore, unless there is a large amount of traffic, involving a good many classifications, to handle. In some long yards where there are large crews of car riders working with the poling engine there is a third track running parallel with the poling track, ladder and distribution tracks, on which a pick-up engine and flat car are kept running to and fro to bring the men back to the poling engine after they have ridden their cars to the proper places.' In this way fewer brakemen are required to keep the poling engine busily at work than would otherwise be the case. Among places where this practice of operating a pick-up engine is to be found may be mentioned the Altoona yard of the Pennsylvania R. R. and the Galewood yard (in Chicago) of the Chicago, Milwaukee & St. Paul Ry. There is a good deal of complaint against the work of poling during dark nights, principally on account of the damage caused by hard-running cars which stop short of the intended point and are run into by the next car switched. As the cars must be given a good start before they leave the ladder, and as the same brakeman is not likely to ride a car down the same track twice in succession, a car which stops short, being in the way of the car following, is liable to do a good deal of damage. In defense of poling it may be said, however, that the presence of a poling track is no hindrance to tail switching, which can be resorted to on dark nights.

The switching pole is sometimes attached to the pilot beam of the engine and sometimes it is attached to a special poling car coupled with the engine. The standard poling car of the Pennsylvania R. R. is 20 ft. long, with a strongly braced frame to stand the racking stresses. The pole is 6 ins. in diam., 10 ft. 1 in. long and is pivoted to a heavy casting bolted against the side sill at the middle of the car. The pole can swing outward to any angle with the side of the car and is raised or lowered or steered into the poling socket on the corner of the freight car by a lever balanced over a post and attached to a stay rod running out to a connection near the end of the pole. There is a longitudinal foot board the full length of the car, each side, and across one end, and a railing 3 ft. high around the ends and sides of the car. The car is mounted on two 4-wheel trucks, is ballasted with old car wheels to hold it down to the track, and in the middle of the car there is a cabin 5 ft. 9 ins. long and 3 ft. 9 ins. wide, furnished with a stove. On some roads the pole consists of an iron or steel strut with a claw or angular-shaped casting on the end to fit against the corners of the cars.

In the "hump" method of switching, the track between the receiving and distribution divisions passes over a mound, so as to rise to a summit. The train is pushed up to the summit by a switch engine and the cars, being cut loose one or more at a time, run down the other side by gravity and are switched onto the different distribution tracks. Usually there is a level track running around the hump to connect the two divisions of the yard, so that trains not to be switched need not be sent over the hump. The hump arrangement is in service in yards on the Philadelphia & Erie; Pittsburg, Cincinnati, Chicago & St. Louis; Vandalia; Chicago, Lake Shore & Eastern and other roads, and is becoming quite popular. In the yard of the road last named the cars pass from the hump over weighing scales and are switched upon the distribution tracks at the rate of one car every half minute from the time the first car is put over the summit. Hump switching is supposed to have been first applied at Speldorf, in Germany, in 1876, and is now extensively used in both France and Germany, where it is commonly known as the "ass-back" (dos d'ane) method of switching. The grade is usually steepest on the leaving side of the hump, running from 0.9 to 3.0 per cent in various yards, according to the length of the incline. In one of the yards of the Paris, Lyons & Mediterranean Ry. the grade of the hump is 1 per cent, and to balance the resistance due to the switches, curves, frogs and guard rails the turnouts are on a grade of about ½ per cent leaving the ladder, the remaining portion of the distribution tracks being level. Before the cars are put over the hump there is marked on the front end of each car or cut of cars the number of the switch it is to enter, and on the back end of the last car in each lot is marked the number of the switch to be opened for the next car following, thus giving the switchmen notice in advance. A man at the summit uncouples the cars at the points indicated by the chalk marks. When cars are being shifted at night the switch numbers are called out by the yardmaster. In this country it is usual in switching movements for the brakeman riding the cut to indicate to the switch tender by hand or lamp signals the number of the track onto which the cut is to be switched.

A gravity yard is one wherein the switching throughout is by gravity alone, the grades of the different yard divisions or sets of tracks being such that the cars will start upon releasing the brakes. For such operation grades of 0.8 to 1 per cent are required, the steeper grades being necessary where the winters are cold, as the freezing of the journal packing makes the cars run hard. In this country there are but few if any yards worked entirely by gravity, but in numerous instances grades are used to assist in the yard movements. In some instances all of the movements are started by locomotives, the grade then being sufficient to enable the cars to hold their speed through the switches and on the standing tracks. Grades of 0.5 per cent on drilling, poling and ladder tracks and through the turnouts, and 0.25 to 0.3 per cent on standing tracks are about right for such work. In other instances the grade of the lead or drilling track is made steep enough to give the cars such a start upon releasing the brakes that they will continue running upon the lighter grades of the standing tracks, but in this country it is seldom that the grade of standing tracks is made steep enough to start cars by gravity alone. Thus, in one of the terminal yards of the Pittsburg & Lake Erie R. R. there is a lead on a grade of 2 per cent for a distance of 200 ft. ending at the point of the first switch, followed by a grade of 0.4 per cent through the switches and that by a grade of 0.3 per cent on the standing tracks. As examples of the arrangement first named, the Galewood yard of the Chicago, Milwaukee & St. Paul Ry. is on a grade of 37 ft. to the mile (0.7 per cent) throughout, and the Altoona yard of the Pennsylvania R. R. is laid to a uniform descending grade of 32 ft. per mile (about 0.6 per cent) in the direction of the switching movements. In both of these yards the switching movements are started by a poling engine. The Galewood yard, which is exceedingly compact and well designed for economy of space, is described and illustrated in the Railway Review of Oct. 22, 1892.

In Europe, where gravity switching is more generally employed than in this country, the cars are lighter, as a rule, and the brakes are arranged at the side, so that the brakemen assigned to catch the cars as they enter the distributing tracks do not have to get upon the cars to stop them. In addition to the car brakes, "shoes" or "skates" are quite commonly used to assist in stopping the cars. These devices are inclined castings or wheel chocks grooved to fit over the rail and slide under the weight of the wheel when the same runs upon it. When the car stops, the wheel rolls back off the incline and releases the shoe. To have them convenient for use they are distributed along on the ballast, between the tracks, at intervals of 50 to 60 ft. For catching runaway cars, on which the brakes have failed or which get beyond control through other cause, "chain drags" are in considerable use. This device consists of a chain of large size weighing four or five tons, stretched out in the track or coiled up in a well under the track. At the end of the chain is a large hook which can be raised by a lever in control of a switchman. If a car gets away the hook is thrown

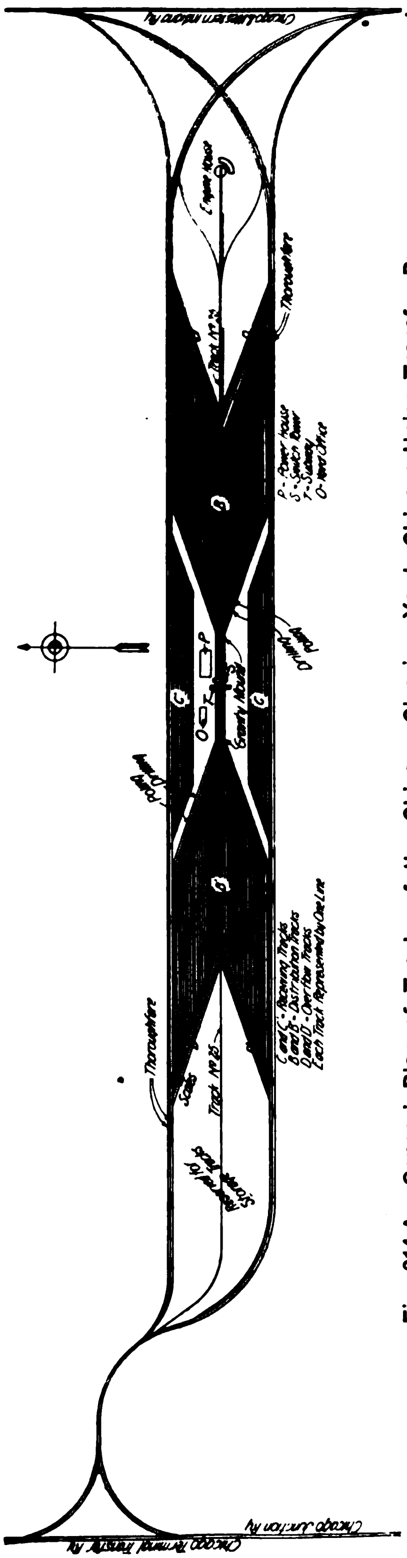

Fig. 214 A.—General Plan of Tracks of the Chicago Clearing Yard, Chicago Union Transfer Ry.

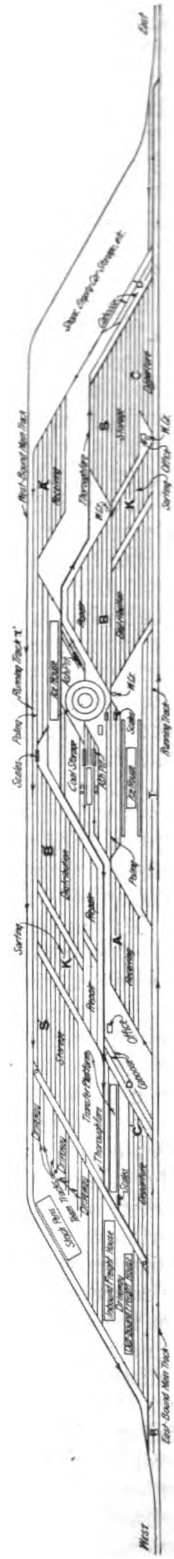

Fig. 214.—Typical Division Freight Yard Layout.

up to catch an axle of the car, and the heavy chain dragging over the ties soon brings the car to a standstill. Sand tracks (Fig. 180) are also in use for the same purpose.

Yard Arrangements.—In treating the subject of yard tracks it is conventional to illustrate the application of the principles of yard design by typical plans. As the requirements of each yard depend largely upon the traffic situation and conditions peculiar to the locality, it is seldom if ever that such plans are closely followed in practice, but they serve as a basis for the consideration of yard movements, and in this way may be of some value. Where an abundance of space is available there is no difficulty in arranging yard tracks to suit almost any of the requirements for switching cars, and the study of yard design is much simplified. In working out typical plans economy of space is therefore one of the prime considerations. A fascinating scheme is to design a layout of east-bound and west-bound yards lying opposite each other between separated double tracks, with a roundhouse between the yards. While such a location for a roundhouse is not the one usually chosen in practice it is nevertheless recommended by practical students of yard design, and a consideration of the advantages in such a layout is interesting. In putting such a layout on paper it is customary to have the outlines of the same symmetrical with respect to an axis formed by extending the main tracks straight through the yards. Such a condition is not, however, an essential of space economy or to any special convenience, and land is no more likely to be available in that shape than it is if selected to lie entirely upon one side of the general alignment of the main track, in which case only one of the main tracks need be deviated from the general course.

Figure 214 shows a layout of division freight yards for traffic in two directions, each yard containing four main divisions, namely, receiving, distribution, departure and storage tracks. The two yards, east-bound and west-bound, are duplicates as to facilities, but for sake of showing a variety of arrangements they are not laid out in exactly the same manner. The receiving tracks for east-bound movements are located at *A*, the distribution tracks at *B*, leading from a double or V-shaped ladder, with sorting tracks for the local trains at *K*. The tracks *S* may be used for storing cars detained for shipping orders and in emergency for the overflow of the distribution tracks. The departure tracks are indicated by *C*. For the west-bound movement the corresponding divisions are indicated by *A'*, *B'*, *K'*, *S'* and *C'*. The figure is not drawn to scale and the frog angles have been purposely exaggerated. No significance attaches to the number of the tracks in each division of the yard, as such could in any case be arranged to suit requirements. In constructing a yard for a growing business, room for additional tracks should be left between *A* and *B'* and between *A'* and *S*, or by spreading the main tracks farther apart room could be had for extensions to all the ladders.

In locating and laying out a yard the future extension of the system without materially changing or abandoning the original tracks should be in view, and the matters of grades and drainage are, of course, important. To locate a double yard such as is here shown, on a descending grade throughout its whole length, would favor the yard for traffic in one direction and operate against that for the other direction. In a situation of this kind the arrangement would usually be changed: the receiving tracks for both yards—that is, for traffic in both directions—would be located at the upper end, and the switching in both yards would all be done in the direction of the falling grade. In the Altoona yards of the Pennsylvania R. R., where the grade descends toward the east (32 ft. per mile) the whole distance, the switching movements in the west-bound yard proceed from west to east the same as in the east-bound yard. In the west-bound yard the receiving tracks lie west of the distribution tracks, so that trains arriving from the east must pull on by the distribution tracks in order to enter the receiving tracks. The best location for a double yard is one which divides the two yards across a summit, but it is seldom that ground with conditions so favorable can be found where yards are needed. In order to obtain the assistance of grades it is sometimes necessary to run the yard tracks out at an angle with the direction of the main line instead of parallel with it.

The poling track connecting divisions *A* and *B* is arranged between two standing tracks, the idea being that while the poling engine is at work with cars on one of these tracks a switch engine in the rear may run a train to position on the other track, thus keeping the poling engine steadily engaged at the work of poling. In order to give room for the poling engine to begin work on the train the poling track should be a quarter to a third longer than the longest trains to be put through the yard. For the east-bound movement there are weighing scales on each standing track, near the advance end, the advantage of the arrangement being that there is a set of scales in reserve in case either set gets out of order. Between divisions *A'* and *B'* the scales are located in the throat, just in advance of the distribution tracks, where they catch every car passing through the yard, and hence it is immaterial which track is used for poling. A piece of "dead" track is usually gantleted with the track passing over the scales, so that cars which do not have to be weighed may be switched over the same and pass without bearing upon the scales. It will be noticed that the ladders branch from a principal side-track *T*, which serves as a "running" or "thoroughfare" track along one side of the yards. At the west end it connects with the main track by a crossover and extends past the same, forming a "run-by" *R*. This arrangement obviates any necessity for fouling main track in switching movements, as the run-by permits trains to back past the crossover without using it. The run-by is here shown merely for the purpose of illustration, and not because it is needed in this particular yard.

A question of importance is the location of caboose tracks Cabooses should be left where they will not be disturbed by the shifting, as oftentimes they are used by the crews for sleeping quarters. A good arrangement is to have two tracks: one for the cabooses of regular trains and another for those of the extras. Those for regular trains can then be taken out in consecutive order, so that no shifting is required; while those for irregular trains will usually be taken out in the same way, the common rule being "first in, first out." A location for these tracks has been selected at *D*, being near the point where the caboose enters the yard and near to the set of tracks from which the train will depart that will take the caboose on its return trip. In any case caboose tracks should be double ended, and when located as at *D'*, it is an advantage to have the tracks elevated sufficiently to form a short incline at the outlet end. With such an arrangement the service of a switching engine to deliver the cabooses to outgoing trains is not needed, as each train when leaving the departure tracks *C* may stop with the rear car just past the switch leading out of the caboose track, and the caboose may be pushed out by hand and coupled on.

It is desirable that the engine house or roundhouse should be so located that ingress and egress between it and main track cannot be blocked by the movement of trains in the yard. Where it is between two yards, as in Fig.

214, it is necessary to cross drilling tracks, and some interference in this respect cannot therefore be avoided. As, however, the liability to obstruction in every case is by moving trains, serious delays are not to be expected. In connection with the roundhouse there must be facilities for supplying coal, water and sand, ash pits for cleaning the fire boxes and means for turning the engines. It saves time to take water and sand while the engine is coaling, and usually the water cranes and sand bins can be located to permit this to be done. The usual arrangement in connection with an ash pit is a depressed track alongside for spotting cars to haul away the cinders. (This subject is treated fully in § 178, Chap. XI). Coaling, watering and ash-cleaning facilities are usually located on the track leading into the engine house, but sometimes on both the outgoing and incoming tracks on opposite sides of the engine house; and sometimes the outgoing and incoming tracks are on the same side of the engine house and separated to permit the location of coaling pockets between them. To prevent the obstruction of the passage to the ash pit or engine house by engines that are taking on coal, water etc., there should be a run-around track, as shown in Fig. 214. In large yards it is well to have water cranes at convenient points some distance from the roundhouse, as they save time which would otherwise be consumed by the switching engines in running back and forth to take water. In yards where trains pass through unbroken, without detaching the locomotive, facilities should be provided for taking coal and water and dumping cinders on the thoroughfare track. A line of water pipe, with hydrants or hose attachments at intervals for the use of inspectors and repair men, is a great convenience.

The repair tracks for bad-order cars should be convenient to the drilling or poling track, so that the separation of these cars from the rest may take place while the train is being broken up and shifted into the distribution tracks, and without extra movements. It is desirable that repair tracks should be short—not to exceed 15 or 20 car lengths—and in order to secure the necessary room to work upon the cars they should be spaced farther apart than the usual distance between yard tracks—say 18 or 20 ft. c. to c. A convenient arrangement is to lay these tracks in pairs about 16 ft. c. to c., with a clear space of 25 or 30 ft. between the pairs for piling material in case cars have to be unloaded. If the room is scarce part of the tracks may be spaced 16 ft. centers and used for light repairs, while for cars needing heavy repairs other tracks may be spaced farther apart. It saves a good deal of switching and delay to put the cars needing only light repairs on tracks separate from those occupied by cars requiring heavy repairs. In estimating the capacity of repair tracks allowance should be made for an open space of 10 or 12 ft. at each end of each car, for handling material and for convenience of the repair men in other ways. This arrangement requires 45 or 50 ft. of track for each car. The space set apart for material supplies should be at one end of the repair tracks, so that it can be easily trucked into and along the openings between the tracks. In Fig. 214 the repair tracks in both east-bound and west-bound yards lead from the distribution ladder.

The ladder for the storage tracks S leads from a continuation of the poling or drilling track through the distribution division B, and therefore admits of straight-ahead switching into the storage division. The order of operation would usually be to take the string of cars accumulated on the said "continuation" track in the course of breaking up one or more trains, and then tail-switch them into the storage division. The ladder for the storage tracks S' also leads from a continuation of the poling track past the distribution division B'. No storage track should be so long that a switching engine cannot handle all the cars it is capable of holding.

The location of ice houses and tracks for icing refrigerator cars is important, and in order that the work of icing may proceed without delay the arrangement should be such that the cars will be switched directly to the icing tracks while the train is being broken up. In Fig. 214 the icing tracks are located between the receiving and distribution divisions, lying next the tracks on which the cars stand for poling. With this arrangement the cars to be iced would be set out by tail switching before the poling of the cars in the remainder of the train would begin. The icing of solid trains of refrigerator cars not to be rearranged in the yard could take place on the track south of the ice house without sending the train through the receiving division. Another arrangement would be to have the ice house stand alongside one of the outer tracks of the distribution division, but as yards should be laid out with a view to enlargement, if necessary, ice houses and other permanent structures should not be located where they will obstruct the extension of the system.

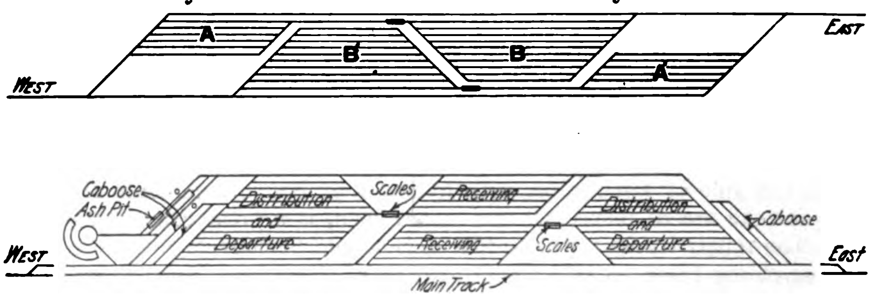

Fig. 215.—Division Freight Yard Layouts.

The lower engraving of Fig. 215 shows an arrangement for economizing space by locating the receiving tracks of a double yard side by side. The connections as drawn are for a single track, but the layout is equally feasible between the separated lines of a double track. The outer track of the receiving set may be used as the drilling or poling track, or, as is frequently the case in practice, poling may be done on any of the parallel tracks of the receiving division. The receiving and distribution tracks of each yard might, however, be separated far enough for a poling track between, as in Fig. 214, which would leave considerable open space to the east of the east-bound rceiving tracks and to the west of the west-bound receiving tracks that might be utilized for storage tracks or other purposes. By the arrangement shown the bad-order and "hold-for-order" cars would be held on certain tracks of the distribution set, as is commonly done in practice. In case yards arranged in this manner were designed to lie between the separated tracks of a double-track road, the outlet ladder of the west-bound "distribution and departure" division would run diagonally the other way, or from southeast to northwest. The upper engraving in Fig. 215 shows another arrangement for making most use of land at disposal, A and B being respectively the receiving and distribution divisions for the east-bound movement and A' and B' constituting the west-bound yard. With this formation as a basis a double yard of larger functions might be developed.

Yard Accessories.—In addition to the facilities already named there are numerous arrangements which have an important bearing upon yard operation and the handling of freight. For the safety of the main-line traffic, where full speed is maintained past the yard, connection should be made with main track only at each end of the yard, and each of these connections should be operated under the protection of interlocked signals. The usual practice where interlocking is not employed is to put up "Yard Limits" sign boards far enough out to protect trains using the switches at the ends of the yard, and require that between these limits all trains shall proceed with caution. For the working of a large number of yard switches some form of machine operation from a central tower is preferable to hand-throwing stands on the ground. In yards the interlocking of switches is not usually necessary.

The switches on the distribution ladder in the Altoona yard of the Pennsylvania R. R. are thrown by compressed air cylinders controlled by electro-magnets operated from push buttons in a tower. The switch movement is of the direct-acting type, the switch points being connected to the piston of the air cylinder without the locking movement. The arrangement of the valves admitting air to the cylinder is the same as on the regular Westinghouse electro-pneumatic switch movement (described in the following section and illustrated by Fig. 225), with the exception that the lock cylinder and magnet are dispensed with. The push buttons are arranged in two rows along the side of a box, two buttons for each switch, the one in the top row serving to close the switch and the one in the bottom row to open it. All of the 24 push buttons or keys can be conveniently reached by a person standing or sitting in one position. The ladder and tracks leading from the same are divided by insulated joints into blocks embracing each turnout, and one of the point rails of each switch is insulated from the main rail. On the operating board, above the set of keys for throwing each switch, is an indicator, in circuit with the insulated rails of the switch and turnout. Normally, that is when the ladder track is clear, the indicator shows white, but if a car comes upon the block on the ladder, or within fouling distance of the frog, on the turnout, or if the switch has not completed its throw the aperture of the indicator will show a red target. The operator is therefore able to follow the course of each car by the successive appearance and disappearance of the indicators, and the switching movements can take place as fast as the cars can be shunted at safe intervals. As a matter of record, 133 cars have been switched in an hour, and an average rate is 95 cars switched per hour. The operator is provided with a schedule of movements required to distribute the train, and the only observance necessary on the part of the switching crew is to send the cars along at the proper intervals. The air pressure is 60 lbs. per square inch and the furthest switch operated is 1500 ft. from the tower. The machine and circuits are more fully described in the Railway and Engineering Review of Aug. 28, 1897.

Team tracks, upon which cars are spotted to be loaded from or unloaded into wagons, may usually be arranged to best advantage as a series of short parallel spurs branching in pairs from a ladder track, as shown at the left in Fig. 214. These tracks may hold 10 or 12 cars each and should stand at as large an angle to the main lead as may be practicable —say 45 to 60 deg. The two tracks of each pair may be spaced as close as 11 or 12 ft. c. to c., but the driveways between the pairs should be 40 ft. wide, so as to afford room for teams to back wagons against the cars and still permit teams to drive between the team in this position and a team on the opposite side of the roadway. To facilitate the prompt removal of freight during all seasons of the year the driveways should be well paved or planked. A planked driveway across the team tracks, alongside the main lead, affords the team ingress to the driveways, so that all the outbound teams may drive straight ahead, without turning around. By this arrangement of tracks empty cars may be removed or loaded cars placed without disturbing any considerable number of persons engaged with teams at loading or unloading other cars.

Freight houses, for handling less than car-load merchandise freight, are usually long buildings with parallel tracks closely spaced, on one side, and a driveway for teams on the opposite side. By placing the cars on the several tracks so that the doors stand opposite one another the loading or unloading of the freight may proceed by trucking from or to the freight house through the car doors. There is, however, by this plan of working some interference between empty and loaded trucks in passing one another, and in switching considerable time is consumed in spotting the cars with their doors directly opposite, and again in coupling up when the cars are hauled away. It adds to the convenience of trucking and switching to have a platform 8 or 10 ft. wide between each pair of tracks, as then the trucking need not be done in direct lines and the cars need not be spotted to stand with the doors exactly opposite. Where a large volume of business is handled it is customary to have separate houses for inbound and outbound freight. To limit the trucking distance from the point of delivery by team, outbound houses should not be wider than 24 to 30 ft. Inbound houses may be 50 to 80 ft. in width, as, owing to the necessity of unloading freight into the house and holding it for delivery, more room is required than in outbound houses. The width required for a stated capacity depends, of course, upon the length of the building. As cars at inbound houses can be unloaded rapidly there is usually no advantage in having more than two tracks at the house, in which case it is only necessary to unload through one car. At outbound houses the situation is different, for cars must ordinarily remain at the house a considerable time, perhaps all day, to receive a full load, so that, in large cities, the cars which must be set to load for shipment to many points require a number of tracks, making it necessary to load through four or five, and sometimes through six or seven, cars.

An outbound freight house should be so located with reference to the inbound house that the cars made empty at the latter can be moved quickly and without interference to the outbound house for loading. In some cases it might be feasible to build the houses adjoining, so that cars made empty at the inbound house could be loaded from the outbound house without being switched. Another advantage in having the outbound and inbound houses close together is that wagons may deliver a load to the one and take a return load from the other without loss of time in light mileage. An arrangement that is sometimes provided where inbound, outbound and transfer houses are consolidated at one point is to have parallel stub tracks, with the inbound house on one side, the outbound house on the opposite side and the office between them, at the stub ends of the tracks. Car-loads to be transferred are spotted on the various intermediate tracks, which are separated by platforms for trucking. An advantage in a layout of this kind is that the cars unloaded at the inbound house may be quickly turned over to the outbound house, or, perhaps they may be loaded for outbound shipments without being switched. Such a layout of tracks suggests another type of freight house, which abuts upon a street with tracks running up to its rear side at right angles. Between each pair of tracks there is a covered platform about 12 ft. wide on which freight may be trucked to all the cars without passing through any of them.

Freight houses which stand parallel to a street should set back from it at least 20 ft., so that when wagons are backed up against the house the teams will not obstruct the street. The roadway leading from an inbound house and the approach to an outbound house should not be so steep as to burden the teams of the locality. In this connection it is well to take into consideration that in a city where the streets are level or nearly so, teams are generally loaded heavier than in hilly cities and towns. To obviate the necessity of spotting cars at freight house doors it is usual to have a platform 8 or 10 ft. wide on the track side of the house. On the Michigan Central and the Louisville & Nashville roads freight houses are built on what is known as the "continuous door" arrangement. The whole side of the house is taken up with a series of doors which slide past one another. A door can be opened at any point, and there are no posts in the side of the house. No matter where a car is placed, a house door can be opened opposite the door of the car. At such a house it is not necessary to have a platform between the first track and the house to avoid spotting cars.

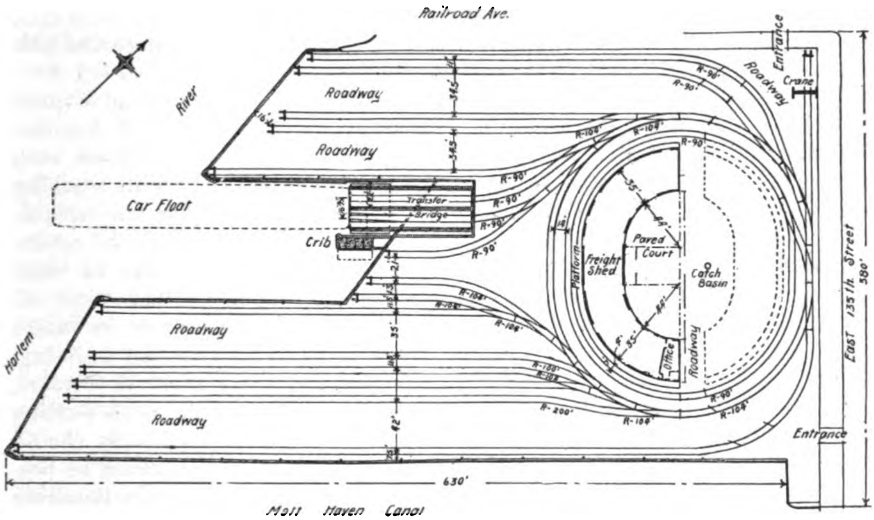

Fig. 216.—Freight Terminal of Harlem Transfer Co., New York City.

At freight houses it is desirable to have a crane for transferring heavy loads from cars to wagons or from wagons to cars. A revolving crane is an ordinary arrangement, but an overhead crane spanning two tracks, a platform and a driveway is a more flexible arrangement, as it may be used to transfer loads from car to car, to platform or to wagon. In the vicinity of busy freight houses there should be a small auxiliary yard or set of tracks holding at least as many cars as the freight house tracks accommodate. With such an arrangement the cars at the house can be pulled out and new loads or empties set in with a minimum delay to the work of loading or unloading at the house. At an inbound house, for example, a cut of loaded cars can be shoved in as soon as a cut of empties is pulled back to one of the auxiliary yard tracks. The necessity for such auxiliary tracks is obviously greater at inbound than at outbound houses.

An interesting freight terminal of the loop type, designed by Chief Engineer Walter G. Berg, of the Lehigh Valley R. R., and built for the Harlem Transfer Co., on a city block 330 ft. wide, at 135th St. and Railroad Ave., New York, is shown as Fig. 216. The terminal is planned for the business of receiving and delivering freight, either in car-loads or in less quantities. The cars are transferred on the usual car transfer boat operating in connection with transfer bridges, to or from any of the railroad trunk line terminals on New York harbor. The striking feature of the design is the complete loop, from which the side-tracks and connecting lines diverge. A short tangent inserted in the loop track permits a cross-over to be laid to an interior loop track distant 14 ft. c. to c., which serves as a standing track for an oval-shaped freight house 240 ft. long, with an interior courtyard for teams. All the driveways have block paving. The switches are of the split pattern, 10 ft. long, with ground-throw stands. The minimum curve radius is 90 ft. The gage on these curves is widened ½ in., and the outer rail is elevated 2 ins. The switching engine is a 4-wheel inclosed tank dummy locomotive, 27 ft. long over all, 6 ft. 6 in. wheel base, 44 in. wheels, 17 in. x 24 in. cylinders, and weighing about 90,000 lbs. There is no difficulty in passing cars around these curves, but special long links are provided for coupling, as with couplers of various kinds some difficulty is had with links of ordinary length. With locomotives of short wheel base and special coupling bars freight cars of ordinary construction may be handled on curves laid to a 50-ft. radius, but the wheels of long cars that are low hung will cramp against the sills on curves of 100 ft. radius and perhaps longer.

In reference to tracks at water-front terminals the following is quoted from a committee report to the Roadmasters' Association of America in 1893: "Where piers and warehouses are built with a dock on each side, from one to three tracks down the center of the pier, with trucking space on the outside, between the tracks and the edge of pier, are needed. Where warehouses are parallel with the wharf front, space can be economized by having tracks enter the building at the side and run at right angles therewith, or nearly so, and about half way across the width of the building. This method of layout will give more car room, or rather more loading room, than where the track is parallel with the building. This is especially the case where tracks are in pairs, say at 12 ft. centers, with trucking space of 15 to 20 ft. between one pair and the next, putting in as many sets of tracks as are needed. The ends of the tracks should be within a reasonable distance of the wharf front, to save as much as possible in the work of trucking, a very considerable item of cost in handling freight. Tracks abutting on wharves or ending in warehouses should be level, or there would be danger of running cars into the water, or against the building."

The transfer of freight by hand for the consolidation of less than car-load freight into car-load lots and for the release of cars at the end of a company's line is usually made across or through a long platform, shed, or freight house 16 to 20 or 25 ft. wide, between parallel tracks. For the transfer of cotton and other commodities in bales a less distance between the cars is more convenient, and platforms not wider than 10 or 12 ft. are desirable. Transfer platforms should be at the proper hight for trucking in and out of car doors, and to protect goods from wet weather they are frequently covered. There should be a bridge crane spanning two closely spaced tracks, with a trolley hoist for lifting heavy masses, like large stones, machinery etc., to be transferred from flat car to flat car. A common arrangement for the transfer of grain is high and low tracks, side by side, at a difference of elevation of 5 to 6 ft. and spaced about 10 ft. 6 ins. c. to c. The cars are spotted on these tracks with the doors opposite and the grain is shoveled into chutes running from the higher to the lower cars. For the transfer of coal, high and low tracks side by side may be used, but coal-handling machinery is the modern means, where large quantites have to be handled. The coal is dumped from or scraped out of the cars into a pocket or pit under the track, whence it is taken by a conveyor and elevated for shooting into other cars (gondola or box) standing on a parallel track. An account of a large plant of this kind operated by the Erie R. R. at Hammond, Ind., is given in the Railway and Engineering Review of Oct. 12, 1901.

The lighting of yard tracks for night work is recognized as a desirable facility. The best means for this purpose seems to be a system of electric arc lamps distributed about the yards on high poles, but the arrangement is not always entirely satisfactory, owing to the shadows cast, which bother the trainmen to some extent. By using a sufficient number of lights, however, the shadows are not so dark as otherwise, and are not so troublesome. Arc lights should not be located where they will obscure main-line signal lights. To expedite yard work it is also necessary to have telephone connection between the various offices and stations about the yard. The yardmaster is usually located near the roundhouse or middle of the yard, and in large yards there are assistant yardmasters near the ends of the yard. Telephone connection between the signal tower at the entrance to the yard, the roundhouse, weighing scales and the various yard offices is especially convenient. Some yards are supplied with air, so that trains can be charged and tested before the engine is coupled on.

A common and convenient arrangement for a passenger-car cleaning yard is a series of parallel tracks 20 ft. apart centers, or in pairs about 36 ft. centers with the tracks of each pair 16 ft. apart centers. In some cases the yard is connected at both ends, but usually it is composed of stub-end tracks with a car-cleaners' supply building at the dead end and at right angles to the tracks; if the yard is connected at both ends this building is located at one side. With the former arrangement space is reserved at the ends of the tracks for trucking material to the openings between them. These openings are paved or planked, and between alternate tracks water, steam and air pipes are laid, with connections about 50 ft. apart. Plants for supplying gas or electricity are installed in the vicinity. The yard should be drained and lighted for night work. The yard is usually located near the terminal station, and the tracks should be long enough to handle trains without cutting them. Where sufficient room is available a Y-track is usually provided for turning trains.

Definitions.—Tracks are said to be arranged in parallel when they have a common cross connection at one or both ends (Engravings *A* and *B*, Fig. 213). It is not essential that they should be absolutely parallel in direction. Tracks are said to be connected in series when the general route through them is continuously forward (Engraving *D*, Fig. 213, shows two sets of tracks in series, and sets *A* and *B* in Fig. 215 are in series).

A railroad yard, as understood in practice, is a system of tracks for switching cars in making up, distributing or rearranging trains; or for the exchange, separation, accommodation or storage of cars. The unit of a yard layout is a set of tracks arranged in parallel, and a yard may consist of one or more of such units connected in series, or otherwise disposed. When the facilities are duplicated as to traffic in two directions, or as to separate channels of traffic in the same direction, the systems composing the same are then recognized as distinct yards, and the combination is commonly known as a "double yard," or as east-bound and west-bound yards, etc. (Fig. 214).

In order to constitute a yard the layout of tracks must form a system. The test as to whether a layout constitutes a yard or only a portion of one, depends upon the completeness with which it serves the purpose of the traffic handled through it. Thus, a single set of tracks branching from a ladder, as in *B*, Fig. 213, if used for all the purposes of receiving, distributing and forwarding trains or parts of trains, would be a complete yard; but if it was used in connection with a set of receiving tracks, it would then be only part of a combination fulfilling a terminal purpose, and would not be a complete yard. Different sets of tracks, as receiving, distribution, departure, storage or other tracks, when used in one combination, are therefore not separate or distinct yards. An isolated system of tracks, as when a set is used for storage, is a yard.

The term yard is used with the same latitude of expression that is conveyed when speaking of a house. A building used as a residence, even if composed of but one room that answers the various purposes of cooking, eating and sleeping combined, is a house; and any one of the several combinations to be had by adding a bed room, dining room, parlor, bath room, etc., does not constitute anything more than a house.

A terminal includes all the facilities provided by a railway at the end of its line, or at division or junction points, for the conduct of its business, such as yards, engine houses, coaling stations, elevators, docks, warehouses, freight and passenger stations, etc.

Some Yard Layouts in Service.—To further illustrate the application of some of the aforementioned principles of yard design reference may be made to two or three existing yards. At Harahan, La., nine miles from New Orleans, the Illinois Central R. R. has an extensive layout of yard tracks with assisting grades, that is commonly known as a gravity yard. As may be seen in Fig. 217, the tracks entering the yard branch from the main line by a "Y" having double-track legs, converging into a double track running directly north and south, and nearly at right angles to the main line, the particular object in following this direction being to secure a large area which was free from public road crossings. The site selected covers a tract about one-half mile wide and three miles long, comparatively free from obstructions of the kind referred to. The portion of the yard as first constructed is shown in full lines, the dotted lines indicating extensions. The double-track branch line leading from main track passes to a receiving division containing 10 parallel tracks each 2,000 ft. long, and having a capacity of 500 cars, into which all south-bound trains are taken. Each train is then taken to the gravity lead, which is 2200 ft. long, on a ½ per cent grade, with a poling track alongside. Here the cuts of cars are started by a poling engine and pass to either of two sets of distributing tracks arranged in the shape of a fish tail along diverging ladders, each set having 17 tracks and a capacity for 832 cars. The tracks in one of these sets take even numbers and in the other set odd numbers. In switching, cars laden with coal and export freight which is to be held

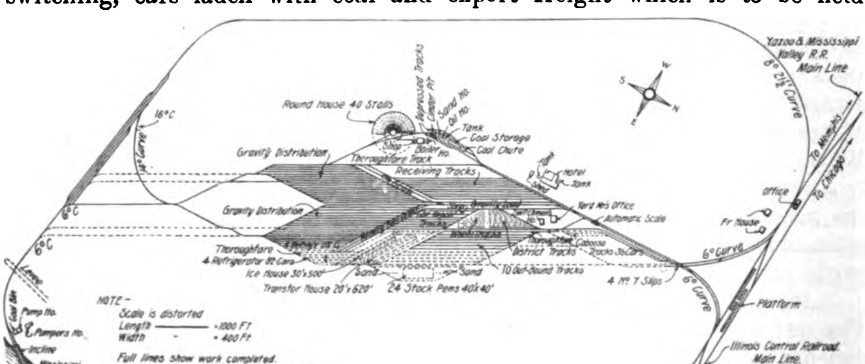

Fig. 217.—Gravity Yard, Illinois Central R. R., Near New Orleans.

for orders are sent to the odd-numbered tracks, while the even-numbered tracks take care of cars to be delivered to the various docks, cotton sheds, connections with other roads, the various yards about New Orleans, etc. Near the entrance to the ladders, on the double lead track, there are cross-overs for diverting cars from one track to the other. Cars loaded with commodities to be weighed are shunted onto the scale track, which runs between the south ladder of the receiving division and the north ladder of the west set of distribution tracks. On the rear end of each car or cut of cars sent down the gravity lead is chalked the number of the track for which the following car is destined, thus giving the switch tenders time to throw the switches, as heretofore explained. At the south end the distribution tracks have an outlet into a long side-track extending to the Southern Pacific car ferry on the Mississippi river, on the one hand, and into a belt line which returns by a 14-deg. curve, at the south, and an 8-deg. 21½-min. curve at the north, to the main line.

It will be noticed that space was left for additional tracks in the receiving division and that a 40-stall roundhouse, with cinder pit, coaling station and other necessary auxiliary facilities are located near by the exterior thoroughfare track. All the necessary accessories in the way of caboose tracks, wheel tracks, and car repair tracks were provided for, as shown. A gravity track for bad order cars branches from the main lead and runs parallel with the north ladder of the east distribution division. A plant for icing cars and a large transfer house were planned to be located north of the east gravity distribution tracks, and still north of these buildings there are stock pens and a set of outbound or north-bound departure tracks 2000 ft. in length, with a capacity of 500 cars. North-bound trains pass into the receiving tracks and through the distribution tracks in the same way as the south-bound traffic and are then assembled into trains on the departure tracks for the road engines. At the outlet of the departure tracks there is a set of caboose tracks, from which the caboose is picked up just before the train leaves the yard. West of the departure tracks, there are ten stub tracks constituting a sorting set, for arranging cars in "district" or station order. All the tracks arranged in sets are laid 13 ft. c. to c. The total length of tracks as planned is 48 miles and the capacity 3600 cars. The two-story office building is located at the head of the gravity lead, and opposite the same there is a hotel built and furnished by the railroad company.

A interesting example of a "hump" gravity yard on an extensive scale is the Chicago Clearing Yard, operated by the Chicago Union Transfer Ry. The general purpose of the yard is to accomplish for railroad freight traffic entering and leaving Chicago a service corresponding to that which a clearing house does for the banking business of a large city. The interchange of freight cars between the 20 and more roads is carried on over belt lines, and it is evident that with these cars collected at one point they can be distributed to the various roads, already made up into trains, with fewer switching movements than would be necessary if transferred direct by the belt-line crews making the rounds of the numerous terminal yards. In the clearing yard the switching is done once for all, economizing in switching movements and expediting the delivery of the cars. The cars set out at the terminal yard of each road for delivery to other roads are taken to this clearing yard, in any order in which they may happen to be made up, and there are distributed to the various roads and arranged in such order as the receiving road may desire, as, for instance, loads and empties, division, or other order.

A general plan of the yard reduced to convenient size, but not drawn to scale, is shown as Fig. 214 A. The yard extends east and west, connecting with the Chicago & Western Indiana R. R. on the east and with the Chicago Terminal Transfer R. R. and the Chicago Junction Ry. on the west, occupying a tract 13,000 ft. long and about 670 ft. wide. It contains 105 miles of track, with sufficient vacant space conveniently located for 25 miles of additional overflow and storage tracks, and, when built, was the most extensive system of yard tracks ever constructed at one location. The yard is far removed from the built-up section of the city and is not crossed by any public thoroughfare. All the connecting roads above named are belt and switching lines of Chicago. Although the primary object in the establishment of the yard was to provide facilities for receiving and forwarding cars with the utmost dispatch, the possiblities in the way of future extensions for the accommodation of such auxiliaries as naturally attach to railway terminals has not been overlooked. In the vicinity of the yard the company owns 3700 acres of land, intended to meet the space requirements of manufacturing establishments, grain elevators, storage warehouses for general merchandise, coal etc.; or for the duplication of the present clearing yard as a unit. The connection of the yard with the two belt lines at the west end has been laid out with a view to joining with a similar parallel yard lying immediately north. It is not improbable that this clearing yard may be found a desirable location for the temporary storage of cars of grain and other produce awaiting reshipment at the call of the markets, and when the demand for such storage facilities materializes, the necessary tracks can readily be added to the yard, as now laid out.

Extending along both north and south boundaries of the yard for the whole distance east and west there are three thoroughfare tracks with double-track "Y" connections at each end to the belt lines. At the center of the yard, from north to south, and near the east end, is located the engine house, and from this engine house, running straight west on the middle line of the yard, is a through track known as Track No. 25, which is referred to in connection with the switching movements. At the west end this track and the three outer tracks on each side of the yard merge into a double track which makes a "Y" connection with the Chicago Junction Ry. and the Chicago Terminal Transfer R. R. The general arrangement of the layout consists in two sets of distribution tracks (*B* and *B′*) each 2400 ft. long, extending the full width of the yard and leading from double ladders on either side of the artificial gravity mound, with receiving tracks (*C* and *C′*) 1600 to 3200 ft. long symmetrically arranged north and south of the gravity mound. East and west of the distribution tracks there are overflow tracks (*D* and *D′*) running parallel with the distribution ladders, intended for use in case the distribution tracks become filled. To the west of the west distribution tracks (*B′*) a large amount of space has been reserved for storage tracks, repair tracks, icing houses and like facilities. The number of parallel tracks in a north and south direction is 49, occupying a space 660 ft. wide. The spacing of the distribution and receiving tracks is 13.3 ft. center to center, and of the thoroughfare tracks on the outside of the yard, 14 ft. and 15 ft. c to c, respectively, progressing outward. Parallel with the double ladder at the mound end of each distribution set there are two tracks, the one next the ladder being a poling track and the outside one a drilling track. The double ladders of each distribution set converge at a three-throw switch into track No. 25, so that over the summit of the gravity mound there are five parallel tracks, with leader tracks and crossovers as shown. The gravity mound or "hump" is 5000 ft. long. For a short distance each side of the summit there is a grade of $1\frac{1}{2}$ per cent, arranged to start the cars quickly from the summit, and then a long grade of 0.9 of 1 per cent for a distance of 1900 ft. running into a grade of $\frac{1}{2}$ of 1 per cent for a further distance of 350 ft. The foot of the gravity lead is something like 400 ft. beyond the ends of the distribution ladders. The summit of the gravity mound is 22 ft. higher than the elevation of the level tracks of the yard. As protection against wind and wash from rains, the side slopes of this mound are covered with a layer of cinders, in some places, and in other places with riprap stone.

The arrangement of the yard permits of a flexibility of operation that is remarkable. Trains approaching from one of the "Y" connections at either end of the yard are run into one of the receiving tracks, where the power is detached, taking a return load from one of the distribution tracks in B or B', by way of one of the outlet ladders of the distribution tracks. A switching engine of the clearing yard then takes the train, backs up, and pushes it over one of the drilling tracks alongside the distribution ladder. In continuation of each of these drilling tracks there is a leader extending across all five of the parallel tracks over the gravity mound. This leader connects with each track by means of a slip switch. As the train is pushed up the summit the couplers are disconnected between each cut of cars, and as the cars go over the summit they separate from the train and run into and down track No. 25 to the three-throw switch at the apex of the distribution ladders, where they are switched to either side of the double ladder, and finally into the desired track of the distribution set. By means of the leader on either side of the summit, switching can be carried on simultaneously with two engines, in both directions; that is, into both the east and west distribution tracks. Each train of cars to be split up is pushed over the mound and distributed to such roads and sub-classifications as would naturally be taken out of the set of distribution tracks into which they are first dropped. The cars which would naturally be taken out of the opposite set of distribution tracks (east or west of the summit) are dropped to one or more tracks specially designated for that purpose, until a string accumulates, when they are pushed back over the hill and classified into the other set of distribution tracks. It is thus seen that by two switching movements, at most, trains of cars for any number of roads can be arranged in desired order. The capacity of the yard is 5000 to 8000 cars switched and forwarded daily.

The purpose of the poling track between each distribution ladder and the parallel drilling track, is to permit the assistance of an engine in case the cars should stop short, owing to heavy winds opposing the movement of the car under gravity, extreme cold weather or snow. It is known that such causes, particularly hard, opposing winds, are some of the difficulties attending the operation of gravity yards. As this yard is arranged, however, adverse winds can never operate to the disadvantage of switching in more than one direction at a time; for, when blowing against the switching of cars to the westward, for instance, the direction of the wind will then be with the movement of the cars that are being switched toward the east, thereby assisting the action of gravity. The arrangement for returning the brakemen who ride the cars down the gravity tracks consists of a light engine and car running forth and back on either the center track or on one or both of the poling tracks. On the tracks near the middle the first cars which are dropped down from the summit are stopped a short distance beyond the ladder connection, and then dropped further down, from time to time, as cars accumulate on that track. By this arrangement a few men can easily attend to dropping cars down, so as to leave room at the head end, and thus fewer men are required to brake the cars down from the summit. On the tracks at the sides of the distribution groups, whereon there is a considerable stretch of level, the men catch the cars at the lower end.

In this yard there are approximately 450 switches, and of these the 120 switches along the ladders of the distribution tracks are operated by Westinghouse electro-pneumatic cylinders. The design of these cylinders is similar to that of the standard machines of that type for interlocking work (Fig. 225), with the exception that the central or lock magnet is omitted. The control of the switches is by means of electric push-button machines in an operating cabin arranged upon a bridge standing over the summit of the gravity mound. The cabin is 30 ft. above the track and the span of the bridge supporting it is 68 ft. From this cabin there is an unobstructed view of the yard from end to end, or for a distance of two miles in both directions. For the 120 switches there are 10 push-botton machines, each machine controlling the movement of 12 switches. A similar installation is in service in a yard of the Pennsylvania R. R., at Altoona, Pa., as already described. For convenience of night work the gravity tracks are lighted by arc lights arranged on poles at intervals of about 300 ft., at the sides of the distribution ladders. These lights are shaded on the side toward the operating cabin. This arrangement permits the light to be thrown straight ahead into the distribution tracks, but protects the eyes of the cabin men and of the brakemen riding cuts of cars, from the direct rays. The switch lamps are lighted by incandescent electric lights of 8 candle power, as described in the section on switch lamps in this chapter (§ 66).

Figure 214A shows the location of the engine house, near which is the coaling station; the power house, for lighting, air compressing and pumping; the yard office and the operating tower. The water supply for the yard is forced from artesian wells by compressed air into an underground concrete reservoir, from which it is pumped into a tank of 100,000 gals. capacity, built on a tower 62½ ft. high standing between the office building and the power house. From the tank there are lateral pipes running to each side of the yard, where they connect with mains running the whole length of the yard and supplying 15 water cranes. Altogether there are 12 miles of water mains throughout the yard. The connection between the tank and these mains is such that in case of fire the tank valve can be shut off and direct pressure can be put upon the mains through fire pumps in the power house.

The drainage of this yard and the construction of the roadbed for the tracks are also interesting features. The surface of the land on which the yard was located was smooth and practically level, no part being 2 ft. higher than the general contour. This fact, taken in connection with the flat country surrounding the yard for a long distance, made it desirable to provide an extensive drainage system. Running westward along the north side of the yard there is a main sewer, with lateral sewers every 600 ft. The main sewer begins at the extreme east end of the yard, and for the first half mile it consists of 18-in. vitrified pipe, where it enlarges into a 27-in. vitrified pipe for the next half mile, and then into a 36-in. concrete sewer for the next mile, then a 48-in. concrete sewer for ½ mile, and for nearly all the remaining distance out of the 4½ miles there is a concrete sewer 7½ ft. in diameter, with a shell 1 ft. thick. The section of the concrete sewer in each case is circular and the figures refer to inside measurements. The sewer falls 30 ft. from end to end, or in a distance of 4½ miles, and its depth below the surface is 6 to 25 ft. At the west end of the property it empties into an open ditch which drains into the Illinois & Michigan canal. At this point the sewer is arch shaped, the span of the arch being 9 ft. and the hight from the bottom of the sewer to the crown of the arch about 7 ft. The vitrified pipe of the lateral system of sewers is 8 to 15 ins. diam. and the aggregate length of lateral sewers is 12 miles.

The grading of the roadbed or the foundation of the yard tracks consisted in depositing a 2-ft. layer of sand over the entire area enclosed by the tracks—a strip of land about 670 ft. in width and 2¾ miles long. In this shallow fill there was deposited 1,200,000 cu. yds. of sand, and in the gravity mound 400,000 cu. yds. additional. Over the sand there is a 6 to 8-in. layer of broken slag serving as a sub-ballast. On this the track was laid and ballasted with gravel in some places and cinders in others. For leveling off gravel unloaded from the cars for ballasting purposes a car with winged scrapers was used. The tracks were laid with new 75-lb. rails. In the thoroughfare and gravity tracks the ties are oak, while in the receiving tracks and on the level portion of the distribution tracks they are of cedar, laid 2800 to the mile. A full description of the yard, with numerous illustrations, was published in the Railway and Engineering Review for Nov. 16, 1901.

82. Machine Operation of Switches.—At points where switching movements are frequent or numerous, and especially if it is desired that the switching shall be done without stopping the trains, as at the end of double track, at junctions and in busy yards, it is customary to employ regular switch tenders. If a number of switches are near together one tender may be able to operate all of them, but if they extend beyond the

Fig. 218.—Typical Switch and Signal Tower of American Railroads.

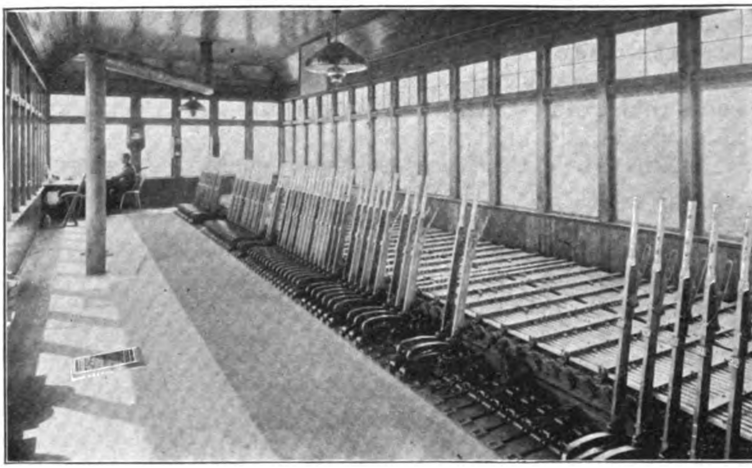

Fig. 219.—Interior of Signal Tower, Showing Interlocking Machine.

limits of convenient running distance, economy of time in the movement of the trains may require either more than one tender or that the means for throwing the switches be concentrated at a central point where the attendance can accomplish more efficient service than would be possible by running from stand to stand among switches widely separated. The latter alternative calls for machines operated at or from a distance. These machines, or the means for controlling the same, are usually assembled in the high second story of a switch or signal tower located in some commanding position where a view of the tracks may be had over the tops of cars, and unobstructed by other buildings. Figure 218 fairly illustrates a typical switch and signal tower, the intention of the closely placed windows extending entirely around the building being obvious. As the operation of main-line switches from a tower is in connection with interlocked signals, the two are usually considered together. In a comparatively few instances, however, as in yards, switches are thus operated without interlocking, and for the purpose of an elementary treatment, which is all that is here intended, it will conduce to clearness to take up the two subjects separately, referring first to the several types of mechanism for throwing switches, and their manner of operation, and then following on to the fundamental principles and appliances of interlocking.

Devices for throwing switches at a distance are of two general types, namely, hand machines and power machines. The hand machine consists of a lever or number of levers with pipe-line connection to the switches, 1-in. pipe being the size commonly used. These levers are pivoted to a frame and are spaced closely side by side, so that a large number can be placed within the distance of a few steps of the towerman. The levers of a machine, commonly known as a "mechanical interlocking machine," resemble very much the reverse lever of a locomotive, as will appear from Fig. 219, which shows the interior of an interlocking tower. The line of pipe connecting with each switch is carried on roller bearings mounted upon supports 7 or 8 ft. apart, known as "pipe carriers," and change of direction is by means of bell cranks. To automatically adjust the line of pipe for expansion and contraction due to change of temperature, the pipe is cut at intervals and compensating devices are inserted. A simple device for this purpose is a rocker or straight bar, pivoted at its center and connected at its two ends with sections of the line. It is readily seen that expansion or contraction in either section of the pipe line is compensated by that in the other without affecting the adjustment of the line. This device reverses the motion of adjacent sections of the pipe line, and takes up considerable space, the latter feature being objectionable where there are several pipes running parallel. A compensator which continues the pipe in the same straight line, called by convention a "lazy jack," is shown in Fig. 220. It consists of two bell cranks of supplemental angles, pivoted to a base casting and united by a short link. In this way the direction of motion of the two halves of the pipe line is reversed, as with a rocker, and contraction and expansion are provided for. Bell cranks, if inserted between sections of pipe line approximately equal in length, in such a manner that the pulling of one section pushes the other, perform the function of compensators. For distances less than 100 ft. no compensator is needed and in long lines of pipe one compensator is usually provided every 400 to 700 ft. Switches are operated by pipe line as far as 2000 ft. from the tower, and sometimes farther, but such distances are unusual.

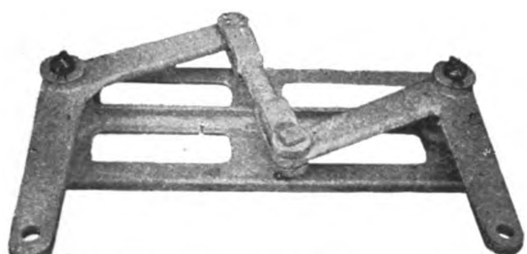

Fig. 220.—"Lazy Jack" Compensator.

Where switches are thrown from a tower there is not opportunity for the man at the levers to learn from observation, at every movement, whether the point rails have made a full stroke. As a safeguard in operating main-line switches in this manner it is therefore necessary to have some means for testing the action of the switch, so as to make known any defective working of this kind. This check upon the reliability of the switch movement is by means of a device for locking the switch in each rest position, which acts or refuses to act according as the switch works properly or improperly; it also serves the purpose of a double connection to hold the switch firmly to position under train movements. Of locks for this purpose there are two arrangements, the distinction depending upon the fact as to whether the device is actuated by the same lever that throws the switch or by a separate lever. The facing-point lock is of the latter class. It consists of a flat lock rod attached to the switch points and working through a slotted casting, and a bolt or plunger operated from the tower and working through the same casting at right angles to the lock rod, as shown in Fig. 221. In the lock rod

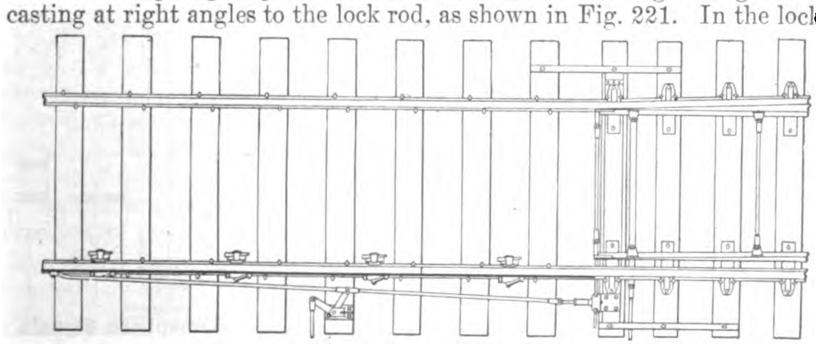

Fig. 221.—Facing-Point Lock, Outside Connected.

are two holes, corresponding to the closed and open positions of the switch, and when the point rails are in proper adjustment the plunger registers with one of these holes for each rest position of the switch. Before the switch can be thrown from either rest position the plunger must first be withdrawn, and should the point rails not move entirely home the registration of the plunger will be obstructed by the solid metal of the locking bar, making it impossible to throw the lock lever in the tower, thus indicating that the switch is out of adjustment and in need of immediate attention. As is explained more in detail in the following section, the switch and lock levers are interlocked with the signal lever, and the sequence of operation is such that if the lock fails to work, the signal must remain at danger until the switch is properly adjusted. The lock shown in the figure is known as the "outside" pattern, taking its name from the position of the plunger casting. With an "inside" facing-point lock the plunger casting is secured to the same tie, in the middle of the track, and the locking takes place at the middle of the tie bar instead of on an outside extension of the same.

By the "switch and lock" movement the lock and switch are thrown by the same lever. The arrangement is shown in Fig. 222. Instead of connecting the throw rod to the switch points direct it is made to actuate an escapement crank (*A*), otherwise called the "switch crank." By this means there is, at both the beginning and ending of the stroke, about 2 ins. of dead motion in relation to the switch, which unlocks the switch before the point rails are acted upon and locks them up after they have moved to place. Briefly described, there is a base casting with guides for the throw rod or driving bar and for the lock rod. The driving bar consists of two straps bolted to end pieces so as to straddle the escapement crank. The engage-

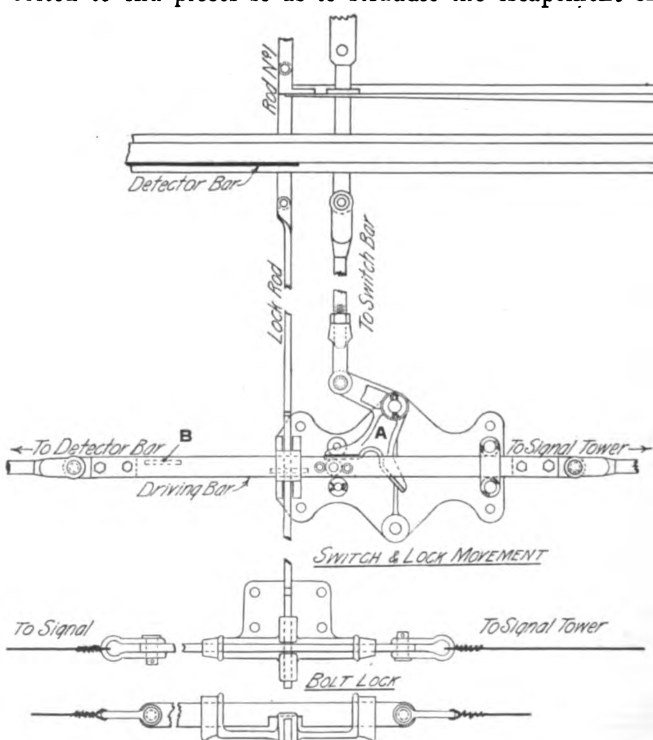

Fig. 222.—Switch and Lock Movement and Bolt Lock.

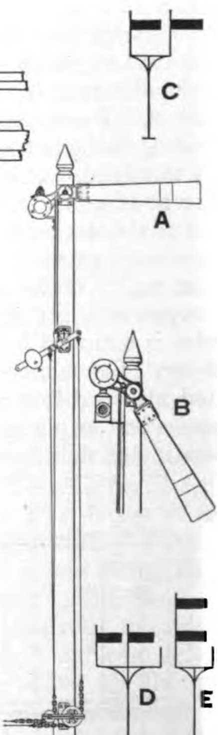

Fig. 223.—Semaphore Signals.

ment with the escapement crank is by means of an operating roller carried between the two straps of the driving bar. The driving bar and lock rod cross each other at right angles, there being a locking stud or lug (*B*) on the former to fit a corresponding notch on the lock rod for each position of the switch. On some patterns other than that shown the locking is by means of locking pins on the driving bar fitting corresponding holes through the lock rod. The full stroke of the driving bar is 8 or 9 ins., and the manner of operation is as follows: During the first 2 ins. of the stroke the locking stud is withdrawn, releasing the switch, but as the operating roller travels parallel with the arm of the escapement crank against which it bears there is thus far no tendency to move the switch. The operating roller next meets the other arm of the crank, swinging it some 4 or 5 ins. and throwing the switch. During the last part of the operation the roller again moves parallel with the crank arm against which it bears, a further distance of about 2 ins., bringing the locking parts into engagement after the motion of the switch points has ceased.

As the switch and lock movement dispenses with one lever for each switch, it effects an important economy in apparatus and in the number of movements, and consequently time required, to operate the switch, but in mechanical interlocking the use of facing-point locks on the important switches seems to be the preferable practice. In the switch and lock movement the travel of the parts is so slight (only about 1½ to 2 ins. in the throw rod) during the locking operation that by springing the connections in the case of a long pipe line it is sometimes possible to get the lever over when the lock refuses to work. As with the facing-point lock the stroke of the plunger is 5 or 6 ins., and some 4½ ins. past the lock rod, it is impossible with this device to throw the lock lever when the plunger will not enter the locking hole. A safeguard in the case of the switch and lock movement is the use of a bolt lock, described in the following section, in connection with interlocking. In the switch and lock movements of the Chicago, Milwaukee & St. Paul Ry. the driving bar has a stroke of 12 ins., with 3 ins. of locking travel at each end, which is supposed to be sufficient to prevent the latching of the lever when the locking movement is obstructed by misadjusted switch points. This lengthening of the driving bar stroke decreases the leverage. As with derailing switches it is necessary to lock the point rail only in the closed position (unless operated on the same lever with the lock for a turnout switch), the 3 ins. of locking travel may be obtained with a total travel of only 8 or 9 ins. in the driving bar. An interesting discussion of these matters was presented before the Railway Signaling Club in September, 1896, by Mr. W. H. Elliott, then signal engineer, Chicago, Milwaukee & St. Paul Ry. (See the Railway Review for Sept. 26 and Nov. 21, 1896, pages 536 and 650).

As the switch tower is necessarily somewhat removed from many or all of the switches, it is necessary, in order to facilitate rapid switching movements, to provide some device which will prevent the switch being thrown under a car or train. This device is known as the detector bar, shown in Fig. 224. It consists of a flat bar *A*, somewhat longer than the longest distance between car wheels (usually 45 or 50 ft.), which is held in position against the outside of the rail head by links *B*, pivoted to clips *C* attached to the rail as shown in the end elevation. There are lugs on the clips which limit the movement of the links and prevent the bar from getting out of adjustment. The bar is connected with the switch movement (or lock movement, in the case of a facing-point lock, as in Fig. 221), so that before the switch can be moved the bar *A* must be swung on the arcs described by the radial movement of the links about the pins of the clips

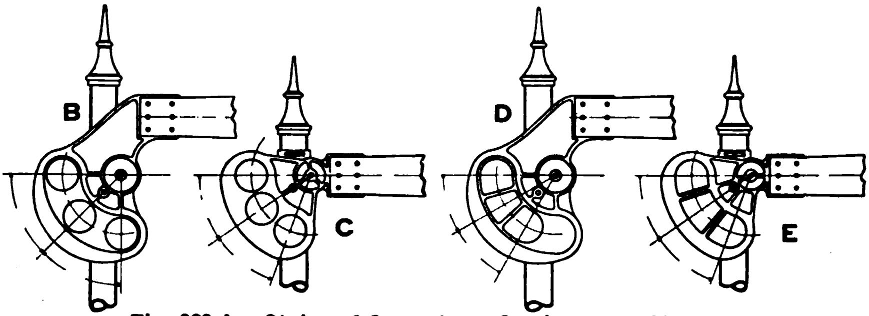

Fig. 223 A.—Styles of Semaphore Castings and Glasses.

as centers. As the bar is held but slightly below the top of the rail it must be raised about one inch above the rail in order to pass through one half of its stroke. If a wheel be resting on the rail at the bar it is obvious that the bar cannot be moved in the manner described, and, being interlocked with the switch or lock bar, no movement of the switch can take place. The operator in the tower can therefore grasp the lever while the train is moving over the switch and make ready to throw it the instant the wheels pass the detector bar, without fear of throwing it too soon. The detector bar is usually placed on the facing side of the switch. If placed on the trailing side two bars are necessary—one on the main track and one on the turnout —so as to protect the switch against a train on either track.

In power machines for throwing switches either one or both of two agents are employed, namely compressed air and electricity; and of these machines there are three systems, namely, the electro-pneumatic, in which the switch cylinder is operated by compressed air controlled by electricity; two patterns of pneumatic machines operated and controlled by compressed air; and an electric machine which is operated and controlled by electricity. Some of the advantages claimed for power machines are that they are more compact than hand machines, affording a closer concentration, which permits of smaller towers in large installations, and less attendance upon operation; that track room is not occupied by the connections between tower and switches, and as movable connections are not employed there is none of the

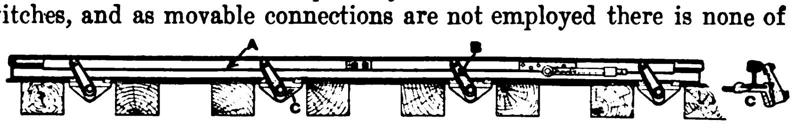

Fig. 224.—Detector Bar.

difficulties incident to the settlement of filled ground; that pipes for compressed air and insulated wires for electric currents can be laid farther than pipe lines can be readily worked; that over long distances the connections with the power machines are cheaper; and where there are complicated switches, crossings, sharp curves, etc., the connections are not only cheaper but far less complicated and less liable to derangement, as they can be buried up out of sight, where they will be secure from accident or molestation; and that fewer levers are required in the tower, thus reducing the expense of large installations and decreasing the time of operation. The last-named advantage is due to the fact that the number of mechanisms which can be operated simultaneously from one lever is limited only by the restrictions imposed by traffic requirements, whereas in the mechanical system—that is, by hand operation—the physical energy and endurance of the operator measures the capacity of each lever.

The Westinghouse electro-pneumatic operating mechanism as applied to a simple switch is shown as Fig. 225. The switch cylinder is 5 ins., and sometimes 6 ins., in internal diameter and the stroke of the piston is 8 ins.

The air for operating the cylinder is piped to it at a pressure varying in different installations from 45 to 80 lbs. per sq. in., but usually about 65 lbs. per sq. in. Under the cylinder there is a small auxiliary reservior to receive the condensation from the moisture in the air. The control of the valve for admitting air against the piston is by means of three electro-magnets secured to the side of the cylinder and operated on electric circuits connecting with the interlocking machine in the signal tower. The functions of these three magnets for a single movement of the switch are as follows: The middle one of the three magnets operates a lock which controls the movement of the valve admitting air to the switch cylinder. The other two magnets operate pin valves controlling the admission of air to and exhaust from two small auxiliary cylinders secured to the side of the switch cylinder, the pistons of both of which operate upon the slide valve which admits and discharges the larger volume of air used by the switch cylinder. The mechanism of the lock magnet device consists of a plunger, applied normally by a coiled spring which forces it into a recess in the slide valve, and which is withdrawn by exhausting the air from above the plunger piston by means of a magnetic pin valve, thus permitting the full pressure in the valve chamber to overcome the spring and force out the bolt. By de-energizing this magnet, which takes place as soon as the slide valve has moved, the exhaust passage operated by the pin valve is closed and the pressure, being admitted through a small leak hole through the piston of the plunger, gradually equalizes on both sides of the piston and permits the action of the spring to again lock the slide valve. In operation this lock must be withdrawn before the slide valve can be shifted to admit air to actuate the switch cylinder. The electrical contacts of the switch lever on the machine in the tower are so arranged that the three magnetic valves of the switch mechanism are operated in proper sequence to withdraw the lock previous to each attempt to shift the valve. In setting a switch the operator in the signal tower throws a lever (Fig. 235) through a portion of its stroke, making electrical contacts with circuits connecting with the valve magnets on the switch cylinder. The first movement, as previously stated, is the action of the pin valve of the lock magnet, which operates to unlock the slide valve, and this slide valve is then acted upon by air pressure controlled by

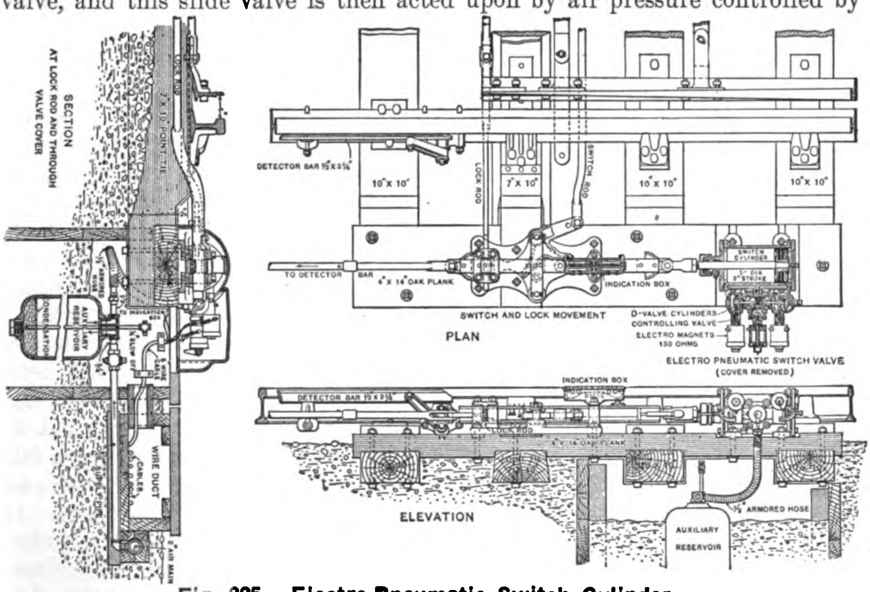

Fig. 225.—Electro-Pneumatic Switch Cylinder.

the movement of the pin valves in the outside electro-magnets. The movement of the lever beyond the point where the lock magnet is actuated discharges one of the valve magnets, permitting the air to exhaust from the auxiliary cylinder controlled by that magnet, and energizes the other valve magnet, admitting air to the auxiliary cylinder on that side and forcing over the piston which works the slide valve. The movement of the slide valve admits pressure against the piston of the switch cylinder, the piston rod of which is connected with the switch and lock movement and the detector bar shown (Fig. 225).

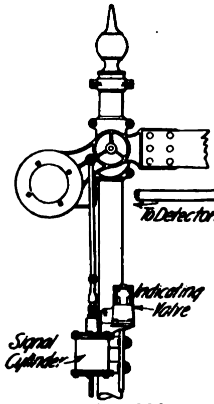

Fig. 226.

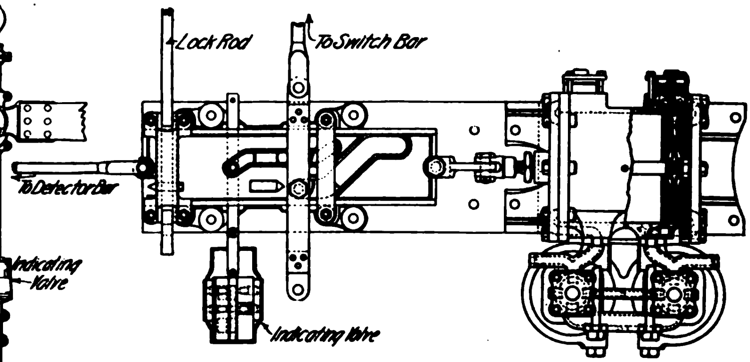

Fig. 227.—Switch and Lock Movement for "Standard" Pneumatic System.

In operating switches from a tower it is necessary that some indication be received by the operator to assure him at each movement that the switch has properly completed its stroke. With the hand machine the indication of a failure of the switch to complete its throw is given by the refusal of the locking lever to make the full stroke. The indication with the electro-pneumatic mechanism lies in the ability to complete the throw of the operating lever in the signal tower. When this lever is first manipulated for moving the switch it is thrown up against a stop, making only a partial movement, as stated. The position of this stop is controlled by an electro-magnet on a circuit operated in connection with the locking device of the switch mechanism. If the switch has been thrown to proper place and locked a contact is made which causes the electro-magnet in the signal tower to withdraw the stop, permitting the lever to be given its full movement, thus indicating to the operator that the mechanism at the switch has properly performed all of its functions. If the stop is not withdrawn the stroke of the lever cannot be completed and the signal lever is locked in the danger position, as explained farther along.

The "Standard" apparatus for throwing switches is controlled, operated and indicated by air pressure. The pressure for the controlling and indicating movements is 6 lbs. per sq. in. and that for operating the switches is 20 lbs. per sq. in., the difference in pressure being obtained by means of reducing valves. This is known as the "low pressure pneumatic" system. The operating bars or "levers" of the interlocking machine (Fig. 237) are straight steel bars with upright handles, pulling straight out to the front. The manipulation of a lever for a switch movement is as follows: The lever is first pulled out about half its stroke, where it stops and air is admitted to the controlling pipe running to the switch cylinder. It there operates a valve which admits air against the piston of the cylinder. The movement of the switch points operates apparatus sending an indication current of air back to the machine in the tower, and this indication current completes the stroke of the lever. This automatic completion of the stroke of the lever is the "indication." The switch and lock movement of the Standard system is by means of a "motion plate," as shown in Fig. 227. This device is a sliding plate attached to the piston rod of the switch cylinder, and the means for imparting motion to the bar connecting with the switch points is a diagonal slot, and an operating roller attached to the switch connection. The two ends of this slot are parallel to the direction of movement of the motion plate, the purpose of which is to utilize the beginning and ending of the stroke, severally, to unlock and lock up the switch, as only the diagonal portion of the slot can operate to impart side motion to the bar connecting with the switch. The indicating valve is operated by a slot in a similar manner, the parallel part of this slot corresponding to the diagonal part of the slot operating the switch. The working of the locking mechanism is apparent from the illustration, it being observed that the slot operating the indicating valve is so arranged that it cannot actuate the valve rod until the locking stud engages with the notch in the locking rod.

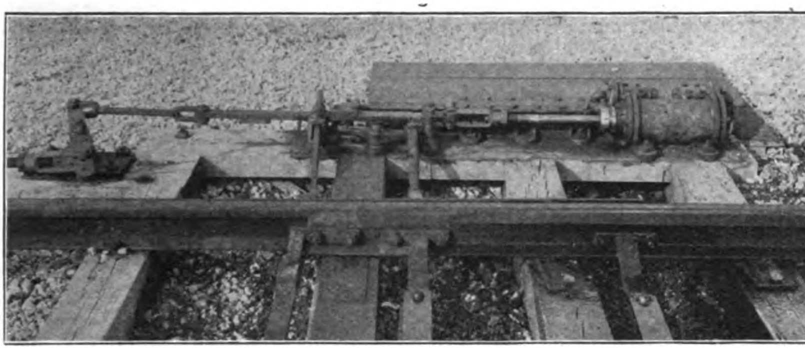

Fig. 228.—Thomas Pneumatic Switch Cylinder, N., C. & St. L. Ry.

In the Thomas pneumatic system for handling switches and signals the movements are controlled, operated and indicated by compressed air. It was designed by J. W. Thomas, Jr., general manager of the Nashville, Chattanooga & St. Louis Ry., on which road a number of installations of the system are in service. The distinctive feature of this system is the working of the valves admitting air to and exhausting it from the switch cylinder by means of pistons of the equalizing type, which are actuated by a sudden increase or decrease of the air pressure on opposite sides of the piston. Secured to the switch cylinder (Fig. 228) near each end there is an air chest in which is a valve controlling the admission and exhaust of the air to and from that end of the cylinder. Each of these valves is in pipe connection with a pressure-controlling valve operated by a lever in the signal tower (Fig. 229). In these two pipes leading to the switch mechanism there is a difference of pressure of 10 lbs. per sq. in., the pressure in one of them being 70 lbs. and that in the other 80 lbs. per sq. in. In the switch cylinder, under the normal condition of things, there is a pressure of 80 lbs. per sq. in. on one side of the piston, with the other side open to the atmosphere. When it is desired to throw the switch a lever is pulled (half stroke) in the signal tower, which operates a controlling valve, increasing the pressure in one of the controlling pipes from 70 to 80 lbs. per sq. in. and decreasing it in the other (by exhaust into an empty reservoir) from 80 lbs. to 70 lbs. per sq. in. This change of pressure shifts the valves on the switch cylinder, admitting air at 80 lbs. pressure to one side of the piston and exhausting it from the other, thus operating to throw the switch.

Through the piston of each valve at the switch cylinder there is a small leak hole, which permits the pressure to equalize on both sides of the piston soon after it has been actuated by a sudden change of pressure in the controlling pipe. By this arrangement the conditions are always such that the valve piston is in readiness to act at the next change of pressure, be it an increase or a decrease; in fact action will take place without waiting for the pressure to equalize. To increase the capacity of the air supply, so as to move the valves quickly, there is a small reservoir under each end of the switch cylinder, in communication with the valve chest on that end. In connection with the switch operating mechanism there is an "indication chest" in communication with a valve on the interlocking machine in the signal tower through two pipes in which the pressure stands at 70 and 80 lbs., respectively, as in the controlling pipes.

The operation of the switch is by switch and lock movement, and on the driving bar of the same there is an arm which works the indication chest. As soon as the switch points have been thrown fully up this arm comes into engagement with the stem of the valve in the indication chest,

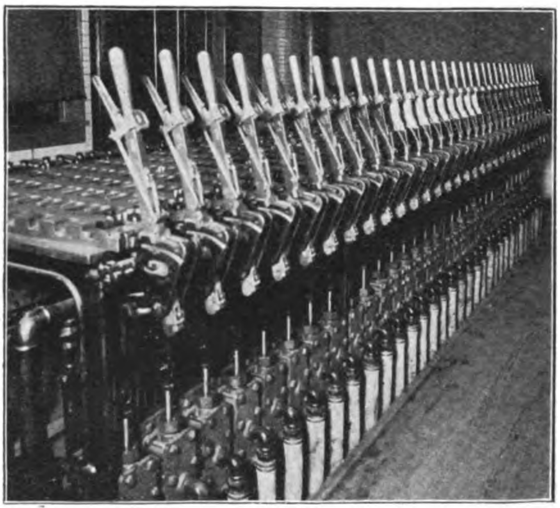

Fig. 229.—Interlocking Machine of the Thomas Pneumatic System.

the shifting of which throws ports into connection which reduce the pressure in one of the indicating pipes from 80 to 70 lbs. per sq. in. and increase it in the other from 70 to 80 lbs. This alternation of the pressure operates the above-mentioned valve on the interlocking table, which withdraws a stop pin, releasing the operating lever and permitting the completion of its stroke. Until this indication is received, by the response of the switch, the lever cannot be thrown from the midway position of its stroke, where it was stopped as soon as the controlling valve had been shifted to throw the switch. In Fig. 229 the controlling valves appear at the front of the interlocking machine, directly under the levers. The time consumed in operating a switch 250 ft. away, including the indication, is about one second; at a distance of 1000 ft. the time is 3 seconds. To give some idea of the rapidity of the movements a switch 250 ft. away has, by actual test, been operated 28 times per minute.

The Taylor switch machine, shown in Figs. 230 and 231 with the cover removed, is operated by an electric motor, the capacity of which for a single switch is about 1 horse power; but the power required is but little more

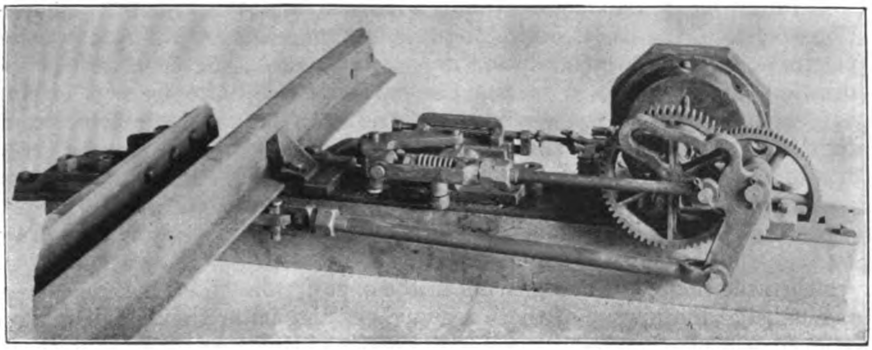

Fig. 230.—Taylor Electric Switch Machine (Switch Open).

than half of this, being usually 7 amperes at 60 volts. The current for operation is usually supplied by a storage battery in the signal tower, charged at intervals by a gasoline engine and small dynamo, or from some other source of electrical energy. In throwing the switch a bar or "lever" on the interlocking machine (Fig. 238) is pulled half stroke, closing a circuit which causes the motor to turn 20 revolutions in about two seconds, driving the train of gear wheels shown. Through this gearing the main driving wheel is revolved one revolution, actuating by means of a crank pin the cam movement which throws the rod connecting with the switch points. The switch lock is operated by a rod connected to the crank pin of the main driving gear, this rod appearing just above the switch connecting rod, in the picture. This rod acts upon the lock bolt through a bell crank and withdraws the bolt from the lock rod before the switch connecting rod begins its stroke. After the stroke of the switch is completed the lock bolt is reinserted. The movement of the lock rod compresses a spiral spring encircling the rod of a pole changer. The final movement of the lock bolt releases this spring and its energy operates to reverse the pole changer, opening the driving circuit, reversing the armature connections and closing the indication circuit. In machines of later design the pole changer is operated by positive action, the power to do so being derived directly from the lock bolt, but is available only after the bolt has passed through the lock rod. This power is transmitted from the bolt to the pole changer through a pivoted lever having a movable fulcrum, the same being moved by the lock rod to one side or the other of the pivot as the lock rod follows the movement of the switch point to one position or the other.

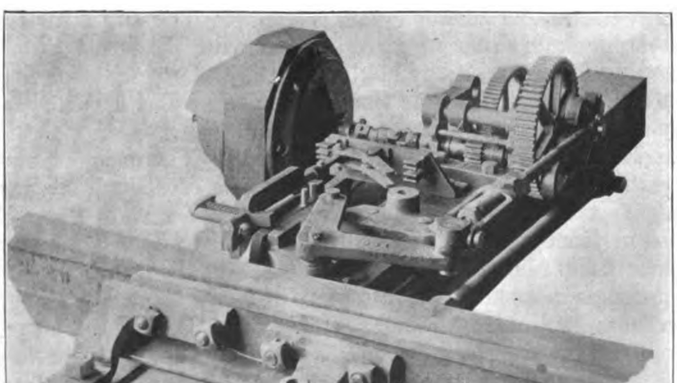

Fig. 231.—Taylor Electric Switch Machine (Switch Closed).

Immediately the motor circuit is broken and the armature connections reversed, the motor begins to act as a generator, setting up a counter electromotive force which opposes its own momentum and energizes the indication circuit. The indication current actuates electro-magnets on the interlocking machine, which release the lever and permit the operator to finish the stroke of the same. Hence if the switch is not moved fully home the lock bolt is obstructed, there is no indication, and the inability to complete the stroke of the lever shows that the switch is out of adjustment. The throwing of the switch in the reverse direction is accomplished by pushing the lever in the interlocking machine toward the normal position, which turns the motor and gearing in the opposite direction, the cam movements being the reverse of the foregoing. If the motor should fail to stop at the proper time it is automatically thrown out of gear. Where it is desired to operate a mechanical detector bar (Fig. 224) in connection with

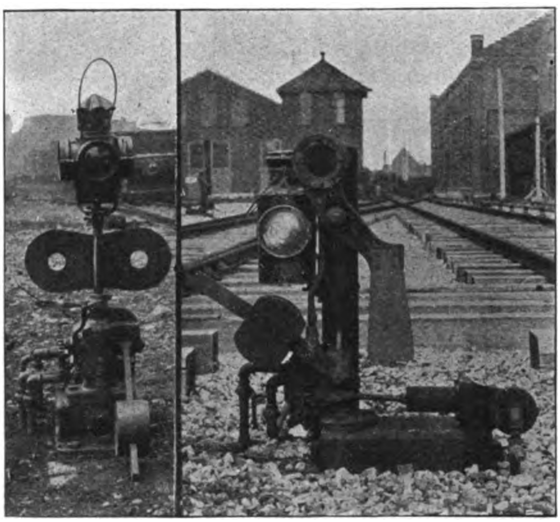

Fig. 232.—Dwarf Signals, Thomas Pneumatic Interlocking System.

this machine a T-crank is substituted for the bell crank to operate the lock bolt, and the detector bar connection is attached to the spare arm of the T-crank. In some installations of Taylor apparatus the dectector bar is dispensed with and a track circuit is made to serve the purpose. With this arrangement the closing of the track circuit by the presence of cars opens the battery circuit leading to the switch machine. The two figures are views of the machine from different directions, showing the positions of the parts corresponding to two positions of the switch. At Bridge Junction, Ill., on the Illinois Central R. R., near the long Cairo bridge, a switch is operated by a Taylor machine that is 5300 ft. from the tower.

83. Interlocking Switches and Signals.—The most common form of railway signal is the semaphore, which consists of a blade or arm pivoted to a post or pole so as to show on the front side and to the right of the same as seen from approaching trains governed by it. Semaphore signals are of three kinds: home, distant and dwarf signals. In home and distant signals the semaphore arm is a thin piece of board about 5 ft. long, tapering in width from 10 ins. at the outer end to about 7 or 8 ins. near the pole. Home and distant signals differ in shape only at the end, the home signal having a square end, as in Fig. 223, and the distant signal a notched or fish-tail end, as in Fig. 245. In block signaling the end of the semaphore is sometimes pointed, to distinguish it from interlocking signals. These signals are usually placed at the top of a pole standing about 25 ft. high above the track, and wherever it is practicable the pole is located at the right-hand side of the track which the signal governs. The semaphore blade is bolted to a pivot casting called the arm plate, and the movement of the signal is by means of a vertical rod connecting this casting with a "balance lever" some distance down on the pole. This balance lever (Fig. 223) is usually worked by a pair of wires connecting with chains passing around pulleys at the foot of the pole and running to a lever in the signal tower. On some roads, however, it is the practice to operate home signals by pipe connection, in the same manner that switches are operated from mechanical plants. The balance lever is weighted on the longer arm so as to overbalance the semaphore blade and hold it in or pull it to the horizontal or normal position in case a wire should break. The arm plate casting is designed to overbalance the blade and bring it to normal in case it should become disconnected from the balance lever below. A ladder running to the top of the pole gives access to all the parts. The dwarf semaphore signal (Fig. 232) has a blade about 1 ft. long with a square end, and is placed on a low post at a hight of 2 or 3 ft. above the rail. As this signal is usually placed close to the track or between tracks that are close together its blade is usually made of thick rubber, so as to avoid injury in case it is struck by a passing object. Another arrangement is to hinge the blade to the arm plate and provide springs to return it to the straight-out position in case it should be knocked around by anything passing. Dwarf signals are used to govern movements from main track to side-tracks, movements from one side-track to another, yard movements; and movements on main line against the normal direction of the traffic, as, for instance, "back-up" movements on double track.

Home and dwarf signal blades are usually painted red (and sometimes yellow) on the face and white on the back, and the blades of distant signals green or yellow on the face and white on the back. As, however, the semaphore is a position signal its color is without significance, the idea being to select the color which is most conspicuous at a distance, in daylight, and then, to add to the distinctiveness, a bar is painted across the face of the signal in some color which bears a striking contrast, like white on red or green or black on yellow.

A home or dwarf signal blade in the horizontal position (*A*, Fig. 223) is an indication of "danger," and the engineer is supposed to stop and wait until the signal is changed. The blade of any signal (home, dwarf or distant) hanging vertical or obliquely downward (usually 65 to 75 deg. from the horizontal), as in Fig. 232, and at *B* in Fig. 223, is a "clear" indication and gives the engineer permission to go ahead at full speed. There is some difference in practice as to the exact position of the semaphore for clear, as on a few roads, including the Pennsylvania Lines West, the blade hangs vertically downward for this indication, while on the majority of roads, as above intimated, it stands out 15 to 25 deg. from the pole. The latter position is the preferable one, as the blade is more conspicuous when swung out clear from the pole than when hanging in close by its side. With the blade in the latter position the appearance of things bears too close a resemblance to a pole without a blade, and with enginemen habitually controlled by such a signal a pole with the blade broken off might easily be mistaken for a clear indication. Engineers accustomed to seeing the blade stand out clear of the pole for all indications would quite likely detect something wrong in the absence of the blade. On some roads there is a third position (the blade standing at an angle of 45 deg. with the pole, in some instances above the horizontal and in other instances below it) signifying caution, but such practice is unusual. As the purpose of the distant signal is to indicate the probable position of the home signal, the horizontal position of the former is an indication of "caution," and is a warning to the engineer to bring his train under such control that it can be stopped at the home signal in case it should be found at danger.

The night indications are by lights of different colors. The arm plate holds in rear of the pivot one or more colored glasses, called "spectacles," which are moved to stand in front of a lamp in correspondence with the signal positions of the semaphore blade. This lamp is designed on the style of a switch lamp and is placed upon a bracket so as to come within the sweep of the spectacle arm. In universal practice a red light is the night indication for danger, and hence on home and dwarf signals this is the color of the spectacle glass which covers the signal lamp when the blade is horizontal. On the majority of roads in this country the clear indication on home, dwarf and distant signals at night is a white light, in which case the spectacle arm carries only one glass (for a two-position signal), that being colored, of course. To show a white light in that case it is only necessary to swing the blade so that the spectacle casting will uncover the signal lamp. The corresponding indication for caution at the distant signal is a green light. Practice is gradually changing, however, to the use of a green light for clear at home, dwarf and distant signals, and a yellow light for caution at the distant signal, white light not being used for any signal. On the Chicago & Northwestern Ry. the home signal at night shows a red light for danger and a green light for clear. The distant signal shows a green light for clear and a combination red and green light for caution. This double light is produced by one lamp shining through two lenses—through one lens direct and through the other by reflection. The lamp carries green and white lenses, the green lens being outside the sweep of the spectacle arm. The upper ring on the semaphore casting carries a red glass, and when the blade is at caution this glass stands in front of the white lens of the lamp. The lower ring of the casting carries a metallic shield, and when the blade is at clear this shield covers the white light and leaves only the green light visible. This arrangement of lights was devised by Mr. E. C. Carter, chief engineer of the road.

The objection to a white light as a signal indication is the trouble likely to arise from a wrong indication due to the chance breaking of a spectacle glass, or to the liability of mistaking a street or house light for a signal light, particularly if the signal light in the vicinity has gone out. In any case engineers should make it a practice to observe whether the position of the blade corresponds with the lamp indication. Where a green light is used for clear, it is of course necessary to have two spectacle glasses for all two-position signals. In the back side of the signal lamp there is usually a small lens, the light from which shines through a blue glass when the blade is in its normal position, so that the operator can at night see one side or the other of all signal lights, and thus be able to tell whether they are burning. This blue glass is held in a back-light casting attached to the semaphore shaft, which runs through the pole or through a casting attached to the side of the pole.

An important question with semaphore signals is the night indication for positions intermediate between those for danger and clear. In times of snow or sleet or when rain freezes to ice, or in case of derangement of parts, semaphore blades will sometimes droop considerably from the horizontal position when set for danger. With a casting like that shown at *A*, Fig. 223, the blade might droop sufficiently to uncover the signal light, thus giving a clear indication. One way of preventing the display of a white light with the arm in an intermediate position is to attach a shield to the bottom of the back casting, so as to cover the light until the arm swings to the clear position. This scheme of protection is based upon the principle that the absence of a signal is a danger indication, but it is not an indication that can be relied upon, for unless the engineer knows precisely where he is he may not be aware of the situation. The same difficulty would arise, of course, in the case of a casting holding two colored glasses with a blank between. All trouble from this source is overcome by the use of what is known as the "continuous-light" principle of design. By this arrangement the back casting carries red glass to cover the sweep of the arm all the way from the danger to the clear position, so that a danger indication will be given until the signal is entirely clear. Engravings *D* and *E*, Fig. 223A, show castings designed for this purpose, the two top glasses in each case being red. Engraving *C* shows the same arrangement with round glasses. The casting shown in Engraving *B* is not designed on the continuous-light principle.

Where diverging routes are to be governed two blades are used on the same pole, generally 6 to 12 ft. apart, such being known as a "route signal." The upper blade is the signal for the superior or high-speed route and the lower blade the signal for the inferior or slower-speed route, as, for instance, where freight traffic diverges from the main passenger tracks. At junction points, or wherever there might be any doubt as to which route is the superior one, the upper and lower arms and lights are assigned to the routes they govern by bulletin notice. On some roads, one of which is the Delaware, Lackawanna & Western, the lower blade of a double-arm home signal is full size only where both of the diverging routes are for fast-speed trains; if one of the routes is for slow movements into sidings, yards, etc., a blade of dwarf signal size is used for the lower signal. In using a two-arm home signal on this road it is the practice to obscure the light on the lower arm when it indicates danger, so that red lights will not be displayed against high-speed trains the movements of which they do not control. The standard two-arm signal of the Chicago, Milwaukee & St. Paul Ry. has, for the diverging route, an arm of dwarf size about 10 ft. above top of rail, and 17 ft. below the arm for the high-speed main-line route. The lower light in its normal position is then blinded, so that the engineman of a high-speed main-line train will get a high signal for the high-speed route and will not have to run against the red light for the diverging route.

Owing to close spacing of tracks it frequently happens that the pole for a signal cannot be placed next the track which it governs, in which case a pole of extra hight is set to the right of all the tracks, or as far to the right as it may be convenient to go in order to find necessary standing room, and the signals for the tracks are then arranged on posts set upon a bracket or cross arm in the order of the relative position of the tracks. Thus, Sketch *C*, Fig. 223, shows the arrangement for signaling two tracks lying consecutively next the pole. In case one or more tracks intervene between the pole and the track or tracks to be governed by the signals which it carries, stub or bladeless posts are placed upon the bracket to represent the tracks which are not signaled, the relative position of the stub posts corresponding to the relative position of the tracks which intervene between the pole and the tracks to be governed by the signals on the bracket. Sketches *D* and *E* (Fig. 223) illustrate the arrangement. At night these stub posts carry blue lights to indicate their number and relative position. If the bracket extends to only one side of the main pole and carries only one signal post the indication is the same as though the signal was on a straight pole. Such an arrangement is sometimes employed to afford a better view of the signal. Where more than three tracks have to be signaled at the same point the usual practice is to erect a light truss bridge over the tracks and place the signals upon it, each signal directly over the track which it governs. Figure 233 is an illustration of this arrangement, the signal bridge being located over six parallel tracks at the entrance to a subway, with double-arm signals over the first, second and fourth tracks from the right. Through terminals where the tracks are closely spaced and all trains run at slow speed the use of dwarf signals for all the tracks, main and sidings, is a plan sometimes followed. Two advantages with this arrangement are that the signals are much cheaper than high semaphores and each signal can be placed just where it belongs, namely at the side of the track which it governs.

Fig. 233.—A Signal Bridge.

Having briefly described the mechanisms of different types and patterns for operating switches from towers, and the most ordinary arrangements of semaphore signals for controlling train movements, it is in order to explain the purpose of interlocking the switches and signals of a route or of two or more conflicting routes, and to describe a few of the simple applications of the same. To start with, it should be understood that a thoroughgoing treatment of the subject is not intended. On nearly all roads in this country the installation and maintenance of interlocking plants and connections are in charge of a department separate and distinct from that of the track; and the practice of railway signaling, as well as the appliances thereof, is so diversified that a separate volume is required to treat it comprehensively. There is, however, between the two departments some division of work and responsibility, and some of the applications of signaling and interlocking require alterations of the track construction, as well as special adjustments and attachments. Interlocking is now so extensively employed that men in charge of track should have at least a general knowledge of such installations and the operation of the same. The aim in the elementary treatment here presented is merely to cover that much ground.

The interlocking of a switch with one or more signals is an arrangement whereby the levers or other means for throwing and setting the same are so controlled that the signals cannot be cleared until the switch has been properly set and locked; and, conversely, so that the switch cannot be moved while any of the signals is indicating a clear route over the same: in short, a clear signal cannot be given contrary to the position of the switch. The scheme of operation in this simple case applies likewise to all the switches and signals of a route controlled from the same point or tower. Two or more tracks crossing each other at grade are said to be "conflicting" or "opposing" routes, because it is unsafe to permit trains on either route to run past the crossing unmindful of the movements on the other route or routes. Routes converging to a junction are also conflicting, because right of way over the junction cannot be given to more than one route at a time.

At unprotected grade crossings the only safe practice is to require all trains to stop before reaching the crossing. A signal much used for giving the right of way over crossings without requiring the train signaled to stop is a gate hinged to a post standing in the angle between the tracks. The gate carries a danger target for day indications and at night a red lantern, and is in charge of a watchman who gives the right of way by swinging the gate over the opposing track. In some instances the gate post is a high pole and the swinging of the gate is made to operate a signal at the top of the pole which indicates the position of the gate. One form of signal for this purpose is a cross arm pivoted at the middle. The normal position of the arm is diagonal, or at an angle of 45 deg. with the horizontal, which is a danger indication for both roads. The horizontal position is a clear signal for one of the roads and the vertical position a clear signal for the other. At night a red lantern is suspended from each end of the arm to indicate its position. Another arrangement is the use of two gates—one for each track. Each gate stands normally across its track, and to give the right of way to an approaching train the gate in front of it is swung to clear. Still another arrangement is the use

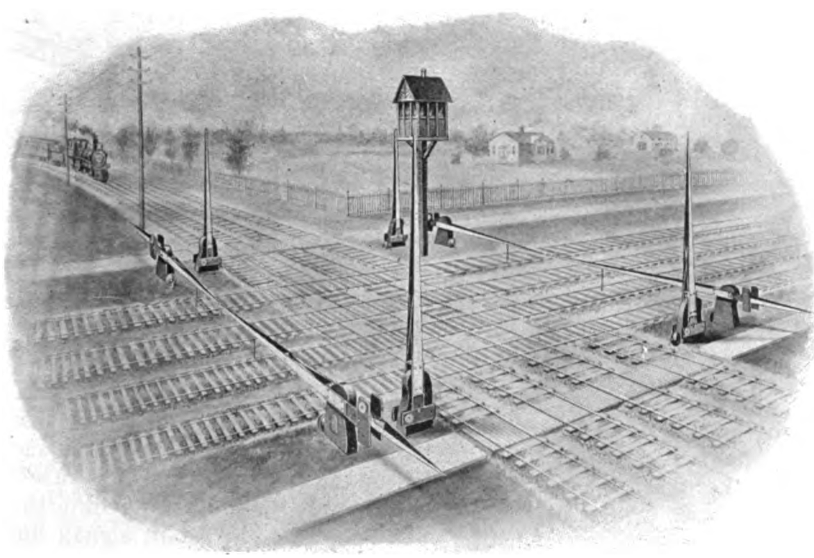

Fig. 233 A.—Double Interlocked Gates at a Track Crossing.

of two sets of gates—one set for each track—interlocked so that one set is always down while the other is up, thus making it impossible to clear both routes at the same time. Such an installation is in service at the crossing of the Illinois Central and the Wabash roads at Decatur, Ill., arranged as shown in Fig. 233A. Similar installations are used to some extent at crossings of steam and street railways.

It is to be remarked that with signals of any kind at the crossing only, the trains must be run under such control that a stop can be made within the limits of vision. The next step in advance is an arrangement of home and distant signals to control the movement of trains on each track, all the signals being so interlocked that only one route over the crossing can be cleared at a time. Normally all the signals on both routes stand at danger, and after a signal on either route is moved to clear, all the signals on the conflicting route or routes are locked at danger and cannot be moved so long as any signal on the first route stands at clear. The placing of signals at a distance in this manner permits high speed over the crossing, but, like the gate, does not always give protection, as engineers sometimes fail to regard the signals and a collision on the crossing sometimes occurs. The only sure means of protection against collision that is in general service is to interlock the signals with derails in each track, one in each direction from the crossing, the derails remaining open while the signals on the same track stand to danger. If the derails are located farther from the crossing than a derailed train can run over the ties a collision at the crossing is a physical impossibility. In the East it is quite commonly the practice to protect crossings with interlocking signals without derails, while in the West the use of derails at interlocked crossings is the rule. Where derails are used at proper distance from the crossing collisions are avoided, but from non-observance of signals derailments occur with more or less frequency, sometimes doing considerable damage. As between the two systems that which makes use of derails seems to be the preferable one and to be increasing in favor.

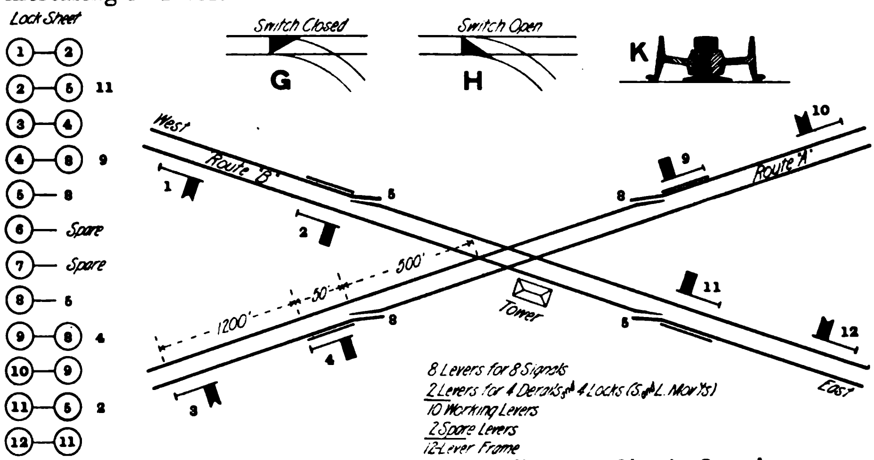

Fig. 234.—Interlocking Signals and Derails for a Simple Crossing.

The Rowell-Potter system of interlocking uses automatic brake-setting devices in lieu of derails. The arrangement consists of a track instrument, known as a "safety stop," that is interlocked with the signal in such a manner that when the signal is at danger the track instrument is raised in position to trip a valve on the engine and apply the brakes. At interlocked crossings this track instrument is placed near each distant signal, and a train approaching the crossing on one of the tracks, while still at a safe distance, causes the distant signals on the conflicting route to be set to danger. Should an engineer disregard one of these signals set to danger the safety stop will automatically apply the brakes and bring his train to a standstill. The device is used with block signals as well as at interlocked crossings. The energy for moving the signals and other parts of the apparatus is derived from a "power-storing" machine that is worked by the undulatory motion of the rails under traffic. The operation and control of the system is thus automatic, no operator or attendant being required. An installation of this system at a crossing of the Peoria, Decatur & Evansville and the St. Louis, Peoria & Northern roads, at Hawley, Ill., was fully described and illustrated in the Railway and Engineering Review of Jan. 6, 1900. An illustrated article on the system applied to block signaling, on the Milwaukee division of the Chicago, Milwaukee & St. Paul Ry., was published in the Railway and Engineering Review of March 15, 1902.

The interlocking tower or cabin is located where a clear view may be had along both tracks. In selecting the location one should seek to avoid the possibility of having to move the tower to make room for laying a second track. Derails are usually located 300 to 500 ft. from the crossing, the distance in some states being regulated by law. With the increasing speed of trains 500 ft. is not too far. Unless the ground on that side is unfavorable, and other conditions do not interfere, derails are placed on the engineer's side of the track. If, however, the tracks cross at a small angle it is in accordance with what is considered best practice to place the derails on the side of the larger angle, as in Fig. 234, with the pipe lines on the opposite side of the track. To hold a derailed train to the ties a guard rail is laid 8 to 12 ins. inside the opposite rail, extending from the derailing point to within a distance of about 100 ft. from the crossing. The home signal is located 50 ft. in advance of the derail, and the distant signal 1200 to 4500 ft. in advance of the home signal, depending upon the grades, but usually 1200 to 2000 ft. for level track. The detector bar for derails extends from the derail toward the home signal, nearly or quite covering the distance between the two. Hence, after an engine passes the home signal at clear the derail cannot be opened. To prevent a derail from being opened while a short train is on a crossing or anywhere between the derails at either side of the crossing, detector bars are sometimes placed on the rails near to and each side of the crossing. Where electric locking is used, as described further along, this precaution is unnecessary.

The ordinary arrangement is to have all the signals and derails stand normally at danger, and upon the approach of a train the derails, switches and signals controlling that route are cleared. The mechanism of an interlocking machine is so arranged that the levers controlling a route must be thrown in a certain sequence, which provides that all the switches and derails of the route must be closed and locked before the home signal can be moved to clear, and the home signal must be cleared in advance of the distant signal. Conversely, no switch or derail on any route can be opened until first the distant and then the home signal has been set to danger; and the closing of a derail or switch on one of the routes locks up all of the derails and signals set to danger on the conflicting route or routes. No switch or signal controlling a route can be cleared until all the switches and signals on the opposing route or routes have been restored to normal —the locking will not permit any lever to be thrown out of its turn. Conventionally, the "normal" position of a lever on an interlocking machine is that in which it stands when pushed from the operator, as in Fig. 219. In pulling a lever to move a signal to clear or to close a derail or switch the lever is said to be "reversed."

A sketch and diagram of the simplest case of interlocking the signals and derails for a crossing of two tracks are shown in Fig. 234. To simplify matters it will be supposed that the derails and detector bars are operated by switch and lock movements. The two derails on each track are thrown by one lever, and the eight signals by one lever each, making ten working levers in the plant. As, however, mechanical interlocking machines are usually built up in sets of eight levers each, with a half set to finish out with in case a full set is not needed, a 12-lever machine is usually provided, so that in the plant under consideration there would be two spare levers. It will be understood that the levers of the machine are numbered to correspond with the derails and signals which they operate. Referring now to the figure, suppose it is desired to "set up" or clear Route "B" for the movement of a train over the crossing from west to east. The first thing to do would be to close the derails by reversing the lever 5. The reversing of this lever locks derail lever 8 in the normal position and releases home signal lever 2. The next movement in order is to reverse lever 2, which locks up derail lever 5 reversed and home signal lever 11 in the normal or danger position, since this signal is used only for west-bound movements; and it is a principle of interlocking not to clear the signals on a track for trains in more than one direction at a time. The latching of lever 2 reversed releases distant signal lever 1. The reversal of distant signal lever 1 completely clears the route for an east-bound train.

The locking is arranged in the most simple manner to effect the purpose, the reversal of each lever locking only such levers as could be thrown to conflict with the route that is being set up. The reversing of a lever does not directly lock every other lever having to do with the control of the route, but only such lever or levers as is necessary to complete the chain of locking—the second lever pulled locks the first, the third the second, and so on. For instance, the locking of derail lever 8 normal by reversing lever 5 accomplishes the locking of all the signals on Route "A," although lever 5 does not directly lock the levers for these signals. To clear the signals on Route "A" it is necessary to first reverse derail lever 8, and hence by locking this lever the signal levers become locked in consequence. Having cleared the signals and closed the derails on Route "B," it is impossible to clear any signal or close any derail on Route "A," and hence by means of interlocking it is impossible for an operator in the tower to give right of way over two conflicting routes at the same time. To assist the operator to quickly pick out the levers of a set, each lever, besides being numbered, is painted in colors to correspond to the kind of service which it performs. The switch levers are usually painted black, home signal levers red, distant signal levers green, lock levers blue; and the levers for switch and lock movements half black and half blue.

It might be said here that the distant signals of mechanical interlocking plants are not always operated by lever and mechanical connections. On the Eastern division of the Pittsburg, Ft. Wayne & Chicago Ry., for example, the distant signals for interlocking plants are operated automatically. They stand normally at caution (that is, 45 deg. from the horizontal, the 3-position signal being the standard block signal on this road) and are cleared through a circuit closer on the home signal when that signal goes to the clear position. They are located a full block (about $\frac{3}{4}$ mile) from the home signals, which is a much greater distance than is feasible for satisfactory operation by means of wire connections.

In sketching the layout of an interlocking plant it is conventional to illustrate the locking performed by each lever in its reversed position by means of a diagram known as a "locking sheet," as shown at the left in Fig. 234. In this diagram the circles enclosing the figures indicating the numbers of the levers are intended to mean that such levers are reversed; where a circle is not used the lever is supposed to stand in the normal or danger position. For illustration, beginning at the top of the diagram, the reversal of lever 1 locks lever 2 in the reversed position; the reversal of lever 2 locks lever 5 reversed and lever 11 normal; the reversal of lever 3 locks lever 4 reversed, and so on. The conventional sign on a drawing for indicating the position of a switch is a triangular spot, as shown in Sketches *G* and *H*, Fig. 234. When the switch is closed or set for main track the vertex nearest the frog is against the through main rail (Sketch *G*), and when the switch is open or set for the turnout this vertex is against the inner turnout rail, as in Sketch *H*.

Plants with 10 active levers for the simplest case of interlocking a crossing of two tracks, working both derails in each track on one lever, with switch and lock movements, are frequently used, but in what is considered best practice the locking of the derails is by means of facing-point locks, each facing-point lock and detector bar being operated together and by a lever separate from that which throws the switch. In this arrangement there is one lever for the two derails and one for the two facing-point locks, in each track, besides eight levers for eight signals, making 12 working levers in the plant. Where detector bars are used at the crossing there is another lever, making 13 working levers, and requiring a 16-lever frame. Where facing-point locks are used it is necessary to reverse a lever locking up the derail before the home signal can be cleared. The home signal lever reversed then locks the lock lever reversed. The interlocking of a crossing on double track can be performed by the same number of levers, numbered in the same manner as those shown in Fig. 234, except that the home signals when reversed do not lock the home signals governing trains running in the opposite direction, as is the case on single track; on double track the two home signals governing trains in opposite directions on the same route are cleared at the same time. On double track it is usual to protect the crossing against reverse movements by means of a "back-up" derail located on each track as far beyond the crossing as the derail for direct movements is in advance of it. The position of these back-up derails is indicated by means of dwarf signals, which are locked in the normal position by reversing the home signal lever, as was explained for movements on single track.

Interlocking Machines.—Of mechanical interlocking machines in use in this country there are two different patterns, known as the Stevens and the Saxby & Farmer. Both of these designs, as now used, are improvements upon the early machines invented and first used in England. With the old form of Stevens machine the locking was accomplished by the initiatory movement of the lever, making it possible to bring a heavy strain upon the interlocking parts in case an attempt was made to throw a lever which had not been released. With the Saxby & Farmer machine the locking takes place preliminary to the movement of the lever, during the operation of unlatching the same, and the releasing is subsequent to the lever movement, while the lever is being latched up at the end of the stroke. This style of locking is known as "latch locking." On the improved Stevens machine latch locking is employed. The improvement of the Saxby & Farmer machine has been the substitution of dog and tappet for dog and "flop" locking and the use of a single tier instead of a double tier of locking bars. The interlocking machine shown in Fig. 219 is of the Saxby & Farmer design, as made by the Union Switch & Signal Co. The levers are spaced 5 ins. apart, and, lacking those omitted in the "spare" spaces, there are 92 of them in view. The levers are all pivoted to a long frame running lengthwise the building underneath the floor. But little more than half the lever appears in the view. The levers are L-shaped, being bent out at a right angle at the lower end and pivoted at the bend, with the vertical switch, signal or lock connection attached to the end of the arm. For the double wires of signals an extra arm, called a "tail piece," is bolted to the lever on the side opposite the bent arm, for attaching the back-pull wire. The lever is latched into a quadrant, like the reverse lever of a locomotive.

The locking of the levers is effected by two sets of bars at right angles to each other, working in combination, each bar of one of these sets being attached to and actuated by the lever latch. Starting with the lever, the latch rod carries a sliding block which works in the slot of a rocker centrally pivoted to the side of the quadrant into which the lever is latched. This slotted rocker or "rocker link" appears at the front of each lever, in Fig. 219, and by means of a link and crank its back end is connected to a horizontal "locking shaft" extending under and at right angles to the "locking board." This locking board is the horizontally arranged system of parallel bars appearing back of the levers, and consists of "locking bars," running lengthwise the machine or building, and other bars known as "cross-locks" which are seen lying across the locking bars at intervals. Each locking bar is driven longitudinally by a locking shaft, which, as above explained, is in connection with the latch of one of the levers through a crank, link and slotted rocker. The cross locks consist of notched bars

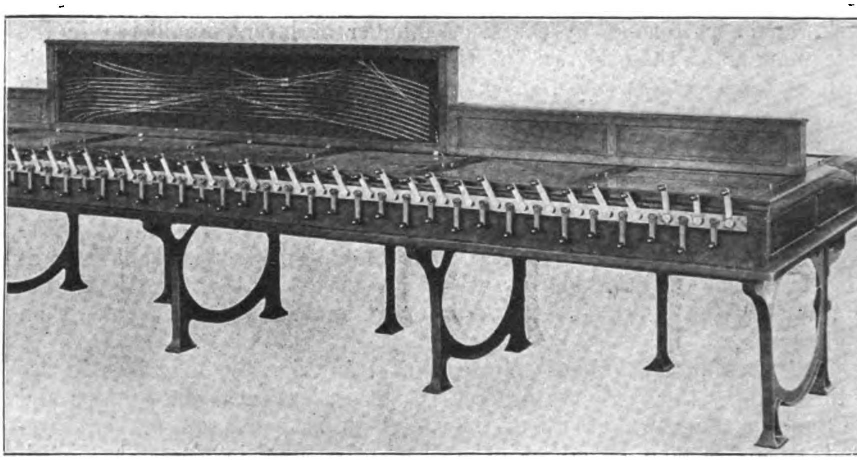

Fig. 235—Electro-Pneumatic Interlocking Machine (Front View).

or tappets, each of which is notched once for each lever to be locked. The motion of the cross locks is imparted by means of bevel-ended lugs, called "dogs," riveted to the locking bars, which engage with the bevel-shaped notches of the cross locks. When the operator starts to reverse a lever he pulls upon the latch handle, and, if the lever is not locked, the back end of the rocker is lifted, throwing a locking bar and locking such levers of the conflicting routes as are not already locked by some other lever. This locking is accomplished by the movement of the dogs on the locking bar into the notches of all cross locks which could be moved by the levers thus locked. In reversing the lever the rocker remains stationary, the radius of the slot in the same being equal to the distance from the sliding block on the latch rod to the pivot of the lever, the latch rod meanwhile being stopped against dropping down by the top of the quadrant. When the lever is thrown to the reverse position the latch spring forces the latch bar into its notch at the end of the quadrant, which acts to depress the end of the slotted rocker, throwing up the opposite end and imparting further longitudinal motion to the locking bar, which releases the lever to be thrown next in sequence.

On the Stevens machines made by the National Switch & Signal Co., some years ago and extensively put into service, the arrangement of the latch and rocker is the same as in the Saxby & Farmer machine just described, except that the rocker is lower than the top of the quadrant, being under the floor. The locking board is also under the floor, being arranged vertically on the frame of the machine. In the locking of this machine the rocker of each lever is attached to a tappet bar working vertically on the locking board, and the locking is by means of dogs attached to narrow bars working horizontally. Each dog is made longer than the distance between two tappet bars by the depth of a triangular notch cut in the tappet bar which it locks. The end of the dog is shaped to fit this notch, and when it slides into the same it leaves the other tappet bar free to move. In order to release one lever and lock up another—call them, for the purpose of illustration, levers 1 and 2, respectively—the notch in the tappet of lever 2 must be opposite the notch in the tappet of lever 1, which is engaged by the dog. Then by throwing lever 1 the beveled face of the tappet notch will force the dog over into the notch of the tappet of lever 2, locking lever 2 and releasing lever 1. On general principles the locking of the two patterns of machines is the same, the locking bars and dogs in the one case actuating the tappets (cross locks) and in the other case (National machine) the tappets actuating the dogs, which are attached to what would correspond to the locking bars of the Union machine. The arrangement of the Johnson machine is quite similar to that of the National, the only material difference being in the location of the rocker, which is pivoted to a bracket fastened to and moving with the lever instead of being attached to the frame of the machine, as is the case with the National.

The locking of the levers of the different power machines is by means of a mechanical locking board or "locking bed" arranged on the dog and tappet principle, as already described. Stated in a general way, the signals in each of the several power systems are operated by mechanisms of the same class as those which operate the switches. The interlocking machine of the electro-pneumatic system (Fig. 235) differs from a mechanical machine in having a crank and shaft in place of the upright lever and rocker. These cranks constitute the "levers" of the machine, those in the upper row usually operating the switches and those in the lower row the signals; although in some instances the two classes of levers are grouped, and intermixed between the two rows. The shafts turned by the cranks extend under and engage with the locking bars, as on a mechanical machine. The connection between each shaft and its locking bar is by means of a segmental pinion on the shaft and a rack cut in the bar. The locking is by locking bars, dogs and cross locks, as with a mechanical machine. In operating a "lever" the shaft across the machine is rotated about 60 deg., making electrical contacts at the rear end which close the circuit controlling the valves of the switch or signal cylinder. Figure 235 is a front view of part of a machine of this type, showing the operating levers and a miniature model of the tracks controlled. This model is formed of light brass strips, and the switches on the same, being in mechanical connection with the levers, on the back side of the vertical board, move in harmony with the switches on the roadbed, thus representing at all times the actual track connections. The working parts of the machine are enclosed in a wooden case with a glass top. A rear view of the machine with the casing removed, showing the half-size Saxby & Farmer improved interlocking and the electrical switches and indication attachments at the rear of the locking shafts, is presented as Fig. 236. Each switch consists of a section of hard rubber tube mounted upon a locking shaft, to insulate small brass bands which extend partly around the tubing and form contacts with springs bearing against the tubing. As the shaft is turned the brass strips connect the pairs of springs, closing the circuits in succession, and in the order in which the bands are arranged on the roller. As the electro-pneumatic system uses current at all times, whether movements are being made or not, the electrical supply is usually furnished by a small dynamo operated in connection with the air compressor plant, with storage batteries to maintain operation while the dynamo is not running. The electromotive force of the switch and signal circuits is usually 12 to 16 volts.

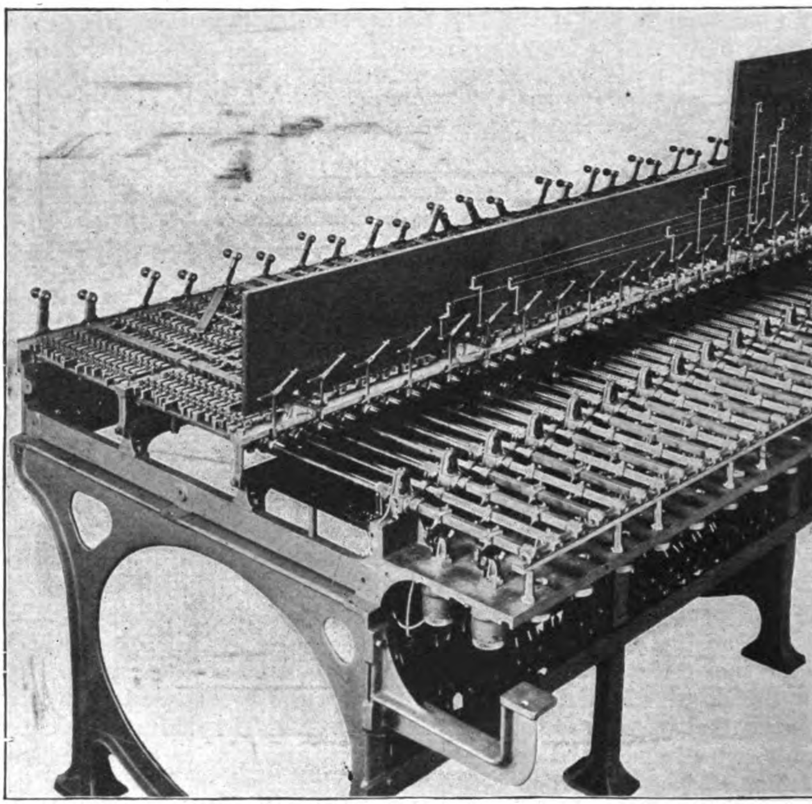

Fig. 236.—Electro-Pneumatic Interlocking Machine (Rear View, Cover Removed).

Each signal is operated by a cylinder of 3 ins. diam. and 4 ins. stroke, the valves admitting air to and exhausting it from the same being controlled by an electro-magnet. As the signal or semaphore arm is counterweighted to rest by gravity in the danger position the cylinder is single-acting only. Air is admitted to move the signal to safety, and when it is exhausted the counterweight or overbalance of the back casting brings the blade back to danger. To prevent the lever from being returned to normal in case the signal should fail to go to danger after the air is exhausted from the cylinder there is an electro-magnetic lock which engages the lever, upon making a partial stroke with the same toward normal. This lock is under the control of a circuit which makes contact with the signal movement. The failure of a signal to return to danger thus prevents the return of the operating lever to normal, and until this can be done the switches remain locked to safety and cannot be moved. The signal cylinder is sometimes placed high up on the pole and sometimes it is located under cover at the foot of a hollow iron pole, operating the signal by means of a rod passing up on the interior of the pole.

In the Standard or low-pressure pneumatic system of interlocking, the signal cylinders, which are attached to the poles, high above the ground (Fig. 226) are worked by valves and operating pipes of the same general style as those for the switches. The locking of the levers (Fig. 237) is by dog and tappet arranged on a vertical board similar to that in service in ordinary mechanical interlocking. At the switch there is a valve which controls the flow of air to the signal cylinder in such manner that the signal cannot be cleared until the switch is in its proper position. The mechanism for operating the signals is arranged to give an indication for only the normal or danger position of the signal. This indication is given in the same manner as the switch indication. It is considered unnecessary to require an indication for the signal in its clear or safety position.

In the Thomas pneumatic interlocking system the semaphore is brought to the normal or danger position by a counterweight. The control of the valve admitting pressure to or exhausting it from the working cylinder of the signal is by means of a piston of the equalizing type actuated by a sudden increase or decrease of pressure, as explained in connection with the operation of the switch cylinder. With the signal mechanism, however, there is only one controlling pipe. Normally the pressure in this pipe is 70 lbs. per sq. in., and to put the signal to safety it must be increased. As in the operation of the switch cylinder, this is done by manipulating a valve on the interlocking machine (Fig. 229) and admitting air at 80 lbs. pressure. To restore the signal to the normal position the valve is moved to establish communication between the controlling pipe and an empty reservoir, reducing the pressure again to 70 lbs., causing the controlling valve at the signal cylinder to shift and exhaust the air from behind the working piston, thus permitting the counterweight to take the signal to danger. When the signal is in its normal position the indication pipe contains air at maximum pressure, the indicating mechanism being

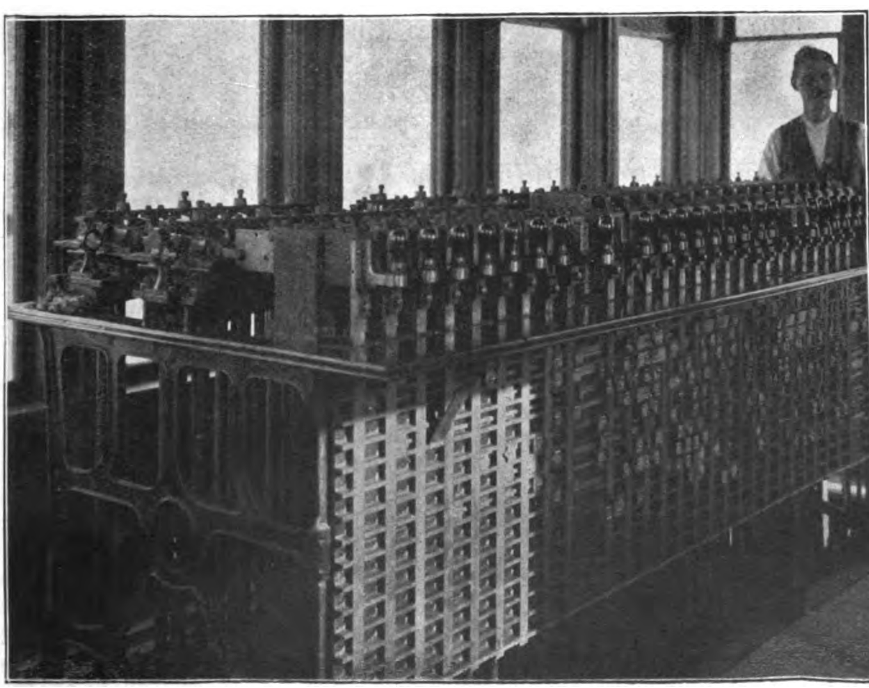

Fig. 237.—"Standard" Pneumatic Interlocking Machine.

so arranged that an increase of pressure must take place in the indication pipe before the lever operating the signal can be thrown full stroke or near enough to its normal position to release conflicting levers. When the signal is moved to clear, it actuates the indication valve, reducing the pressure in the indication pipe to 70 lbs. and permitting the lever to be thrown full stroke. Should the signal fail to respond properly to the lever movement this reduction of pressure would not take place, the lever could not be moved its full stroke, and hence all conflicting levers would remain locked. The time required for operating a signal 300 ft. away is about one second; at a distance of 1000 ft. it is three seconds, and at a distance of 2000 ft. 5½ seconds. It is not necessary to wait for pressure to equalize. By actual test a signal was handled 20 times per minute at a distance of 1000 ft. The levers of the Thomas machine are mechanically interlocked on the cross-locking principle.

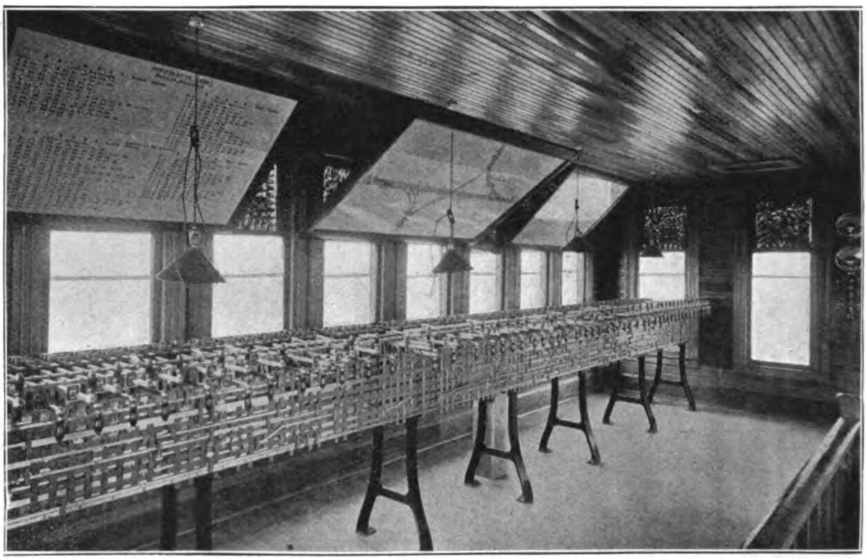

Fig. 238.—Taylor Electric Interlocking Machine (Casing Removed).

The "levers" of the interlocking machine of the Taylor electric system (Fig. 238) are straight steel bars with handles at right angles, pushed from the operator for the normal position and pulling straight out to the front when reversed. Each lever is connected with a circuit closer on the switch or signal circuit, as the case may be, and the levers are interlocked in the ordinary mechanical manner. The signal machine is worked by a motor of one-sixth horse power placed on a bracket fastened to the side of the pole some distance from the ground. To bring the signal from the normal or danger to the clear position the motor turns a sheave which winds up a chain and lifts the weighted end of the balance lever, pushing up the signal rod and throwing the semaphore arm down. As soon as the signal reaches the clear position a pole changer is operated, as in the action of the switch machine, closing the circuit through a brake magnet which holds the signal in this position and opens the main circuit to the motor. The pressure generated by the motor sends a current for the back indication to the interlocking machine and checks the momentum of the armature, the same as with the switch machine. To return the signal to normal the electro-magnetic brake is de-energized and the counterweight pulls the blade to the horizontal position. As the blade swings up to this position it operates a circuit closer which returns an indication to the tower. The indication current operates an electromagnet which works a releasing latch on the lever, permitting the stroke of the same to be completed. As with all other power machines, the first movement of the operating lever, either from the normal or the reverse position, is only partial stroke. Without the indication the full stroke of the lever and the release of conflicting levers interlocked with the same cannot take place.

Attention should be called to the practice of lighting signal lamps by electricity in connection with the Taylor system of electric interlocking. The generators and storage batteries used with this system afford special facilities for lights of this kind. Incandescent lamps of 4 candle power are generally used, and besides the signal lamps the lamps on switches in near-by yards, thrown by hand stands, are sometimes lighted from the same source. The dynamo for charging the storage batteries for a plant of this kind is usually located in the first story of the tower, or in a small building outside, and is driven by a gasoline engine attended to by the tower man, it being necessary to keep the charging plant running only a small portion of the time. Batteries in sets of 55 cells each, supplying current at 110 volts, is a common arrangement. It is also customary to arrange the connections of the dynamo circuit so that the interlocking machine may take its supply of electricity direct from the generating plant instead of from the storage battery. By this arrangement there is provision for maintaining the plant in operation in case it should become necessary to temporarily cut the battery out of circuit for repairs. In large plants it is usually arranged to have two sets of generators and batteries, each of which has a capacity sufficient for operating the plant.

The machine shown in Fig. 238 has a 136-lever frame and is 22 ft. long. It has 51 levers for operating switches and derails, 55 signal levers and one lock lever, the switch levers being disposed in the upper row and the signal levers in the lower row. There are two sets of storage batteries of 55 cells each, having a capacity of 150 ampere-hours each. There are duplicate generating sets, each consisting of a 2-k. w. dynamo and a 5-h.p. gasoline engine. In lieu of detector bars at the crossing of the tracks controlled from this plant track circuits 400 ft. in length are used; that is, they extend 200 ft. each side the crossing in each track, or nearly to the derail. This arrangement prevents the opening of a derail when an engine or short train is anywhere between the derails on either side of the crossing, and gives better protection than the ordinary arrangement of crossing bars with mechanical plants, where a detector bar 40 to 50 ft. in length is used on either side of the crossing to prevent opening a derail when an engine or short train is standing upon or moving over the crossing. The conducting wires of the switch and signal circuits are carried in wooden trunking, supported just above the surface of the ground on stakes set about 8 ft. apart.

Auxiliaries.—A safety device known as "electric locking" is frequently applied to an interlocking system to prevent the derail of a route being opened in front of a train after it has passed the distant signal set to clear. Unless some protection of this kind is afforded derailments may sometimes occur, for instances have been numerous where the operator took the home signal from a train and opened the derail when the train was so near that a stop could not be made before being derailed. The explanation of such performances is that an operator will sometimes forget, momentarily, that a train has entered the interlocking region, and out of confusion or while in a sleepy condition may take the signals from this train and give them to a train on a conflicting route. Electric locking is also a check upon an engineer who goes off at the derail and claims that the operator "took the rail" from him after passing the distant signal at clear. The mechanism of electric locking consists of electro-magnets arranged on the locking board in position to engage with the locking bars of the derail or switch levers or the lock levers. Normally the armature bars of these magnets are held up, but when a distant signal is cleared the circuit through the lock is broken, de-energizing the magnet and dropping the armature, which engages with a lug on the locking bar and thus locks up the derail lever. To prevent the operator from getting at these locks to lift an armature, prematurely, each of them is enclosed in a heavy case the cover of which is secured by a padlock. In this manner the control of a route is taken out of the hands of the signal operator after the signals have been cleared for an approaching train, and cannot be recovered until the train has passed over the crossing or out of the interlocking.

The circuits controlling these magnets are arranged in various ways. Sometimes circuit breakers are attached to the signal levers, so as to open the circuit when the lever is reversed, and sometimes the circuit breaker is operated by the blade of the distant signal. In interlocking practice the distant signal is returned to the normal or caution position as soon as it is passed by the train for which it is cleared, and the usual arrangement to prevent the locking circuit from being restored when this is done is a track circuit between the distant and home signals. When a train is on this circuit the armature of the relay breaks the circuit through the locks. As soon as the train passes the crossing or the derail beyond the same a track circuit arrangement restores the lock circuit, lifting the latches and releasing the derail levers. Others arrangements are described in papers read before the Railway Signaling Club: one by Mr. W. H. Elliott, Nov. 12, 1895, and another by Mr. V. K. Spicer, May 12, 1896 (The first-named paper was published in the Railway Review for Dec. 7, 1895, and the last-named in the issue for May 16, 1896. A discussion of Mr. Spicer's paper was published in the issue for July 25, 1896.)

To provide for unlocking the machine in case a train should stop within the interlocking limits, or the track circuit become short-circuited, or after trying the levers during bad weather to see if the system is in working order; or, in event of delay to the train for which the route is set, to give right of way over the crossing to a train on another route, a releasing circuit with a switch in a box under a glass cover is sometimes arranged. In order to close the circuit to release the locks it is necessary to break the glass, so as to get at the switch, thus leaving a record of the instance of irregular working, the occasion for which the operator is supposed to explain. Numerous other devices have been used for the same purpose, such as a slow-motion hand releasing screw at an inconvenient point, a releasing button located down stairs or at some distance from the operating room, etc., the idea being to interfere with hasty action and cause the towerman to think of what he is doing, in case his intention is suddenly decided upon, as when awakening from sleep, etc. The tendency with all these special releasing devices has been a too frequent use of the same, with resulting carelessness and disregard of the purpose of electric locking, operators in many instances going so far as to rig up secret circuits, jump wires etc., in order to work the release without special effort.

Time Locks.—The difficulties with the working of electric locks under certain conditions have to some extent led to the use of time locks. The purpose of the time lock is to prevent, for a desired interval of time, the opening of the derail after the home signal has been set to danger. One style of time lock consists of a vertical rack bar placed in engagement with some gear wheels under the control of an escapement. This rack bar is attached to the home signal lever, and controls a lock on the derail lever in such a manner that the derail lever cannot be moved from its reversed position except while the rack bar is down. In reversing the home signal lever, or when setting it to clear, this rack bar is raised, and is not released from the raised position until the home signal lever is set to danger. Upon being released the bar drops by gravity, the gradual descent being timed by the escapement mechanism, which can be set to work to any desired interval of time. At the end of this interval the rack bar reaches its normal position, releasing the derail lever. In some instances this interval corresponds to the time required for a fast train to pass from the distant signal to and over the crossing, and in other instances it is made to correspond to a similar transit of a train running at an average speed or at slow speed. Another style of time lock is operated pneumatically. It consists of a cylinder and piston with a quick-acting valve operating for the motion of the piston in one direction and a small leak hole which permits atmospheric pressure to gradually return the piston to normal position after being forced up by the home signal lever, thereby forming a partial vacuum at one end of the cylinder. The return of the piston releases the lock lever or derail lever. Still another time-lock mechanism which is attached to the levers and locking in the same manner, and operating quite similarly, is a hydraulic device in which a liquid is used instead of air to oppose the quick return of the plunger rod after being released by throwing the home signal lever to normal.

One situation where electric locking or time locks could be particularly serviceable, and where one or the other ought to be applied, is at the end of double track. Bad collision wrecks have happened at the end of double track through the confusion of switch tenders, who, being suddenly seized with an impression that the switch was set wrong, have been known to throw the switch for the second track immediately in front of a fast passenger train, resulting in collision with a train standing on second track. A safe way to operate such switches would be to have a distant signal on the single track interlocked with the switch stand, and then have the stand controlled by a track circuit and electric lock or by a time lock.

Bolt Locks.—Another safety device is an arrangement to prevent the clearing of the home signal in case the switch or derail should fail to close properly or fail to move at all, as might happen if the connection should break. It is known as a bolt lock, the usual form of which consists of two flat bars sliding edgewise in guides at right angles to each other, one bar being connected to the switch and the other to the signal wire or pipe line; each being so notched that when the switch is closed and the signal at danger either bar is free to move, but the movement of one locks the other. The arrangement is shown in Fig. 222 in connection with a switch and lock movement, the switch bar of the bolt lock being an extension of the lock rod. In the position shown the signal is locked to danger. Should the switch now be thrown and the point rail not move properly up to its place the notch in the switch connection will not come in line with the bar on the signal connection and the signal cannot be moved. The notch in the signal connection is long enough to allow some latitude of adjustment due to expansion or contraction of the wire, stretch, etc., but will not permit any considerable movement of the signal wire. The connection to the switch being short and rigid, the width of the notch in that is made to correspond to the thickness of the bar on the signal connection. When the switch is properly closed and the signal set to clear, the bolt lock then locks the switch, the latter then being locked by two devices—the switch and lock movement and the bolt lock. Should a facing-point lock be used and the switch connection break, the switch lever might be thrown without moving the switch, in which case the lock plunger would enter the same hole and lock the switch in the wrong position, releasing the signal lever, so that the signal could be cleared without closing the switch. With the bolt lock such a misplacement cannot occur, for, as above explained, when the switch is open the bolt lock locks the signal to danger independently of the interlocking of the levers on the machine.

To prevent a disconnected switch from being locked in the wrong position the Michigan Central R. R. uses coiled springs acting against lugs on the head rod, to throw the switch away from the stock rail as soon as the lock plunger is withdrawn, thus preventing the plunger from again entering the lock rod. On this road bolt locks are used on distant as well as home signals, where there are facing-point switches and derails without facing-point locks. This practice is to guard against clearing the distant signal in case the wire which pulls the home signal should break between the bolt lock and the lever. A form of bolt lock differing from that above described consists of a lock rod on the switch connection and a plunger on the signal connection.

Selectors.—Another contrivance that has been much used in interlocking, and which deserves mention in any general treatment of that subject, is the selector. This is a device for operating two or more signals, one at a time, by the same lever, the mechanism being so arranged as to automatically connect the particular signal which governs the route for which a switch has been set. The collection of signals that can be worked by a selector must be such that but one of them need ever be cleared at the same time; as, for instance, the signals governing a succession of branch routes leading from a single track. The purpose of the device is, of course, to reduce the number of levers on the interlocking machine. Selectors are made in several patterns, but the principle involved in the design of all of them is to terminate the connections from the several signals and the connection from the signal lever in one place, to which connections are run from the switches. The arrangement is then such that the setting of the switch for any one of the routes brings the connection from the signal lever into engagement with the connection to the signal governing that route. A common form of mechanism for wire-connected signals is a "hook gear," each signal being connected to a hook-ended bar working between guides on the selector frame, the hook being pulled by a shifting bar or slotted plate connected to the signal lever in the tower, according as the setting of the switch on that route puts the two parts (the hook bar and the lever connection) into engagement. One arrangement for selecting the hook for the proper signal is a driving bar operated by the pipe line to the switch, this driving bar carrying lugs set to throw every hook bar out of engagement except the one to be operated. Another arrangement is a shaft with cam lugs, which, when turned by the switch connection, throw all but the proper hook out of adjustment. A common form of selector for pipe-connected signals consists of slide bars connected to the signals and working in guides on the selector casting, with a shifting slide bar connected to the signal lever. By means of a cross bar in connection with the switch the shifting bar is moved into position to abut against the slide bar of the signal governing that route, and when the signal lever is thrown it pushes the signal to clear, instead of pulling it, as in the case with the selector for wire connections. Such a selector is adapted to be used directly opposite the switch involved in the combination, and the cross bar is usually connected directly to the lock rod of the switch, in which case the selector is made to act also as a bolt lock.

Selectors are known as one-way, two-way, three-way, etc., according to the number of switches connected with it and not by the number of selector rods or signals. It is not usual to make selectors larger than eight-way, and in general practice the size or capacity is seldom as large as that, the preference being with selectors for not more than two signals. The general tendency, however, is to abolish the use of selectors, as with switches less than about 700 ft. from the tower the cost of the selector is as much as that of an extra lever and line of pipe.

To conclude, it may be stated that as far as may be feasible, grade crossings should not be so located that trains on either track, in the vicinity of the crossing, will have to approach it on a considerable down grade. Wherever a difficulty arises in this respect, it is better, if the expense be not too great, to avoid crossing at grade altogether; but if not, then an interlocking plant with derailing switches should by all means be installed for the crossing.

Subways for Interlocking Pipes and Wires.—To carry a large number of interlocking pipes under a track and maintain satisfactory support for the track requires special construction, particularly in the case of lead-out connections at the tower, where the pipes are close together and a large number of them cannot easily be spread apart to dodge the ties. As such pipes are usually spaced 2½ or 3 ins. centers, any support for the track must be arranged to occupy as little space as may be practicable between the pipes. It is evident that if the track support consists of wooden ties the space between each two ties permits of room for only a few pipes, so that in case a large number of pipes are to be laid they must be arranged in groups corresponding to the tie spacings. In case the general course of the pipe line runs diagonal to the track at such an angle that the ties cannot be conveniently skewed to conform thereto, the pipe line is broken by bell cranks and extended squarely across the track. To get room for interlocking connections it is quite customary to lay the ties widely spaced, and to support the rail over these wide spacings in case of breakage it is sometimes the practice to lay a rail on side on either side of each running rail, as in Sketch *K*, Fig. 234.

There are two ways of reducing the space occupied by the immediate supports for the rail without reducing the bearing area on the ballast. One arrangement, illustrated as Plan *A*, Fig. 239, is to use large ties and depress them far enough to carry the rails on small pieces which afford more space for the pipe lines. In order to obtain room for tamping, the rail is supported on 4x5-in. oak strips spiked to the tops of 8x10-in. ties on flat, Servis tie plates being used on the 4x5-in. strips. This arrangement affords good support for the rail and the pipe lines are separated widely enough in the middle of the spacing to permit the tamping bar to be used. Another and more expensive arrangement is to use heavy or closely spaced under supports, with I-beams to take the bearing of the rail. As the thickness of the I-beam web is less than the clear spacing between the pipes, practically all of the space is available for the cross connections. One arrangement of this kind is shown as Plan *B*, Fig. 239, and another as Fig. 240. In the latter case an 8x10-in. oak sleeper is placed longitudinally under each rail, clearing the rail base by 8⅛ ins. The immediate supports for the rails consist of steel ties, three in number, placed across the sleepers and spaced 16 ins. centers. Two 8x10-in. ties serve as bulkheads. The bed sleepers are held rigidly together by 1-in. iron rods. The pipes are led across the track diagonally through the four

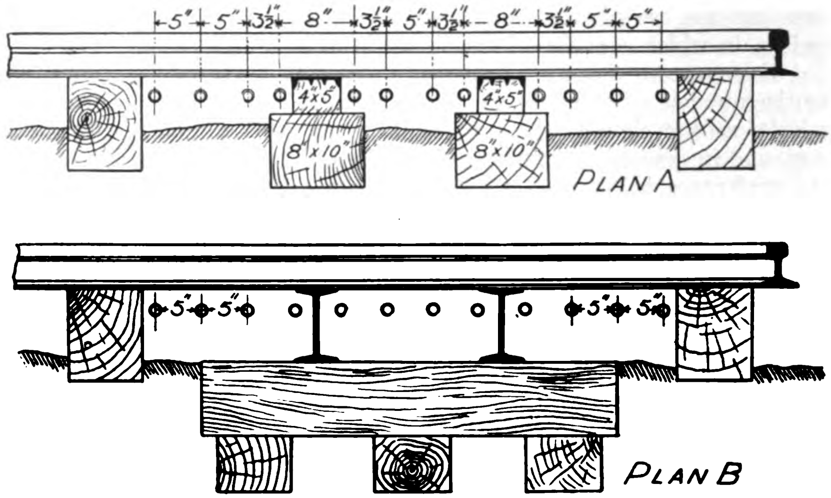

Fig. 239.—Cross Connections for Interlocking, C., M. & St. P. Ry.

openings between the two bulkheads. The rails are secured to the steel ties by clips and $\frac{7}{8}$-in. bolts. The steel tie consists of an I-beam built of an 8x$\frac{1}{2}$-in. web plate, with two 3x4x$\frac{1}{2}$-in. angles for the top flange and two 3x4x$\frac{3}{8}$-in. angles for the bottom flange. The top flange is cut away on one side of the tie, except underneath the rail base, where it is needed as a means of securing the rail clip. Thus practically all of the 64 inches of space between the bulkheads is available for pipes, since the web thickness of the tie support is less than the distance between the pipes.

Where the pipe lines cross the track at a small angle the plan of skewing the ties becomes impracticable, and a subway under the ties, as they lie squarely with the rails, affords the most substantial construction. Figure 241 shows the plan of such a subway for 25 lines of pipe and 10 signal wires. A course of 8x16-in. timbers 10 ft. long, spaced 8 ins. in the clear, was first laid to form a platform, to which were spiked four 8-in. I-beams, each 45 ft. long, spaced 2 ft. 6 ins. centers, forming three passageways for the pipe lines and signal wires. The platform timbers, which are laid on a bed of gravel, are indicated in the engraving as grained wood. In order to vary slightly the angle of the subway, so as to permit I-beams of the same length (45 ft.) to be used throughout, the

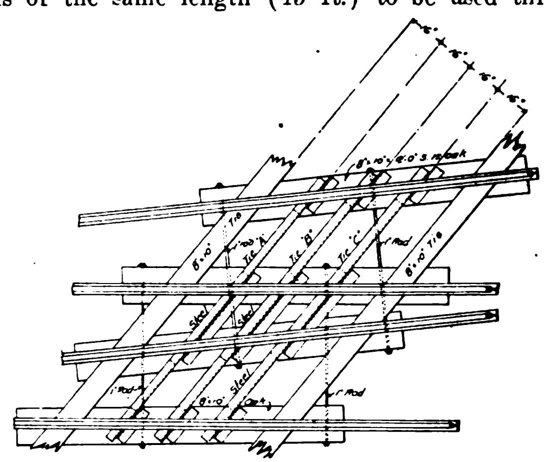

Fig. 240.—Interlocking Cross Connection.

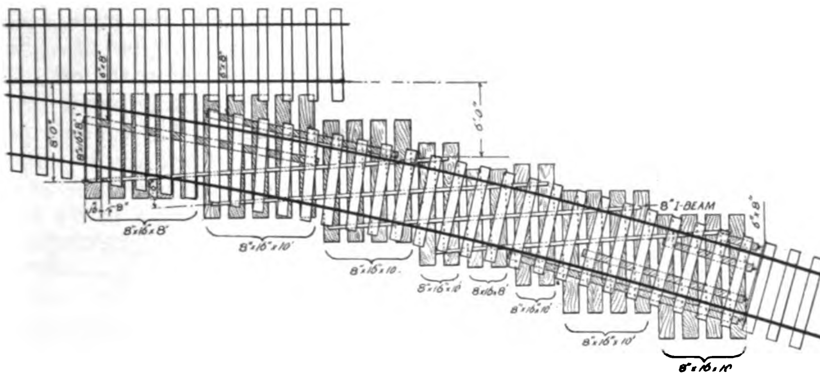

Fig. 241.—Plan of Subway for Interlocking Pipe Lines, C., M. & St. P. Ry.

pipe lines are slightly curved at this point, and the subway does not extend exactly parallel with the main track, as appears from the dimensions in the figure. The track ties supporting the rails are placed squarely across the track and laid upon the I-beams, being supported by 6x8-in. stringers laid upon the platform timbers, where the ties do not get a full bearing upon the I-beams. The general appearance of the subway is shown in Fig. 242, the photograph being taken before the pipes leading through it were boxed over, according to the usual custom, to prevent interference from snow.

The plan of using bell cranks and crossing the track with sections of pipe between the ties usually requires a change in the direction of the lead, with some lost motion in the cranks and their connections; extra length of pipe by reason of the indirect route, and extra resistance from the operation of the bell cranks, and also sometimes from the curve in the lead which is needed to resume the general direction. The construction of a subway of I-beams and timbers requires a good deal of excavation and is expensive. On the Lake Shore & Michigan Southern Ry. use is made of pipe conduits at certain points where interlocking pipes pass under the track. They are easily laid and can be run direct. The use of this style

Fig. 242.—Subway for Interlocking Pipe Lines, C., M. & St. P. Ry.

of underpass is applicable in all situations, but the convenience is especially noticeable where the crossing of the leads is diagonal to the track. Each line of interlocking pipe is carried in a 2-in. conduit pipe filled with crude kerosene oil, with stuffing boxes at the ends to retain the oil. The section of interlocking pipe which works through the stuffing box is turned in a lathe to a smooth surface $1^9/_{32}$ ins. in diameter. The conduit pipes are laid about 12 ins. beneath the ties, and the couplings are of just the right diameter to permit the pipes to be laid to the regular pipe carrier spacing, thus avoiding any difficulty in transition from one to the other.

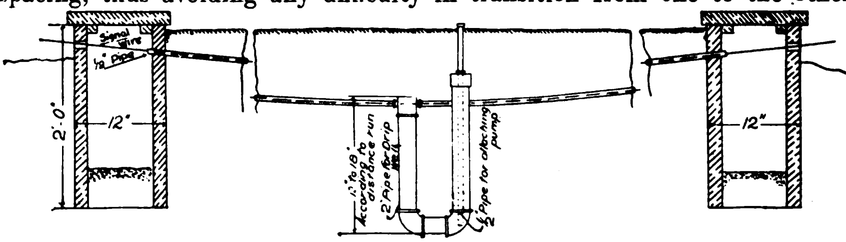

Fig. 243.—Conduit for Signal Wires Under Streets, L. S. & M. S. Ry.

Figure 243B is a photographic view of one of these pipe conduits, the picture at the left showing the stuffing boxes and the capped tubes through which the pipes are filled with oil.

In carrying signal wires under a track they are usually put through the spaces between the ties and left uncovered. As such wires extend considerable distances from the tower they must frequently be carried under public highways or city streets, and at such places a substantial pipe culvert or other subway is desirable. A conduit arranged for the purpose and designed to protect the wires from corrosion is illustrated as Fig. 243. There is a box at either side of the street about 12 ins. square and 2 ft. deep, into which is led one end of a half-inch pipe carrying the signal wire. This pipe sags, and is lowest in the middle of the street, at which point it is joined to a drip well consisting of a piece of 2-in. pipe bent U-shape. Extending upward from the bottom of the "U" there is a short piece of half-inch pipe, capped and made accessible from the street. After the signal wire has been led through its protecting pipe all the pipe is filled with oil from the connection in the street, the oil being permitted to flow to the ends of the pipe in the boxes. During wet weather water follows the signal wire into the protecting pipe and, being heavier than oil, finally seeks the bottom of the U-tube. From time to time the half-inch pipe in the street is opened and a pump is attached and worked until oil

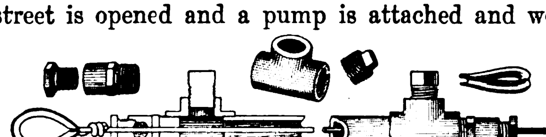

Fig. 243 A.—Wrigley Signal Wire Conduit, Erie R. R.

appears, which indicates that all the water has been removed. The Wrigley conduit for signal wire protection (Fig. 243A), used on the Erie R. R., consists of a line of pipe with stuffing boxes at the ends and T-connections with removable plugs for filling the pipe with crude oil.

84. Switch Protection.—It occasionally happens that a switch is used and carelessly left open to main track, and, if there be no warning, great danger awaits high-speed trains or heavy freight trains approaching in the facing direction. On the whole, railroad companies have been slow to adopt means of protection against such occurrences or the dangers incident thereto. One of the first roads to put into service a contrivance for preventing a switch from being left open to main line after the departure of the train that used it, was the New York, New Haven & Hartford R. R. The arrangement in this instance is a small round house built over the switch stand at facing-point switches, and so devised that a person opening the switch cannot emerge from the house without first throwing the switch to main track and locking it in that position. The doors of these "switch houses" are pivoted to a center post, to revolve like a turnstile, and are painted one side red and the other side white. As one passes into the house the door is reversed and the red side is turned outward. A flat rod in connection with the switch points passes through a slotted casting under the door, and the attachments are such that until the door is reversed the switch is held by this lock rod and cannot be thrown. The opening of the switch then locks the door, and the only way to get out is by closing the switch and locking it, as stated. The house is not provided with glass windows, but on the track side there is a hole through which the man inside may put his head and watch the train movements. While these switch houses have been in satisfactory service on several divisions of the western district of the road since about the year 1882, the scheme has not been adopted to any great extent elsewhere, probably because the use of the same ties up one of the train crew for the time being.

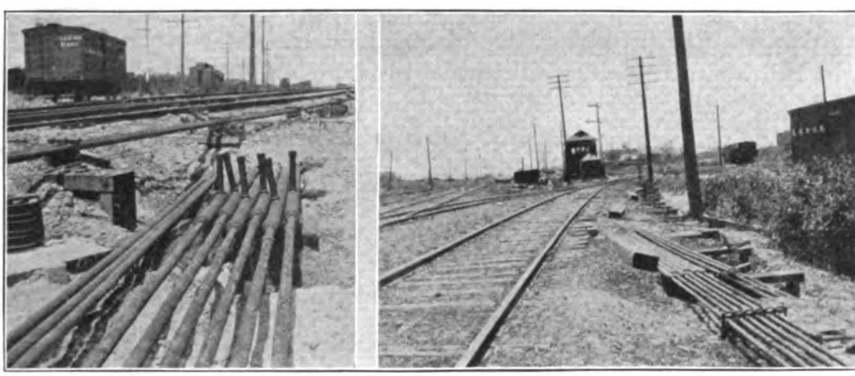

Fig. 243B—Pipe Conduits for Interlocking Pipe Lines, L. S. & M. S. Ry.

The means of protection most widely adopted is a signal displayed at a distance which indicates the position of the switch. It has been well demonstrated that, in the absence of other means of protection, the safety of high-speed trains at facing-point switches requires that advance warning be given of the position of the switch, and particularly at outlying switches where the switch stand or switch light cannot be seen at a good distance away. It has heretofore been pointed out that the high target affords some protection on straight line which is not obtained with the target on switch stands of ordinary hight. On curves, however, any signal at the switch cannot usually give a desirable measure of protection. For this reason it is found necessary to place a signal or signals at points distant from the switch, the same being operated either by the movement of the switch or in connection therewith. The signal most extensively employed at distant points is the semaphore arm operated on a high pole, and experience has shown that the best practice is to operate switch and signal by separate levers. As it is obviously important that the lever operating the switch should not be thrown independently of the lever operating the signal, it is usually arranged to have these levers interlocked in such manner that the switch lever cannot be thrown until the signal lever has placed the signal to danger. This is the essential feature in all modern switch signaling at a distance, the main point of difference in the various devices being in the form and operation of the levers and the method of locking the switch points.

Perhaps the simplest device for interlocking the movement of a switch with a distant signal is a double-lever ground stand, with the signal lever bent to extend across the switch lever, as shown in Fig. 244. In locking the switch the lock then secures both levers. It is plain, however, that this arrangement does not insure that the points have been thrown entirely home, before the signal is cleared, neither does it necessarily hold the switch lever in position for main track until the signal lever has been thrown entirely over to the position placing the signal at danger; that is to say, the switch movement may begin as soon as the signal lever is lifted. A simple device used with facing-point switches on the Chicago & Northwestern Ry. is a horizontal shaft carrying two lugs which are revolved into position straddle the point and stock rails for the closed position of the switch, as in Fig. 141, and this shaft carries a sheave to which wires are attached for working a distant signal. Before the switch can be opened the shaft must be turned down, thus placing the distant signal at danger, and the signal cannot be cleared until after the switch has been closed.

Figure 246 shows a double ground lever stand for operating one or two switches in connection with one or two signals, the levers being so interlocked that the signals cannot be cleared until the switch lever is thrown

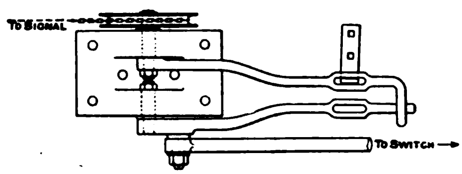

Fig. 244.—Switch and Signal Ground Lever.

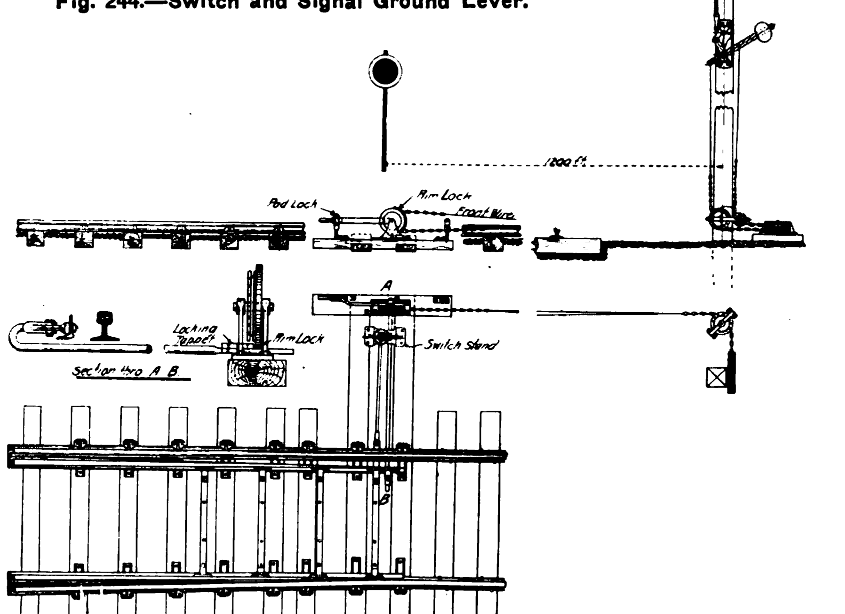

Fig. 245.—Distant Signal Device for Outlying Switches, C. & N. W. Ry.

for the main track and, conversely, so that the switch lever cannot be moved from the main track position until the signal lever has been thrown entirely to the danger position. It is in use on a large number of roads, including, among others, the Chicago, Rock Island & Pacific, Chicago & Northwestern, Michigan Central, Atchison, Topeka & Santa Fe, Wisconsin Central, Pittsburg, Fort Wayne & Chicago, Boston & Maine, Boston & Albany, New York Central and the Central R. R. of New Jersey. The arrangement is what is known as butt locking, in which two locking dogs or pins follow in grooved discs and are actuated by springs, so that the action of one lever locks the other lever fast in each position of the switch. It will be observed that a projecting lug on the signal lever extends over the switch lever and straddles the lock bracket, so that the interlocking cannot be strained by an ignorant or malicious use of the switch lever. As it appears in the figure, the switch lever operates two switches and the signal lever two signals, as at a crossover. In the case of a misadjustment of the switch connection it would, but for another device, still be possible for the signal lever to be freely operated in spite of the fact that the switch points might not be thrown entirely home. This danger is overcome by the use of a flat bar connected to the switch rails and adapted to engage

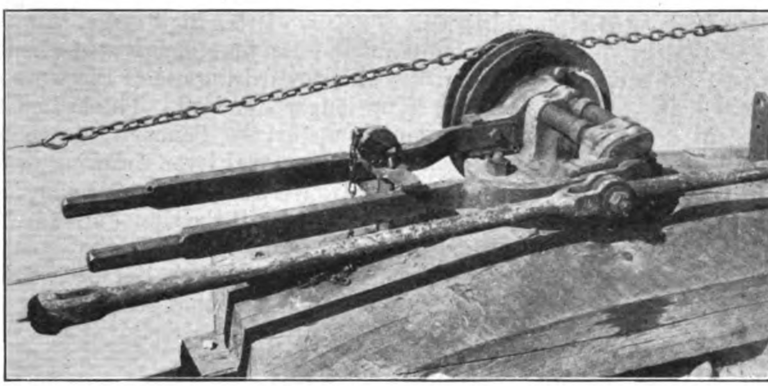

Fig. 246.—Double Interlocked Ground Lever Stand.

the wheel of the signal lever in a way which insures that the switch points shall be tightly closed for main track before the signal lever can be moved and the signal for that track cleared. The device is so strongly made that it will prevent the switch from shifting from its intended position in event the connection with the switch lever should break.

In switch protection work the largest practice is to employ two signals—home and distant—with a lock rod so engaged by the interlocking mechanism that the signal lever cannot be put in the clear position until after the switch points have been thrown entirely home. Figure 245 shows a device used on a number of roads in connection with facing points, designed to use with existing switch stands of any pattern. As shown in plan and elevation, the signal lever operates a sprocket wheel which actuates a chain connecting with the wires operating a semaphore signal placed 1200 or more feet distant. On the sprocket wheel there is a rim, called the "rim lock," extending half way around the same. Attached to the near switch point there is a lock rod which extends under the sprocket wheel, and on this rod there is a "locking tappet" which abuts against the rim lock in every position of the signal lever except that in which the signal is moved entirely to danger. It is plainly seen, therefore, that the switch stand cannot be thrown to open the switch until after the signal has been placed to danger. Conversely, the locking tappet will not permit the rim lock to pass and the signal lever to be thrown to clear until after the switch stand has been thrown entirely home to the main track position of the switch. The semaphore blade is operated through a device on the pole which allows for two inches of expansion and contraction of the signal wire. This is considered an effective substitute for a wire compensator.

The arrangement employed on the Michigan Central R. R. and the Pennsylvania R. R. is a distant semaphore signal operated by double wire from a signal lever at the switch. For a home signal the Michigan Central uses a semaphore also, but the Pennsylvania uses in some places the semaphore and in others only a low combined target and lamp (Engraving *F*, Fig. 139) attached to the switch. The distant signal lever is attached to a horizontal shaft which works a "cam lock" on the switch point rail. This device consists of a lug which is turned up by the shaft against the inside flange of the point rail in its normal or closed position. It thus acts as a stop which will not permit the switch to be thrown until the distant signal has been moved to danger, and after the switch has been opened the lug is under the base of the point rail and the signal lever cannot be moved to clear the signal until the switch has been properly closed. Formerly a high revolving target, arranged on a braced stand, as in Fig. 247, was used a good deal on this road. The use of this high target was due to the installment of apparatus at points where that device was already in service. The tendency, however, has been toward the use of the semaphore, and the high revolving targets are no longer standard. The switch stand shown in the figure is a device gotten up by the Pennsylvania company, and consists of a ground switch lever with a signal lever throwing over and across the same. The two levers are controlled by a disc interlocking device which prevents the switch lever being thrown until the signal lever has been thrown into its extreme position for danger; and, vice versa, the signal lever cannot be moved to clear the signal until the switch has been properly closed. The Michigan Central road employs the double ground lever inter-

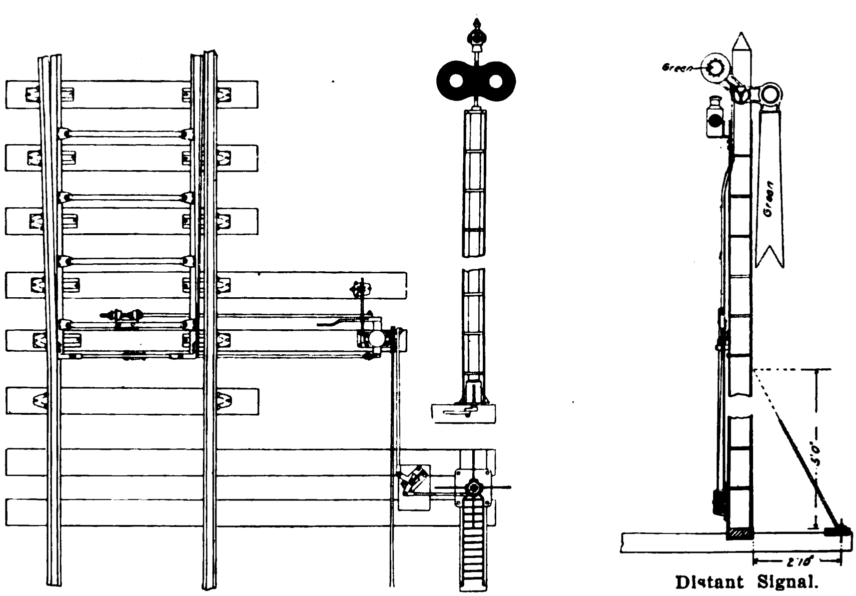

Fig. 247.—High Switch Target and Distant Signal Operated by Disc Interlocking Ground Lever Stand.

locked stand shown in Fig. 246, just described. The Chicago Terminal Transfer road uses apparatus similar to that of the Pennsylvania company, with semaphores for both home and distant signals. The interlocking stand is placed at the foot of the semaphore post instead of a few feet therefrom, as it appears in Fig. 247.

In place of the ground levers the device operating the switch and signals sometimes consists of a framed interlocking machine with upright levers, placed on the ground near the switch. On the Lehigh Valley R. R. facing-point switches are operated in connection with distant signals by a machine of this description. There are three levers: one operating a signal distant about one-half mile from the switch, another operating a signal some 500 or 600 ft. distant, and another operating the switch and a target actuated therewith. The location of the two distant signals in respect to their distance apart, and from the switch, depends upon the physical conditions respecting curvature, adjoining obstructions, etc. In operating the switch the distant signal lever must be thrown first, placing that signal at danger, or in what corresponds to the "caution" position of a distant signal in crossing interlocking. This releases the near signal lever, which is thrown next, thereby releasing the switch lever, which is thrown last of all, setting the switch and placing the home signal at danger. In closing the switch for main track the reverse order of operations must be followed; namely, the switch lever is thrown first, then the near signal and finally the distant signal.

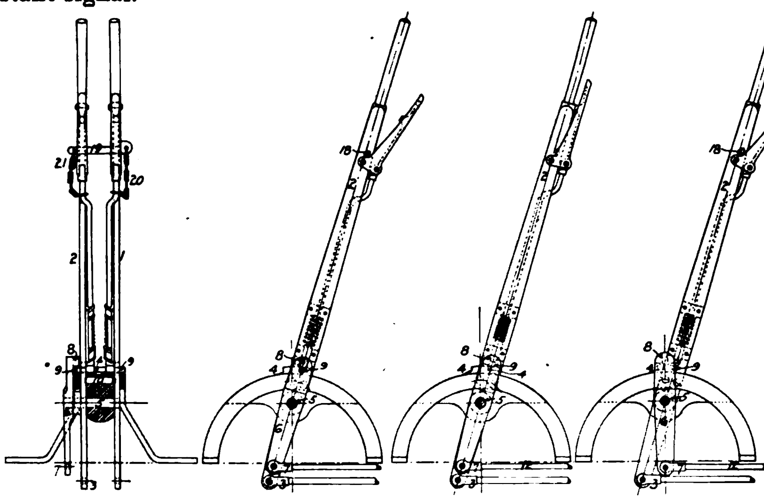

Fig. 248.—Interlocking Switch and Signal Stand, N., C. & St. L. Ry.

On the Nashville, Chattanooga & St. Louis Ry. ground-frame stands with interlocking levers are extensively used to work distant signals in connection with facing-point switches, and by means of an auxiliary lever a stiff connection is had while the switch is being thrown and a spring connection is maintained at all times while the switch is locked. This stand was designed by J. W. Thomas, Jr., general manager of the road, and is shown in Figs. 248 and 249, various parts of the apparatus and different positions of the levers being denoted by the sub-figures 1 to 7. By making a stiff connection while the switch is being operated, it must be thrown home before the switch lever can be latched; and the stiff connection being broken when this lever is latched, leaves the switch free to move to the proper position, against the Lorenz spring, should a train trail through when it is wrongly set. The stand has two levers for manipulation, lever 1 being used to operate the distant signal. Figure 1 is a rear view. Figure 2 is a side elevation showing lever 2 and auxiliary lever 6 in their normal position. If desired, a third lever can be added to operate the switch target 30, Fig. 5. Ordinarily, however, the switch target is coupled direct to the points, as shown in the figure. Levers 1 and 2 are latched in a quadrant at 4 and are pivoted at 5. On pin 5 is also pivoted the short auxiliary lever 6. The lower end of this lever is attached to the switch connection at 7, this connection being a rigid one. When latch 9 of lever 2 is raised (Figs. 3 and 7) it engages with notch 8 on lever 6 and a rigid connection is established between the switch lever and the switch. If lever 2 is now reversed and there should be an obstruction between the point and stock rails it would be impossible to latch the lever in its reversed position. The lower end of lever 2 is connected with the points by spring rod 14 (Fig. 5). Should a train trail through the points while they are wrongly set they would be moved over and the Lorenz spring 15 would be compressed; and as the upper end of auxiliary lever 6 would be disconnected from latch 9 of lever

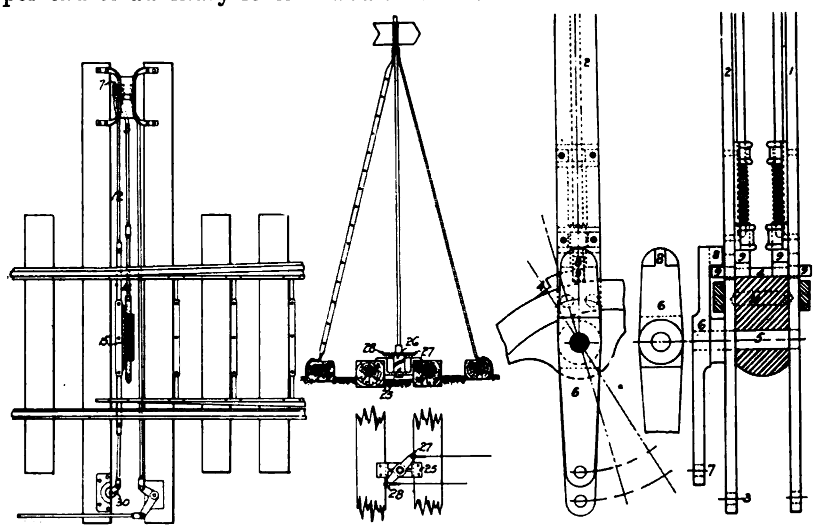

Fig. 5 Fig. 6 Fig. 7

Fig. 249.—Interlocking Switch and Signal Stand, N., C. & St. L. Ry.

2, lever 6 would be free to move and would assume the position shown in Fig. 4. After the train has passed, spring 15 will force the switch back to its place and lever 6 will assume its original position, as shown in Fig. 2. It is thus seen that when lever 2 is latched in either its normal or reversed position, there is but one connection with the switch; i. e., a spring connection; but the moment lever 2 is unlatched, there are two connections between the stand and the switch—one a rigid or stiff connection and the other a spring connection.

Levers 1 and 2 are interlocked by means of pointed pin 10, Figs. 1 and 7. Each lever has a countersunk hole into which pin 10 engages, it being so arranged that it is impossible to move lever 2 from its normal position until lever 1 is fully reversed, the reversal of lever 1 putting the distant switch signal at caution, showing that the switch is either unlocked or set for the siding. The starting of lever 2 from its normal position crowds over pin 10 and locks lever 1 in its reversed position, the lever remaining so locked until lever 2 is latched in its normal position again. To prevent the levers from being handled by unauthorized persons, they are provided with slots, 18 and 18′, through which passes a key 19 (Fig. 1) having the necessary chain and lock. The distant signal shown in Fig. 6 is used with this stand. The bottom casting 25 is bolted to the foundation and the target shaft is attached to top casting 26. This casting is provided with arms 27 and 28, to which the front and back wires are attached. Both castings have inclined surfaces, the lower part of 26 fitting into 25, so as to act as a guide for the lower end of the target shaft. Should the wire break, casting 26, target shaft and target drop of their own weight, the inclined surfaces revolving the target a quarter of a turn, thus making the signal automatic, in that is goes to caution if the connections holding it to safety are broken.

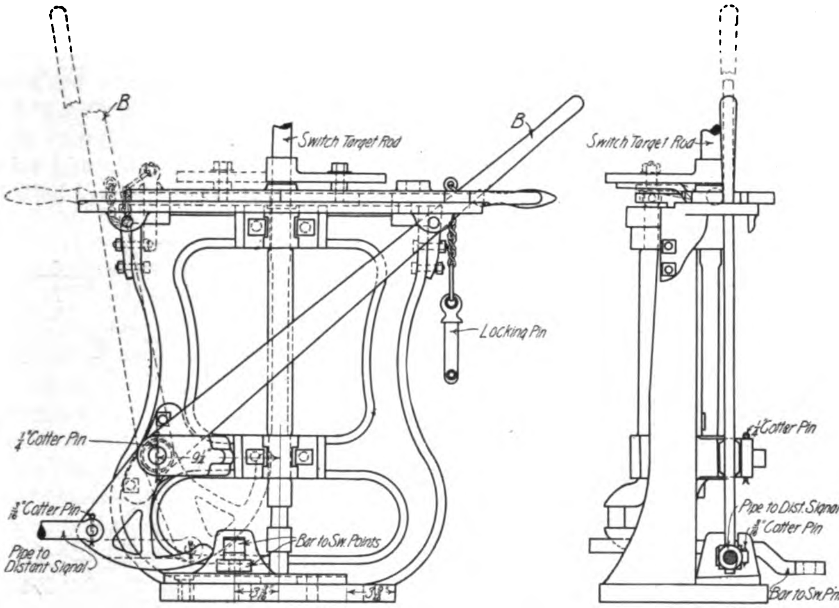

Fig. 250.—Switch Stand with Lever for Distant Signal, L. S. & M. S. Ry.

The protection of high-speed trains against the misplacement of facing-point switches on the Lake Shore & Michigan Southern Ry. is by a distant semaphore worked by a lever attachment to the ordinary switch stand, arranged to be interlocked with the switch points. The standard switch stand of the L. S. & M. S. Ry. consists of a cast-iron frame supporting a vertical shaft, with a horizontal lever throwing 180 deg. for a single movement of the switch (Fig. 250). The banner or target of this stand is of ordinary pattern, consisting of a rectangular blade painted red to show the position of the switch when set for the siding, and a circular blade painted white to show the position of the switch when set for main track. The rod for the target is separate from the main shaft of the stand or that which is connected with the switch points, and is made to turn through the necessary 90 deg. by being connected with the switch stand lever by a slotted crank (*E*, Fig. 252). The arrangement for throwing the distant signal consists of a lever (*B*, Fig. 250) pivoted to a casting bolted to the lower part of the stand, and a locking bar or lever (*A*, Fig. 252) lying horizontally on top of the stand and centered on the target rod. At the bottom of the signal lever there is a sector-shaped arm of $8\frac{3}{4}$ ins. radius which engages with a notch on a locking bar connected with the switch points when the switch is closed for main line and locked. The point rails are thus locked in position by two devices; namely, by the switch stand itself and by the signal lever; and the signal lever is in turn locked in position by the horizontal locking lever, which is secured by a padlock. The locking lever arrangement is shown in detail in Fig. 252. The upper engraving shows the position of the parts when the switch is set for main track and all levers locked. It will be observed that the first movement possible in the order of the locking is that of the locking lever *A*, but before the switch stand lever can be thrown the switch points must first be unlocked by throwing the signal lever *B*. The position of the signal lever corresponding to the danger or "caution" position of the distant semaphore is shown in the lower engraving of Fig. 252 and in Fig. 250. The normal position of this lever is shown in Fig. 251. In starting to close the switch the signal cannot be cleared until the switch points have been thrown to the home position, bringing the notch of the locking bar of the switch points opposite the sector arm of the signal lever, and the pin cannot be inserted (*H*, Fig. 252) for locking the stand without first moving the locking lever to secure the signal lever in the normal position. The arrangement is simple and substantially designed. The parts are all of malleable cast iron, and are bolted

Fig. 251.

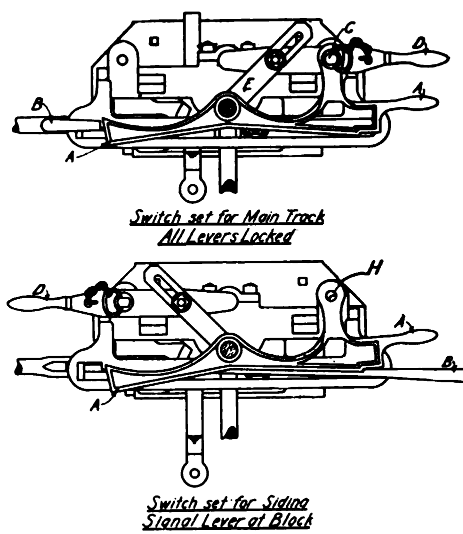

Fig. 252.

in position without changing the old stand as it is found in service and without taking the old stand down. The connection between the switch stand and the distant signal is made either by means of wire or by pipe line, the latter arrangement being the one shown in Fig. 250.

There are several designs of interlocking stands other than those described hitherto. The Gibbs stand resembles very much in general appearance the ordinary upright stand with closed frame. The connecting rod is not actuated directly, as by a crank of common form, but by a "motion plate," which is essentially a horizontally-operated cam. On one side of this cam there is a segment of a gear wheel with 17 teeth, which engages with a grooved gear wheel, around which a chain is passed and connected to the signal wires. Starting from the closed position of the switch, the gears engage and move the signal to danger during the early part of the throw, but the cam does not operate the connecting rod to move the switch. During the later part of the throw the gears disengage and the connecting rod is moved by the cam. In closing the switch the reverse order of movement obtains and the switch is moved entirely home before the gears engage to clear the signal. In the Allentown Rolling Mill Co. interlocked switch stand there are two levers attached to an upright frame: one to work the distant signal and the other the switch and home signal, the latter being carried by the stand. Both signals are semaphore blades of the common pattern. One of the levers takes the form of a T-crank, with the signal wires attached to the two arms. The two levers are interlocked by a vertical sliding bar which abuts against an arc on the top of the T-arm of the distant signal lever. The switch lever is engaged with this sliding bar, and as soon as the distant signal lever has been thrown to the danger position the bar is released, permitting the switch lever to be thrown up, thereby pulling down the sliding bar and hoisting the home signal blade, to which the sliding bar is attached. This movement locks the distant signal lever, which cannot be thrown to clear that signal until after the switch has been closed, the sliding bar raised and the home signal cleared.

The Elliott electrically-locked switch stand, designed by Mr. W. H. Elliott, while signal engineer of the Chicago, Milw. & St. Paul Ry., is arranged to put the control of the switch in charge of a telegraph or signal operator at any distance away, enabling him to prevent the use of the switch within a desired time interval previous to the arrival of a main-line train or to prevent a train from leaving a siding or branch line whenever it is desirable to hold it. The principal feature is an electro-magnet which locks a slide controlling a lock rod or plunger which passes through a lock bar attached to the switch points. Unless the magnet is energized the rod cannot be withdrawn and the switch opened. Upon opening the switch the current in the circuit is broken and an indication is given in the distant telegraph office or signal cabin. Upon closing the switch the circuit is again made and the proper indication given at the distant point. The switch lever cannot be placed in its normal position and locked unless the lock rod drops to its proper position through the lock bar, thus insuring that the points have been thrown entirely home when the indication is received that the switch has been closed. At the back of the switch stand there is a box with a glass-covered opening, in which is an indicator to show when the lever which lifts the lock rod has been released.

Switches thrown by ordinary stands are sometimes controlled by a lock operated from an interlocking tower in the vicinity, and this lock is interlocked with a distant signal also operated from the tower. With such means of protection the distant signal must be put to danger before the main track can be opened. Where automatic electric block signals are in service the connections are such that the opening of a switch sets the home and distant signals controlling the block to danger and caution, respectively. The arrangement consists of a circuit breaker connected with the switch points by means of a rod and crank and enclosed in a cast iron casing or box which is lag-screwed to the headblock. This device is commonly known as a "switch box" or "switch instrument," and is in circuit with the electrically-operated signal at the entrance to the block, or is cut into the track circuit. To make doubly sure that the signal will go to danger when the switch is opened, both the track circuit and the signal circuit are sometimes run through the switch box. The track circuit is also carried through the rails of the side-track as far as the fouling point, so that the signal will show danger until cars are entirely clear of the main line, even though the switch is closed. The opening of either switch of a main-track crossover puts the signals at stop in both directions. It is now extensively the practice, with switches located in the middle of a block or some distance from a block signal, to place a visible or audible indicator at the switch, so that trainmen may know, before opening the switch, whether a train has passed the signal controlling the block, or rather a point 1000 ft. or some safe distance in advance of that signal. A miniature semaphore arm, in a glass-covered case, or a gong bell to ring when a train is on the circuit, are appliances that are commonly used for this purpose.

The switch box is also used, sometimes, with facing-point switches where block signals are not in service. The throwing of the switch opens a line circuit and brings the distant signal to the danger position. In some installations, as above explained, the connection between the switch box and the distant signal is through a track circuit and relay, in such manner that the throwing of the switch, in addition to opening the circuit of the line wires connecting with the signal, shunts the battery from the relay, thereby de-energizing the relay and opening the circuit there. By this arrangement the circuit is opened at two points, namely at the relay and at the switch box, thus making the operation of the signal doubly sure. On the Fitchburg R. R. it has been arranged with installations of this kind to have the track circuit control a lock on the lever of the switch stand, so that after a train passes the distant signal at clear and enters the track-circuit section, the switch cannot be thrown until the train has passed the switch.

On some divisions of the Cleveland, Cincinnati, Chicago & St. Louis Ry., the Baltimore & Ohio R. R., and on some other roads, interlocking machines are installed at block signal towers to work the switches of crossovers and passing sidings. These towers are usually located at such sidings, and by putting the control of the switches in charge of the towerman the trainmen are relieved of the duty of handling the switches. The arrangement saves time, and, as the switches are interlocked with distant signals, the safety of the train operation is unmistakably promoted. The interlocking plant at each tower is usually small, there being but a few switches under control, so that the extra duty imposed upon the tower operators is not at all burdensome.

The practice of arranging distant switch signals varies with the conditions and the requirements to be met. On double track a single facing-point switch needs protection in one direction only, and usually there are but the home and distant signals, although an intervening signal is sometimes provided at a curve. On single track, signals in both directions are sometimes provided: but if for only one direction, that for trains which approach facing the switch is of course the one chosen. If the switch be at a junction, signals would evidently be displayed on both tracks. Derails in side-tracks may be interlocked with the main switch and signals and a dwarf signal interlocked with the rest may be used to indicate the position of the derail. For a facing-point crossover on double track signals would be displayed in both directions and the stand may be placed midway the crossover, so as to throw both switches. On single track where there are two switches near together, but facing in opposite directions, signals must be displayed in both directions; and these may be arranged so that the throwing of either switch moves both signals. Two distant signals can also be made to serve a crossover on double track and a near-by siding on one of the tracks, the arrangement being to have the movement of any one or all of the switches throw the proper signal or signals. Where ground-lever interlocking machines are provided it is usual to have a lever for each switch and each signal, the locking being so arranged that each lever can be thrown only in its proper order. It is feasible, however, to connect two switches or two signals to each lever.

CHAPTER VII.

TRACK MAINTENANCE.

85. Raising and Tamping Low Track.—The expense of keeping track in smooth surface, commonly called "surfacing," is greater than that of any other item of track maintenance. The exact, or even approximate, ratio of the cost of surfacing to the average expense of track maintenance, in general, is a difficult matter to get at; and figures bearing on the subject obtained from a single road or railway system are not a satisfactory criterion, because varying roadbed conditions and qualities of ballast are paramount considerations, and different companies have different ideas as to the relative amount which should be expended on appearances, such as policing, landscape gardening, etc. Reports of the Interstate Commerce Commission show that the expense of track maintenance averages 15.67 per cent of the total operating expenses of railways. The ratio of these two accounts has remained very nearly constant from year to year. The average expense of "repairs of roadway" is 10.66 per cent of the total operating expenses, or 68 per cent of the total expense of track maintenance, the ratio of these accounts also remaining very nearly constant (remarkably so) from year to year. In the classification of the Interstate Commerce Commission the account "repairs of roadway" covers all expense of maintaining the track and right of way except cost of material in renewals of rails, cost of material in renewals of ties, repairs and renewals of fences, road crossings, signs and cattle guards. It should be noted that repairs and renewals of culverts is not included in the above statement, that item being classified with repairs and renewals of bridges. It is next to impossible to segregate the item of track surfacing from other matters included in the account "repairs of roadway" in the reports of the Commission. It is certain, however, that the expense of surfacing constitutes a very large share of the account "repairs of roadway," and, being the chief matter in maintenance expense, it must relatively receive a great deal of attention.

Estimates on the expense of surfacing track, and figures commonly reported from individual roads, run from $95 to about $210 per mile of track annually. Some roads handling light traffic on track ballasted with earth, sand or other poor material expend a good deal of money on track surface, the account sometimes running as high as 150 to 170 days' labor per mile of track per year. On roads of heavy traffic, operating under average conditions of roadbed and track, the figures are not so variable, and in view of the dearth of information on the subject in publications of general circulation, I have gone to considerable pains to investigate. The accompanying tabulation has been compiled from the records of eleven railroads or divisions of the same, the road in every case being ballasted with gravel and the track surface maintained in first-class condition. The figures cover only one item, namely the expense of raising and tamping old track to maintain it in surface. The expense of lining track, reballasting or shimming is not included in any case. Five of the roads (A, B, D, G and J) are double-track lines, but the expense figure in each case refers to one mile of single track, and the traffic data refer to the train movements over one track; or in one direction only, in the case of the double-track roads. The data in every case cover only main track and main line, no branch-line track being included. The roads, except Road C, are generally distributed over the northern part of the United States east of the Rocky Mountains, where the ground is frozen during three or four months of the year. Road C is on the Pacific Coast, being part of an "Overland" route, and the track is tamped during every month of the year. The train movements in each case include both passenger and freight business, and the tonnage covers the weight of rolling stock and freight, including locomotives and cars of passenger trains. The 20 movements of Road C include 12 passenger trains; the 24 of Road E, 8 passenger trains; the 36 of Road F, 6 passenger trains and the 16 of Road H, 4 passenger trains. In the other cases the number of trains of each class is not stated, but Roads B, D and G carry a good many suburban passenger trains. In most instances the figures on the various items are average data covering a series of years.

Yearly Expense of Raising and Tamping Track.

Road	Weight of Rail.	Average No. Trains. 24 Hours.	Average Tonnage 24 Hours.	Average Expense per mile.	Remarks.
A	80	38	41,600	$142.25	201 miles.
B	90	75	58,000	$160.20	149 miles.
C	61	20	13,800	$144.00	60 miles.
D	75	41	32,900	$126.48	One Division.
E	74	24	18,000	$150.00	One Division.
F	80	36	28,400	$174.41	171 miles.
G	75 & 85	90	....	$125.00	One Division.
H	72	16	20,600	$140.73	147 miles.
I	80	Heavy	Traffic	$171.50	One Division.
J	75 & 80	Heavy	Traffic	$157.14	578.8 miles
K	70	Heavy	Traffic	$172.50	One Division.
Averages	76.7	42	30,500	$151.29	

The wages entering into the expense data average about $1.25 per day for track laborers and $1.90 to $2.00 per day for foremen. The remarkable showing of Road G, under the heavy traffic handled, is not due to low wages, for the track laborers have been paid $1.50 per day for some years. The data of this tabulation seem to show roughly, at least, that the average cost of raising and tamping track to maintain surface on heavy-traffic gravel-ballasted roads is roundly $150 per mile per year, the actual average being $151.29. The traffic carried averages 42 trains, with a tonnage of 30,500 every 24 hours, or 10 to 11 million tons annually.

In the present connection it is pertinent to explain that the term "heavy traffic," as generally understood, refers to number of train movements and not necessarily to car-load weights or weight of trains or of locomotives. The International Railway Congress in defining this term has drawn the line between heavy and light traffic at 10,000 trains over each track annually; that is, a track carrying 27 or more trains each 24 hours, or a double-track road carrying that many trains each way, is a "heavy traffic" line. For the use of maintenance of way engineers the definition of the term should convey some idea of the train tonnage. In the absence of any established standard I would suggest that 6 million tons or more, (including weight of rolling stock) passing over a track annually, or an average of 17,000 tons or more passing daily, might be considered "heavy traffic."

The forces which participate in impairing track surface are the natural ones due to the weather, such as the effects of precipitation and freezing, and mechanical forces which result from the operation of rolling stock. In well drained and well ballasted track the last named are the more important for consideration. The tendency of track to settle may perhaps be best understood by comparing its foundation with that of an ordinary building structure. In the latter case the masonry wall is laid in an excavation reaching to a firm sub-stratum. The load per square foot which earth foundations of this kind are supposed to sustain without appreciable settlement is 2 to 3 tons, at the most, but generally it is not more than one ton. Except in cuts, the ordinary bed for track is either the top surface of the ground or loose material or soil deposited thereon, and always subject to the action of atmospheric conditions, barring what protection the ballast may afford. The ballast, however, is part of the track support, and the degree to which the various kinds and qualities of the same are susceptible to the effects of weather conditions has already been pointed out. It is thus seen that track foundation or roadbed bears no comparison to building foundations for stability, and in years will settle of its own weight. As for ballast, it is at best put under the track in loose condition, and it is only by settling that it can become reasonably compact. But consider the load which the roadbed must sustain. In the case of a locomotive concentrating 100 tons on a wheel base of 25 ft. the load will be distributed over a length of, say, 30 ft. of track, or over 16 ties, which afford a bearing surface of 96 sq. ft. or less. The roadbed or ballast directly underneath the ties must then bear up quite one ton per square foot—and this with all the tremor and shock that comes from rapidly moving trains. It cannot be expected, therefore, that track laid on the natural surface or on fills will not settle, and all talk about perfect roadbed is idle. As the track must follow the settlement of the earth, which nearly always takes place more or less unevenly, the occasion for raising and tamping stretches of track from time to time is readily understood and requires no further comment.

It seems likely that a very large part of the wear and tear to track must result from locomotive operation alone, owing to the magnitude of the wheel loads and to the driving or reciprocating impulse, and no doubt the cause for irregular surface is traceable to the same source in similar degree. In the matter of wheel pressure effect upon the track it would seem that the type or class of locomotive is of some consequence, for it is true that, as a rule, the locomotives with heaviest driving-wheel loads are the ones that make the fastest speeds. An investigation of the weights of different classes of locomotives built during the years 1900 to 1902, inclusive, by 30 representative railways of the country, found the average weight per driver of 4-driver engines to be 11.1 tons; the average per driver for 6-driver engines (excluding switching engines) was 10.7 tons, and for 8-driver engines it was 10.4 tons. Five years previously the average was 9.8, 8.8 and 8.3 tons for 4-driver, 6-driver and 8-driver engines, respectively. Heavy 8-wheel passenger locomotives are undoubtedly the most severe on track surface, and the growing practice of putting 10-wheel engines into passenger service is in line with improvement in this respect. Consolidation and mastodon locomotives, which have eight driving wheels, are supposably the easiest on track surface. While it might be thought that a given number of driver loads of stated weights should produce a greater pressure effect than a smaller number of somewhat heavier loads, it must be taken into consideration that as the number of drivers decrease the distance between wheel centers increases; and that the severity of loads on the track is augmented by the distance between the points of application, since the upward flexure of the rail between the wheels permits of an uneven distribution of the load over its proportionate length of track. It would seem, for example, that 10 tons bearing on the rail at each of two points 8½ ft. apart should depress the track farther than 40 tons evenly distributed at four points along 14 or 15 ft. of rail. The work of Mr. P. H. Dudley in measuring rail stresses with his "stremmatograph," shows that as the number of driving wheels is increased or the wheel spacing decreased the stresses in the rails are less per ton of driver load. It is understood, of course, that volume of traffic, as well as weight of rolling stock, is a factor of track impairment. As a matter of illustration, the track in general service a decade ago might be considered quite safe for the heavy locomotives and car-loads of to-day, and might stand up satisfactorily under traffic consisting of a few train movements each day, but under the numerous movements of a heavy-traffic road it would be found too light for economical maintenance.

About the first work, then, which must be done after new track has been used, in order to restore it to its original condition, is to raise the low places to an even surface with the whole and hold it there by tamping. This work is unceasable, for stretches of track will not usually remain in good surface longer than a few weeks or months at a time. It may and should be prosecuted at all seasons when the condition of the ballast will permit, continuing as long as possible before the ground freezes, to get the track in good condition for winter, when the only way to do surfacing is by shimming. The urgency of other work will engage the attention of the section men at times, but the foreman should be continually watching for rough places in the track surface. The extent to which unevenness may be permitted in track surface depends, for the most part, on the degree of comfort which the company expects to afford its passengers. The rate of wear and tear to rolling stock increases very rapidly with roughness in track surface, and the schedules of the fast trains and the reputation of the road will be determined very largely from the ease of riding in the cars. It is for this reason that some railway managers with an eye to business are most particular about the track surface on those portions of the line which cover the dining car runs, aiming to keep that much of the track in smooth condition whether or not the whole road can be maintained to the same standard. Very rough track become dangerous, especially on curves, and when track gets run down the curves are the places needing first attention. When the surface on curves becomes so uneven that the bell will ring from side swaying of the locomotive, it is high time to get action on repairs, but of course track should never be permitted to get into any such condition.

It is not expected to maintain old track exactly to the rail grade stakes to which it was put when new; there could be no particular object in so doing, except perhaps for short distances each way from bridges or wherever there are foundations so permanent as to show too great contrast with ordinary earthwork regarding settlement. If a piece of track, say ⅛ mile in length, settled from the original grade stakes evenly 1 in. at all places it would be wasteful of time and effort to raise it again to the old stakes. What is meant by maintaining track to surface is to hold it to a smooth and even surface, but not necessarily to the original surface or grade line. Many foremen make a mistake in this. They have an idea, somehow, that track must continually be "tamped up;" and so they keep it going on upward. In case they find a few low joints or rails they raise "out of face" the whole stretch of track in the vicinity, instead of merely raising the low places even with the general surface. As track settles with and into the ballast the bed hardens, and as far as it settles evenly it should be permitted to remain; for it is in this condition that it can be held to good surface at least expense. As a general thing there is too much raising track out of face. Much needless expenditure and much inferior track surface result from continually disturbing the embedment at points where there is no necessity for raising the track. There must, of course, be excepted in these remarks all reference to such track as did not have at the first a sufficient quantity of ballast, and to sags in the track due to the settlement of new roadbed. Where now and then a rail or two has settled there will be places which, relatively, look high. If these high places stand at about the same surface or grade, the low places should be lifted up evenly with them, but the high places should not be raised. This is the only economical way to maintain track in smooth surface. Many times it is cheaper and better in every way to cut down portions of the track which have settled less than the rest than it is to raise the whole to an even surface with the highest. In the case referred to, if the whole ½ mile of track had settled evenly one inch, except at two or three places of only a rail or two in length, it would seem like using better judgment to cut down the few high places an inch than to raise several hundred feet of track an inch to conform to them. Under overhead structures where the headroom is near the limit of clearance the general surface of track should not be raised without permission from the engineer in charge. Matters of this kind are usually governed by the printed rules of the road department. As already intimated, the surface of track on curves should be looked after with particular care, for the reason that a low place on the outer rail of a curve or a high place on the inner rail causes a lurch which acts with the centrifugal force in swinging or throwing the car.

To bring to an even surface track which is low for a rail length or less, much depends upon the point at which the rail is raised. Generally the jack or lever should be placed under that portion of the rail which has settled the most; or else near the lowest place and toward that side which has settled the farthest away from the lowest place. To explain the latter point, suppose that a joint has settled lower than any other point along the rail, but on one side of the joint the rail suddenly dips down in a distance of 3 or 4 ft., while the rail on the other side of the joint has settled all the way gradually over a distance of about 10 ft. Then in raising that joint, a single lift at a point 2 or 3 ft. to one side of the joint may raise the whole low portion evenly, where otherwise the quarter would have sagged. The same thing may be observed in raising a rail near the middle, or "center," as it is usually called. Sometimes after a rail has been raised by lifting with the jack set at this point, it appears to hump up on one side of the jack, while on the other side it sags down. If it were not for the hump the sagged portion could be raised satisfactorily afterward; but by letting go and shifting the jack a few feet toward the sagged portion the weight of more ties hanging to the humped portion will pull it down, and the whole stretch may be brought up evenly; otherwise, had a tie been tamped to hold the place first raised, the sagged portion would then have to be raised, and the lifting might throw the humped portion down or it might not. The reason for the failure of rails to rise evenly, sometimes, when lifted about midway of the sag, is because some part, through being low, may have become bent by weight of trains, or perhaps there might be a greater weight of ballast hanging to the ties on one side of the jack than on the other side.

While a rail is being raised an experienced trackman can usually tell by the way it comes up the most satisfactory way of holding it. If on one side of the jack the rail seems to rise less rapidly than on the other side, then, if instead of tamping or blocking the tie adjacent to the jack, the second or third tie in that direction be taken, it may support more evenly the portion raised than by holding a tie near the jack. At all events one should try to take hold of the rail at such points that it will lift evenly. Much of the success of surfacing depends upon the manner in which the track is lifted and held, and a little experience will enable one to see this if some attention be given to the matter. For convenience, the man sighting the rail may designate names for certain portions of the rail, to be used conventionally. In raising or lining track, "center" means the middle point, or the portion of the rail about 15 ft. from a joint. The term "short center" is sometimes understood to refer to a portion about 12½ ft. from a joint, and "long center," 17½ ft. from the same joint. Likewise "short" and "long" quarter refer to portions about 5 and 10 ft., respectively, from the joint. Rails of 60 lbs. per yard and heavier, in loose ballast, usually need to be raised only at the joints and centers in order to get them to smooth surface.

For a year or so after track has been built, tamping, in most all kinds of ballast except broken stone or its equivalent, is better done with the shovel than with the tamping bar. Generally there are sags to be raised out soon after new track is used, requiring it to be lifted 2 ins. or more, so that the tamping bar is not well adapted. A tamping bar is efficient only where the material can be packed into a confined space. It is at its best where there is a hard bottom and the lift not more than an inch. For a lift of more than 1½ ins., on any kind of bottom, it is better to allow for settlement in raising the track and to tamp with the shovel. For a lift of ¾ in. or more, in new track, the ties should be tamped all the way between the rails, but as the space under the ties gets shallower the tamping inside the rail can be narrowed down to the width of the shovel, and finally the tamping inside the rail can be dropped altogether; because the ties which have been raised the least should settle the least after being tamped, and it is not necessary, therefore, to tamp so much of the tie in length. It is better to tamp only a part of the length each of such ties and have the work done well, than to leave it to men to tamp as much of the tie as they would in a high lift, but not quite so well. In tamping with the shovel, where the bed is not hard, men should be careful not to dig down into and break up the old bed.

In old track where the bed is hard and compacted, and where, with an ordinary amount of work done upon it the track does not generally get lower than an inch before it is raised, the tamping bar is the best tool for all kinds of ballast except dirt and broken stone. The ballast filling between the ties must be opened out in order to get under them with the tamping bar. A pick is a good tool for this purpose, using the wedge point to draw the ballast outward to clear the side of the tie. Tamping bars are sometimes made with a sort of flattened end for removing the ballast from the side of the tie, but they can not do the work as well as it can be done with the pick, nor as quickly. Ties should be well opened out directly under the rail seat, as it is important that they should be thoroughly tamped there. If the lift is not high, and particularly if the ties are not well opened out, men are quite liable to neglect the tamping in this place. It requires more time to tamp with the bar than with the shovel, but where the conditions are favorable to the use of the bar it gives much better results than the shovel. In bar tamping, the ties need not be tamped all the way between the rails; a foot to 18 ins. inside each rail is usually sufficient. The track will hold in line better if the middle of the tie is not tamped, and any open space at this point soon becomes filled with ballast jarred or washed into it. To prevent rain water from collecting in such places the space should be loosely shovel-tamped when the track is filled in. Where the lift is not more than ½ in. high the ties need not be tamped between the rails.

In stone or broken rock ballast the tamping pick is the tool to use for tamping. With this tool it is possible to wedge the track up some without previously raising it, but for a lift of any consequence it is better to first raise the track and not to try to do too much wedging. Stone ballast can be most thoroughly tamped where the lift is about 2 ins., because if the space under the tie is too shallow to admit the tamping end of the pick, or the pieces of rock are too coarse for the space, the old bottom must be broken up. In tamping near a joint, in stone ballast, the joint tie or ties should be tamped last, as the tamping usually keeps raising the track slightly, and hence the ties tamped last are the ones most solidly tamped. The practice of tamping the outer end of the tie and next to the rail, inside, more thoroughly than elsewhere, is observed, the same as in gravel ballast. The middle of the tie should not be tamped hard.

In dirt or natural soil ballast it is a difficult matter to tamp the material to compactness with any kind of a tool. The shovel handle is rather better than the shovel blade, as it makes a better rammer. When tamping in dirt ballast much allowance should be made for settlement. A pretty good way to handle low track in this material is to raise the track 3 or 4 ins. and throw the dirt under loosely to fill the space, being careful not to get too much under the middle of the ties, for fear of center-binding them when they settle. While this method may seem like a rather careless way of handling track, still, if done right, and only in advance of slow-speed trains, there is no danger. One way of going about this work systematically, so as to get the right quantity of material under each tie to afford an even bearing, is to follow a method in practice with Roadmaster J. C. Rockhold, of the San Francisco & San Joaquin Valley Ry. (Santa Fe system). The track is lifted to the desired hight and a small heap of dirt is deposited outside the end of each tie and patted down with the back of the shovel to a level with the bottom of the tie in its raised position. The purpose of this procedure is to indicate the hight to which each tie is to be tamped. Such references having been established, the track is then raisd up 6 or 8 ins. higher and the ballast is placed under the ties with the shovel to conform with the level of the heaps outside the ends of the ties. The track is then suddenly dropped. By this method the track can be surfaced when the ballast is quite wet or under conditions which will not permit tamping to be performed by any other method of work. In track where the tops of the ties are covered with filling material, as is usually the case with dirt ballasted track, it is necessary that more care than elsewhere should be exercised not to tamp the ties too solidly between the rails and make the track center bound. The reason for this difference is that inside the rails the tamped material under the ties is confined and held by the filling which reaches to or above the top of the tie, whereas on the outer ends of the ties there is not so much filling, or perhaps no filling at all, to retain the ballast under the tie and prevent it from sliding out.

Sand ballast is usually tamped with the shovel, but where it is in a dry and loose condition the track should not be lifted higher than the surface to which it is desired it should be tamped. Burnt clay ballast of hard quality may be bar or pick tamped, but if it is soft and crumbles badly in working, the usual practice is to raise the track high enough to allow for some settlement and tamp it with the shovel blade. In ballasting new track with this material the shovel blade is used for tamping it. For tamping natural soil, sand and burnt clay or gumbo ballast thick, specially constructed tamping bars, as described in the chapter on "Track Tools," are used to some extent.

As a novelty in tamping tools and in methods of track surfacing, mention may be made of some experiments in tamping ties by air blast on the New York, New Haven & Hartford R. R. during the year 1898. A Root blacksmith's blower was used, the ballast being first passed through a hand screen to remove particles too large to pass through the injector of the machine. It was found that material passed through a ¾-in. screen could be utilized, although the finer particles were worked to best advantage. After the track was raised to the desired hight, the filling was removed from the ends of the ties and the material was blown into the cavities underneath through the opening at the ends. So far as was reported officially, at the time, the results seemed encouraging. These experiments were under the supervision of Roadmaster F. R. Coates, later chief engineer of the Chicago Great Western Ry. More recently the air blast has been used by the Bessemer & Lake Erie R. R. for tamping steel ties of inverted trough section, as described in §169, Chap XI, and shown in Fig. 483A.

The man who sights the rail as it is being lifted should get far enough away to have a good stretch of rail between him and the point where the jack or raising bar is applied. Distance assists the eye to accuracy in prolonging the line of sight beyond the established points in the general surface. In heavy surfacing it is necessary to observe the train schedule, and be careful not to raise a longer stretch of track than can be tamped to hold to place by the time the next train is due. As a precaution, alternate ties should first be tamped outside the rails to make safe for trains which might come before they are expected. In a light or moderate lift the tamping of every tie outside the rails will usually hold the track up under a train movement without settling badly enough to require raising again, and if in addition to this alternate ties are tamped inside the rails there can be no question about it, for a lift of any hight. Although it is desirable to have all the ties fully tamped before a train arrives, it is not very necessary that such should be the case providing as much of the work as is above noted has been systematically completed. By bearing this fact in mind the foreman is conscious of having some leeway in case he should overestimate the amount of work that can be completed in the time available.

Foremen should observe closely to see that the ties are tamped to a uniform bearing, being particularly watchful of new men to get them to tamp wide ties thoroughly, driving or crowding ballast all the way under the ties. Each two men tamping together on old track should carry a hammer, and where spikes are found loose they should raise the tie and drive them down to the rail tightly before starting to tamp. Where the gravel is mostly fine in quality coarse pieces of rock should not be driven tightly under the ties, as they form an uneven bearing. Allowance should be made for tamping, according to the manner of tamping. It is not practicable by any means to make the newly tamped bed as hard as an old bed of ballast; hence low rails should be raised slightly above the general surface. Just exactly the allowance to make cannot be stated in general terms: an intelligent foreman can better ascertain that after he becomes acquainted with the quality of the ballast, the way the tamping is done and the reliance he can place in his men. In high lifting it is well to tamp two ties to hold joints that are being raised, as otherwise the settlement may be so great when the jack lets go as to require lifting the second time. In order to give the joint ties the benefit of a little better tamping than the other ties get, they may be tamped a trifle high, while being held by the jack or bar, and then struck down with a sledge hammer. Such practice is quite frequently followed and gives good results. Wherever tamping is done the track should be filled in the same day, to drain the water off or hold it back in case of rain, but if this work is left some distance behind the tamping operations there will always be something to set the men at in case the track raising is delayed out of hesitation to throw up a rail in advance of a train that is late. Wet weather is not favorable either to tamping operations or the results of the same, because the material is liable to be softened and slide out before it has a chance to pack hard.

Sometimes at joints which have been quite low for a long time the ends of the rails get bent, and this condition gives rise to the term "surface-bent" joints or rails. In raising a joint of this kind the quarters each side will bulge upward higher than the joint. The proper method of treatment in such cases is to raise the joint somewhat higher than would be done if it was not bent, and then tamp the joint tie or ties well, but the shoulder ties hardly enough to enable them to take the bearing they would afford if the ends of the rails were straight. In the case of a supported joint the joint tie may be thoroughly tamped, but at a suspended joint the two joint ties should be tamped hard on the side next the joint, but loosely on the side next the shoulder. After maintaining the support in this manner for some time the weight of trains may straighten the rails. Where the settlement is very low it is best not to raise the joint the full hight all at once and let trains run over it, as there might be danger of breaking the rail. It is a difficult matter sometimes to straighten a surface-bent rail in this way. It helps matters a good deal to put a new and straight splice on the joint after it is raised and tamped, for the old one may be bent so badly as not to permit the rail ends to come to their proper place. A device for straightening bent angle bars is shown and described in § 135, Chap. IX.

In raising track on straight line the level board should be used. Whenever a sag on one side is raised out it should be put level with the opposite rail. For the steady riding of cars it is necessary to have the track level transversely. Quite frequently one may find each rail in fair surface but the track out of level, first one side running low and then the other. This state of things causes the rolling stock to lean toward the low side, bringing a preponderance of pressure on that rail, from which arises a tendency for that side of the track to settle faster than the other. On roads running east and west through a cold country there is a tendency for the south rail to get lower than the other, owing to the fact that that side of the ballast and roadbed is on the sunny side and thaws out earlier in the spring. For a time after the frost has gone out on that side the ground in the shade of the north rail still remains frozen. A convenient and rapid way for section foremen to test their track for level is to find some place where the rails are level transversely and then place a level board across a hand car standing at the point, and block the board to show level. By running the car along slowly with the level board thus arranged one can form a good idea of the condition of the track respecting transverse level, and also note the points where the low rail alternates from side to side. Before using the level board to raise the low side the high rail should be put in good surface, if not already in such condition, and then the low side may be brought up by the board. By making it a practice to use the level board when raising track, foremen will eventually get the rails level transversely over their whole section; neglect to do so will sooner or later result in track out of level. On this point Superintendent W. L. Park, of the Union Pacific R. R., in an address to the section foremen of his division, advised them as follows: "In order to obtain perfection in surface it is essential to use the level. We are aware that you have a good eye, but do not strain it too much. Give the level a show and it will help you out exceedingly."

As soon as the ground settles, after the frost has gone out in the spring, the section crews should get to work at surfacing and pick up the roughest track first. This will generally be found where shimming has been done during the winter. The shims should be removed, the ties raised to the rails and the spikes driven down, the rails raised to surface and the ties tamped. As soon as the tie renewals are made the foreman should begin at one end of the section and go over it thoroughly, raising and tamping to surface all low places as he goes along. Track does not settle so much in summer as it does in the spring, but it settles in places all the while; and with the best track there will be low places enough by late in the fall to make it necessary to go over it again before the ground freezes. Very low places should always be raised as soon as found, but by working over the section thoroughly from end to end, as stated, many low places will be discovered which otherwise would be overlooked.

The surface of track near the ends of bridges should be closely watched. A low place under a rail entering a bridge will give cars a hard jolt. Joints which come on an embankment close to the end of a bridge nearly always give trouble. Where, in course of laying the rails, a joint comes this way it is a good plan to cut the first rail on the bridge so that the joint will be on the bridge a few feet from the end. Then move up a rail so that the first joint off the bridge will be a full rail's length from the first joint on the bridge. Take the piece cut off the rail on the bridge and put it in behind the rail moved up, or if it be too short, use two longer pieces. The end of the embankment, where it meets the bridge floor, should be bulkheaded tightly, so that the ballast may be retained and become compacted instead of rattling through and rolling away continually. Construction of this kind is described in detail under the subject "Bridge Floors," § 153, Chap. XI. In raising track at the end of a bridge it is well to start the spikes on a few of the bridge ties, so that the grade ties next the bridge may be raised and tamped a little higher than would otherwise be the case, thus allowing something for settlement. The same procedure applies to track at cattle pits, stone culverts and other points where the stability conditions of the track support vary widely within a few feet.

86. Lowering Track.—As already stated, sections of track for short distances may remain nearly to the original grade stakes, while long stretches each way from such portions may settle more or less evenly, so that it does not pay to raise the whole to an even grade with the little. The work of letting down track is an easy matter. First, estimate the amount of drop or fall. Then remove the ballast from between the ties and as much lower, between the ties, as the track is to be dropped. This can be done at any time, for it does not interfere in any way with the running of trains. As soon as opportunity offers, raise the track an inch or two, cut out the ballast remaining under the ties and let the track drop. By carefully estimating, it need not be dropped any or much below the desired surface; in case it should be it can readily be raised and tamped to place. If one side only is to be cut down the ballast must be removed to proper depth as far across as the other rail; otherwise, any of the old bed remaining under the ties, between the rails, will cause the side not cut down to be thrown up when the other side drops. If there is a considerable stretch to be cut down, and the force is large, the track may be raised and blocked while the work of cutting under the ties is going on. Of course, proper protection by flags should be looked after, when necessary. In case the trains run at close intervals and the distance the track is to be dropped is greater than the foreman would wish to undertake at one operation, it can be let down by stages of a few inches at a time. Where the track is to be dropped several feet the usual method is to shift it off the old bed, temporarily, cut down the roadbed and then throw the track back to the old alignment.

Another method that is sometimes followed in lowering track is to first dig a ditch on either side as deep as the track is to be let down, allowing the proper depth for ballast, and also dig out between the ties. Then when time is available between trains the track is jacked up and blocked and the ties are bunched, three or four in a place, throwing out unsound ties or such as would be discarded in the course of tie renewals, the spikes, in which should be pulled before the track is raised. The men are then set to work, some in the ditches and others in the spaces between the bunched ties, to cut down the earth core to a level with the bottoms of the ditches. If there is not time to finish the job in the interval between trains, a run-off is made, being laid out by drawing a mark along the bank of the ditch, which serves as a gage for the men to work to.

87. Lining Old Track.—Besides keeping track in vertical alignment or "surface," it must be maintained also in horizontal alignment or "line," as trackmen choose to call it. Track is most liable to get out of line where there is a low place on one rail only, since the lurching of the cars into the sag throws the track over; and low places on curves are more liable to get out of line than are low places on tangents. Track center-bound, or supported more solidly under the middle of the ties than at the ends, will rock and slide out of line, to one side in one place and to the other side in another. Insecure or springy roadbed, heaving by freezing, raising low places with bar or jack improperly set and renewals of ties, are also some of the causes for bad alignment in track. The importance of keeping track in good line, especially where trains run fast, is great; it is next in importance to keeping it in good surface. At the end of every day's tamping the piece of track worked over that day should be lined. It is well to line it before filling in, as then the ties can be moved without side friction in the ballast. Twice a year—just before the ground freezes, late in the fall, and just after the ground settles, after thawing in the spring—the foremen should proceed over their track with a gang and line out all irregularities.

While in lining only a few rails at a time three or four men may be able to throw ordinary track, in a general alignment there is no economy in using less than six men, and each man should be equipped with a bar, so that there need be no doubling up on the tools. Track is thrown easiest after a rain, when the ground has had a thorough soaking, and then is a good time to do it. In dirt ballast it becomes quite difficult to throw track when the ground gets dried out and baked hard, but in gravel the difference between wet and dry weather is not so much. When dirt ballast is wet it is difficult to get short holds with the bars or sufficient leverage to throw the track. Thus more men might be needed in a soft place than where the ballast is hard, simply because a man cannot get a hold with his bar that will stand what he can pull; more than this, ties in wet places, especially in soft material, are generally soggy and heavy to throw. When a specially difficult place of this character is found the track may usually be thrown by laying down pieces of plank or strips of wood under the rail, lengthwise between the ties, and taking short holds with the bars upon the pieces. Another way to move hard-throwing track is to get hold with all the bars under the ends of the ties and pry or loosen the ties from the ballast. Where this cannot be done lift the rail with the track jack set on that side toward which the track is to be moved, and throw at the same time with the bars: or it may be moved by taking a carrying hold with the jack alone—that is, by setting it a little pitching; although it is not a good plan to do this where the ballast is fine gravel, as it may work its way under the ties and prevent them from settling back again to surface. Likewise in sand ballast, where the track throws easily, the bars should not be stuck into the ballast at a low angle, as the lifting of the track may let ballast run under the ties. Where ballast is filled in at the tie ends it must be removed therefrom before track can be thrown. If it is loose ballast it may be jabbed out with the bars, but if it is hard the picks will be needed. In places where track is very hard to throw and ordinary methods of bar lining fail, time can be saved by "spike lining" it, which is done by pulling the spikes, lining up the rails on the ties and redriving the spikes. When the ground is frozen such is the only feasible method.

Tangents which appear to be in good alignment as far as the eye can scan are good enough. Although, for sake of appearance, it may be desirable to take out all long "swings" from tangents, still it is of no importance as affecting the running of trains. On curves the eye alone cannot be depended upon so reliably; for while there are men expert enough to sight a curve to almost perfectly *smooth* alignment, it is impossible for the unaided eye to run in long stretches of track to an *even curvature,* for the simple reason that, standing in any position possible, the lines of sight for different points on the curve cannot lie in a plane with the side of the rail head, as they can on a tangent, and hence the eye has not the points for comparison. Only a comparatively short piece of the curve (depending on the degree of curvature) can be taken in from one point of view; and as long as the curve is smooth, everywhere, an easy grading off into a curvature greater or less in degree cannot be detected. To use a poetic illustration, it may be said that a tangent in good line looks like something mechanically correct, while a curve, if it is smooth, appears to the eye like something beautiful. The test applied to a line to determine whether it is straight is that lines of sight from all of its points to the eye, either unaided or aided by magnifying optical instruments, shall appear to lie in the same plane; this is an accurate test and there is no other. But a test to determine whether or not a line is of uniform curvature or of uniformly varying curvature cannot be performed by establishing lines of sight alone; lines of sight together with linear measurements, or linear measurements alone, must be used. Hence much talk that is heard among trackmen to the effect that some men are able to sight a curve properly, for a distance, without an aid of some kind, is bosh. The best the eye can do is to get the curve *smooth,* but only relatively *even,* and here is where the deception comes in.

A curve is known to be even or circular when, for a chord of any length stretched against the gage side of the rail at different places anywhere along the curve, the middle ordinate measures always the same. This is a very simple test to perform; and when the degree of curve is known there can then be known what the middle ordinate for a string of any length should be. A 62-ft. string is the most convenient to use, since the length of its middle ordinate expressed in inches is equal to the curvature expressed in degrees. If it is found that the middle ordinate to a 62-ft. string is an inch longer at one place than at another, then that part of the curve is a degree or more sharper than the other part; and this knowledge may suggest to the eye what portions of the curve might be thrown out or in to make the curvature even. Stretch the string (of whatever length) from point to point around the curve so that one stretching of it overlaps the one previously taken by half its length; then if the middle ordinates do not vary appreciably, line it smooth and the curve will be both smooth and even in curvature, and consequently in good alignment. If the degree of curvature is not known and the middle ordinates vary considerably, take an average of all the ordinates and line the rail to that. Of course this procedure need not be followed where the curve has been re-centered instrumentally. For spiral curves reliable points of reference must be had at short intervals, or the track cannot be kept in good line.

Quite frequently the splices on curves get bent laterally. Light-weight splices are liable to behave in this manner if the rails have not been curved, especially where there is no filling at the ends of the ties. Under such conditions the rails will sometimes straighten out somewhat, making the splice bars angular or "elbowed." It is difficult to throw such track into good line; for if the joints be thrown in there will generally be sharp bends at the quarters which, if thrown in, will make the joints angular again. The rail can be put in fair line by throwing out all the centers, but it will not stay there very long. The best thing to do in such a case is to change places with all the splice bars, putting the outside bar at each joint on the inside of the rail, and the inside bar on the outside. Then, after tightening the bolts well the track may be thrown to a good curve and it will remain so, at least until the splices bend the other way. If the splice bars are not interchangeable an angle bar straightener can be used to good effect. After track has been relined it is a good plan to tighten up the bolts, as the throwing of the rails will now and then loosen a splice.

Before an attempt is made to line track it should be put in proper gage, especially on tangents. On curves, the outer rail being the one that is lined, the gage, unless it be far out of the way, cannot affect the line of the track in a way to influence the running of cars, as it can on straight line. When lining track the foreman or man sighting the rail should stand as far away from the place which is being thrown as he can see well. On curves this distance must depend largely on the degree of the curve, for one cannot sight along a rail very far distant on a sharp curve; but on tangents a man with ordinary eyesight can best observe short irregularities in line by being at least 90 ft. away, while for long swings he should be farther. Where the alignment is bad it is well to go over the track with the lining crew twice. At the first lining the man who does the sighting should stand off as far as he can see to take out the long swings, and then come up within 60 or 90 ft. and take the crew over it once more to remove the short irregularities. In a general alignment, as well as when raising track, the man who does the sighting should, as he goes along, occasionally cast a glance behind; because the appearance of the line or surface of a rail oftentimes looks differently from different directions. The man sighting should also stand with his back to the sun, for if it shines too directly in his face he cannot see the rail so well. In bright weather, track which runs north and south is not so easily sighted for lining early in the day or late in the afternoon, since at these times the shadows of the men throwing with the bars fall across the rails and bother the man sighting; the same difficulty is found during the middle of the day on track which runs east and west. When sighting for lining a long swing, as in sighting for raising a long sag, a chunk of mud or small stone placed on the rail at reference points assists the eye to establish the general alignment. In lining curves some prefer to have the men work toward the man who does the sighting, the idea being that then the track most conspicuously in view is in good line and in better position to go by than it is when the work of lining proceeds forward. It is thought that in the latter case the corrected alignment lies between the men and the sighter and is too close for convenient comparison with the point where the work is under way.

88. Tie Renewals.—A matter of first importance in the renewal of ties is to determine just what ties need to be removed; or just what ties if left another year would, by their further decay, weaken the track to the danger point. The appearance of ties in the track is liable to be deceptive, because they never rot uniformly alike. Some rot from within, some from without and some rot all through at the same time. The serviceability of a tie on curves is ended as soon as it ceases to hold a spike well, but on tangents not until the tie has so far decayed that it begins to fail as a support for the rail, which does not usually occur until after it has failed in its spike-holding power. On tangents there is but little stress on spikes in holding the rails to gage, as the side pressure from the wheel flanges is small. Moreover, at the moment of service the rails are held to place not alone by their connection through the tie, but also by a very firm temporary connection through the axles of loaded wheels. The strength of this connection is measured by the side friction possible between wheel and rail, and on tangents it is more than sufficient to hold the rails to place. Such being the case, the spikes on tangents are useful mainly to hold the rails when not in service, and the tenacity with which they are held by the ties is therefore not so important. It is a great mistake to inspect with a view to throwing out ties on tangents as closely as on curves. At the least calculation a tie can be of service on a tangent a year longer than on a curve.

The cost of ties for renewals, exclusive of the cost of distributing and laying them, averages 19.7 per cent of all expense of track maintenance, and is more than twice the cost of rails used in renewals, excluding, as in the other case, the cost of distributing and laying them. The reports of the Interstate Commerce Commission show that the ratio of the costs of ties and rails for renewals increased almost steadily, up to the year 1900. In 1895 the cost of ties for renewals was 1.97 times the cost of rails for renewals; in 1898 they cost 2.32 times as much, and in 1900 they cost 2.67 times as much, but in 1901 the ratio had dropped back to 1.87, and in 1902 it was 1.86, the fluctuation quite likely being due to continued high prices in the steel market. The cost of the rails in all cases is less the value of old rails taken up. The cost of laying ties in renewals is much greater than that of laying rails in renewing an equal length of track, as in different kinds of ballast and with different qualities of ties it may amount to from 10 to 40 per cent of the cost of the ties; and when removed there is added an inconvenience and further expense due to disturbing the bed of the tie. Such being the case, ties should be allowed to remain to the full limit of their usefulness, bearing in mind, of course, that it is usual to remove ties but once a year; and not to leave ties in the track which, although they might pass for the time being, possibly, would fall to pieces before another year. In respect to this rule there is some room for judgment, but in many cases foremen of experience, having an acquaintance with the lasting properties of the timber in question might, by carefully inspecting and retaining in the track such ties as would safely last another year, easily save the company one or two month's wages yearly and still leave not the least question or doubt regarding the safety of the track. Roadmasters should watch closely the old ties thrown out by their foremen. On some roads the ties are inspected on each section by the foreman and roadmaster together, a spot of red paint being placed on each tie to be removed. This practice makes lots of work for the roadmaster and casts a reflection upon the competency of the foremen.

As for determining just the time or stage when a tie has decayed so as to no longer hold spikes well for a curve, there is perhaps no general statement which could be taken for a rule. That matter depends somewhat on how many sound ties there may be near the tie in question; for where there are several unsound ties together on a curve the rails will spread or crowd the spikes. The usual way of ascertaining the degree of soundness of ties is the pick test, striking the top of the tie, outside the rail, a moderate blow with a pick. On curves the test should be made outside the outer rail. If the pick enters easily and a large portion of the end of the tie breaks off without much prying, the tie, if on a curve, ought to be taken out. To inspect ties on a tangent pry up on the end with a bar as though to raise the track. If the tie is so unsound that the end is springy (although not necessarily springy enough to break off) it ought to be taken out.

During the first few times ties are renewed after track has been built, there cannot be used the same discretion in tie inspection that is practicable in old track. Ties put into new track are generally more or less uniform in quality and their service begins at the same date for all. About the time decay begins, then, it becomes somewhat general, so that during the first year that renewals would really have to begin with individual ties a very large proportion of all the ties would necessarily have to be taken out at the same time. Moreover, should there be any question about the advisability of removing any of the ties as soon as a considerable number might seem to require it, another year's service would in all probability make necessary the removal of so many at one time that the breaking up of the tie beds would seriously affect the surface of the track. For this reason it is better to begin renewing at least a few, for the first time, a year before the same ties would have to be renewed were they in old track. Ties removed under such circumstances should be more or less evenly distributed, the object being to get new ties in their places where they can afford a general support the next year when the most of the remaining ties must be taken out. After two or three years of renewals it usually happens that about a certain percentage need to be taken out every year; more sound ties are kept in the track continually; and ties need not then be taken out until they can be of no further use.

The best way to change ties in dirt ballast is to pull the spikes from the ties to be taken out, raise the track an inch or so and pull the old ties out with the pick, without digging. Then, after dressing out the sides of the bed occupied by the old tie, pull the new one in on the old bed without disturbing it, unless the new tie is more than ½ inch thicker than the old one. This is the most rapid way to change ties, but it cannot be done in other kinds of ballast, owing to the tendency of the ballast to work its way under the ties, thus preventing them from dropping back to the old bed again. Where there is a sag to be raised, however, and there are ties to come out, this is by all means the method to follow. First, pull the spikes from the ties which have to be taken out, then raise the track in the sag and tamp joint and center ties, as usual, to hold it to surface. It is then but a trifle to pull the old ties out and the new ones in, and to spike them and tamp them along with the rest.

The usual method of removing ties is to dig a trench beside the tie slightly deeper than the thickness of the tie and then to drive or pull the tie sidewise into the trench and haul it out. Where the space on one side of the tie is wider than on the other the trench should be dug in the wider space, so that the new tie can be properly spaced without extra digging. The spikes should be pulled from the tie with a view to using them again and the spikes on an adjacent tie should be started, so that if necessary the rail may be raised and blocked up on a spike to give more room for hauling out the old tie. Dress out the sides of the old tie bed, and the bottom, too, a little, in case the new tie is more than ½ in. thicker than the thickness of the old tie at the rail seat. In the case of rail-cut ties considerable dressing of the bottom of the old bed is sometimes necessary. It is desirable to have the new tie fit in snugly, and it is all the better if it is a little high on its new bed; although men must use judgment in this or they may waste much time trying to get ties out and in where the trench is not deep enough to afford sufficient room. But it is a mistake to dig out a bed for a new tie an inch or more deeper than the thickness of the tie, the whole length of the bed. Where the old bed is dug out too deep the new tie must virtually lie on a new bed of loose ballast. Under the middle of the tie it is well enough to have the bed somewhat deeper than the thickness of the tie, since, owing to the tendency to center binding, it is undesirable to have the bearing at this point as firm as it is under and outside the rails. The foregoing remarks apply more particularly to gravel and other ballast of similar constitution. When renewing ties in rock ballast the old bed, if dressed out at all, must usually be cut considerably deeper than the under face of the tie. The labor of renewing ties on a middle or intermediate track of a 3-track or 4-track road, or in a yard or next to a siding, is greater than on the outside tracks, since a trench must be dug between the tracks in order to get the old tie out. To get ties out of or into the track in a narrow cut, where the bank is too close to permit them to be pulled straight ahead, the trench may be deepened between the rails, so that the outside end of the tie may be thrown up and thus take advantage of the bank slope. After the new tie has been hauled in, take the blocking from under the rails, drive down the spikes which have previously been started on the tie adjacent, hold up the new tie and shovel tamp it, where necessary, raising it high enough to allow for settlement. It is well to tamp the ties before they are spiked, as then if the former work is not well done the ties will settle when they are spiked or under the first train that passes, and the fact will be discovered. If the bed of the track is old and hard the new ties should be bar tamped after a few days, when the trains will have settled them into the shovel tamping. The consolidation of the ballast from the weight of the traffic is necessary to restore stable conditions under the new ties.

In common practice two men usually work together. They should carry a sharp pick, two shovels and a sharply-pointed pinch bar, and a claw bar should be available for each two parties. The work should be so divided between the two men that both are kept busy. In some kinds of ballast no picking need be done, in which case both may shovel out; or else one may pull spikes while the other is shoveling. One holds up the end of the tie while the other shovel-tamps it, then both together tamp the middle and fill in. Where ties are being renewed thickly or close together it saves time, when removing the ballast from between the ties, to cast it back between the new ties just put in, instead of throwing it into piles here and there, inside and outside the rails. In this way the track can be filled in as the work progresses, and the work of once handling a good deal of material can be saved. It is best to have the spiking done by one man or party. The ties should be so stiffly tamped that it will not be necessary to hold them up to the rail with a bar during the spiking. By careful work a new tie can be put in the track so close to the old bed that bar tamping can be done efficiently, but the common run of track labor cannot be depended upon to exercise the judgment that is required in taking out the old ties to permit the new ties to be put in in this manner. And then, of course, there are many places where it becomes necessary to respace the ties to some extent, and the new tie does not go in exactly in the place of the old one, and in that case it does not find a hard bed underneath. The gage should be used in spiking the new ties, and where necessary the gage of the rails on the old ties should be corrected as the crew advances. Ties may be hauled out and in with a pick. It is the easiest way to handle them and does no harm if the pick is sharp, notwithstanding that objections are sometimes urged against the practice. If roadmasters who forbid this use of the pick will personally attempt to get the ties out and in some other way for awhile (by taking hold with the hands, for instance) I feel sure that their rules to this effect will soon be repealed. The ends of the ties should be put to line on one side, measuring from a notch on a shovel or pick handle, and the spacing of the ties should be carefully looked after. The new ties should be spaced to suit as well as may be the space or spaces left vacant by the old ones. For instance, two large ties may answer where three small ties are taken out. Sometimes a small tie may be made to take the place of a large one by respacing the adjacent ties.

Wherever joint ties have become skewed by creeping rails they should be squared around as the tie-renewing crew goes along; and very low joints, when such are found, should be picked up. While the work of tie renewals is under way on sidings it is a good plan to put the track in surface, because many of the low places usually need raising so high that the old ties may be pulled out without digging. I am not in favor, however, of undertaking tie renewals in connection with general surfacing work unless the track is to be reballasted, in which case an excellent opportunity for cheaply renewing the ties is presented; otherwise, one kind of work at a time is enough. Where there are many changes of work in a day much time is lost. The foreman who starts out to "put the track in surface and final finish" as the ties are renewed can spend a great deal of time on a short stretch of track, all to no great purpose if the track has to be overhauled within a short time to tamp the new ties to a solid bed; and this is the usual experience.

An adz should be carried along to use on new ties which may be found winding, and if the bark has not been removed from the new ties it should be peeled before putting them into the track. It will pay in the end. The old ties should be piled up each evening and the right of way cleared of pieces of bark and rotten wood. To distinguish the quality of old ties, those which are to be made further use of may be piled near the track, in locations convenient for loading on cars, and the old ties to be burned on the right of way may be piled further from the track. To distinguish between ties to be used for different purposes, those suitable for fence posts, for instance, may be piled parallel with the track and those to be used for fuel or other purpose may be piled at right angles to the track. Where it can be done as well as not the old ties, for convenience of piling, should all be pulled out on the same side of the track. Old ties should be trucked out of each cut as soon as the renewing crew has worked through it.

Many methods of dividing the crew for tie renewal work are in practice. Some find it advantageous to keep part of the men digging out trenches, while the remainder follow along replacing the ties and tamping them. Others set the whole gang at digging trenches until 50 or 100 are prepared and then go back and divide the men into parties of two for changing the ties and tamping them. Where the traffic is heavy and trains run at closer intervals during some portion of the day than at other times it is well to use this time for digging the trenches, if the method just mentioned be followed. Passing trains are some hindrance to the work of changing the ties, for while on intermediate parts of the rail it may not be unsafe to permit a train to pass with a tie out, such is not the case at the joint. If the tie renewed be a joint tie or one of two going in at the same place, the aim should be to have the new tie tamped by the time the train arrives. In such cases, then, the trains have to be watched. It is a good rule not to have a tie out, in any case, while a train is passing. Whatever method is followed the men should be kept out of one another's way as much as possible. If the men are working by twos, let each party take a rail by itself. If the crew is large enough, let one man do all the spike pulling, ahead of those taking out the ties. A day's work at renewing ties where there is but little or no ballast to dig away at their ends, to get them out of the track, is 8 to 10 ties per man in rock ballast and 14 to 18 ties per man in gravel ballast. In sand or dirt ballast the work is more rapid, the number of ties renewed per man depending upon the method of getting the old ties out of the track; by the ordinary method of digging trenches the number is about 20.

There are those who recommend putting ties of the same quality, as near as may be, together, with the idea that in renewals all will be so nearly decayed alike that they may be taken out together. I regard such practice as both useless and wrong, for of ties of the same quality, apparently, some will outlast others two or three years. Hence to take them all out at the same time would be wasteful; moreover, by taking all out together the old bed is much disturbed. In my opinion the ideal way is just the opposite; that is, not to have more than one tie in a place to come out during the same season, although something is saved in labor, certainly, by taking out two adjacent ties at the same time, since only one trench need be excavated for the two. A tie which will last another year, however, should not be removed simply because a trench is already prepared for pulling it out. Such are my sentiments on the question of renewing ties out of face, and I regard the matter of disturbance to roadbed fully as important, from an economical standpoint, as the waste in timber. There is also another important consideration. In renewing ties out of face, or in patches of many ties in a place, the track, just preceding the time of renewal, must become very much weakened unless the ties be taken out sooner than they necessarily would be in renewing promiscuously. Especially would this be the case on curves. There can be no mistaking the fact that after the tie begins to fail rapidly—as is the case near the close of its life—there is in point of service a time margin favorable to the promiscuous method of renewing ties; and this must amount to at least one year, if anything. On the other hand, if part of the ties in a given stretch be renewed yearly the strength or firmness of the track structure remains at all times more nearly at an average, or practically always the same. In the nature of things this is the condition most to be desired, for it is impossible to keep sound ties in the track at all times, except at great and unnecessary expense. Putting the average life of ties at 6½ years the average number renewed in old track is only two or three ties per rail length each year, so that only a relatively small portion of the roadbed is disturbed. For this reason, if any attention at all be given to the quality of the new ties, it is better to mix the different qualities as much as possible than to group them together. As heretofore stated, where there are wide differences, the hardest and best ties should be placed in the curves.

Touching further upon the question of renewing ties out of face, it is admitted by all that in such practice many ties must be removed which could see further service. In 1897 a committee of the Roadmasters' Association of America took into consideration the scheme of making use of these partly worn ties in side-tracks. The investigation led to an adverse report, it being found better economy to use new second-class ties than ties removed from main track capable of two years' further service. The following extracts from the report give the course of reasoning pursued:

"We have a tie which in some instances will last two years if not disturbed. It is taken out of the main line and placed in side-track, where, owing to its having been rehandled, its life is somewhat impaired; and though there is less running over it, it will not last much longer than it would have lasted in the former place. Assume a first-class tie to cost 40 cents and a second-class tie 20 cents. The labor necessary to renew a tie in stone ballast will amount to about 15 cents, and in gravel about 10 cents; this includes removing the old tie, putting in the new one and tamping once. The life of a tie is taken at 7 years. In renewing out of face we will consider a tie (and there are many of them) which if not disturbed would have lasted 2 more years. The cost of this tie per year is $5\frac{5}{7}$ cents. To remove it will cost one-fourth of 10 (for gravel) or $2\frac{1}{2}$ cents. The cost of labor necessary to replace it in the side-track is 10 cents. Then, not considering the cost of handling, we have:

Cost of tie at $5\frac{5}{7}$ cents per year for two years	$11\frac{1}{2}$	cents
Cost of removal	$2\frac{1}{2}$	cents
Cost of renewal	10	cents
Total	24	cents
A new second-class tie, which would last 7 years, would cost	20	cents
Cost of renewal	10	cents
Total	30	cents

"In the former case the cost per year for side-track is about 12 cents; in the latter $4^2/_7$ cents. Hence, from this standpoint no saving is effected."

It might be added that on the basis of using a new first-class tie in side-track, lasting only 7 years, the cost per year ($7^1/_7$ cents) is still decidedly against the use of the partly worn tie. The report next deals with the interest cost on the investment for a first-class tie. At 5 per cent this item amounts to 2 cents yearly, which means that if two years of service be lost a new investment must be made that much sooner, thus adding 4 cents to the ultimate cost of the tie.

Now in certain special cases where the ties are not easily accessible for removal it pays to renew out of face—such, for instance, as under highway crossings, opposite station platforms and in tunnels. Obviously it would not pay to tear up crossing plank every year to renew two or three ties. In such places a full set of selected ties should replace the old ones each time the support begins to get poor, even if all have not run their full life. In renewing ties under a crossing the hard surface of the road or street should not be torn up to make room for hauling ties out at the side of the track. Either take up the rails to let the ties out and in or else throw out all the ballast between the ties and slue them around parallel or diagonally to the rails so as to get them out and in. Extra tamping is required at crossings. To remove ties in a narrow cut, or long switch ties where the adjoining track interferes, pull all the spikes on one rail and raise it off the ties high enough to let all the ties out on that side. At a pinch it may sometimes pay to split off the top of the old tie (where badly cut into by the rail, for example) or to cut it in two between the rails. In side and yard tracks also, where ties may be allowed to decay to a degree not permissible in main track, it may pay to renew ties out of face. If the foreman can arrange for the exclusive use of the side-track for a time the best method of renewing is to disconnect stretches of rails, pull all the spikes and throw both strings of rails clear off the ties. Then lift out the old ties, clean out the beds, replace with new ties, connect up and spike down the rails and surface the track. By watching carefully for high ties before the rails are thrown in not much surfacing need be required unless the track was previously out of surface.

The renewal of ties should begin in the spring, just as soon as the track has been gone over and brought to fair surface. It is a mistake to prolong this work all through the summer. The main essentials of good track are sound ties and smooth surface and alignment. Just after the departure of the frost the surface and alignment conditions of the track are at their worst; and since the renewing of ties is always more or less detrimental to the surface, it is not usually advisable to do a great amount of smoothing up until after the work of renewals is over. The latter should therefore be done as rapidly as possible, in order that all the new ties may be in before the track is thoroughly gone over and tamped, because it is a waste of money to spend much time tamping ties which must be taken out soon; but if the new ties are put in early this need not be done. It is better to hire extra men to push this work and then decrease the force afterward sufficiently to make up for it, if need be, than to have the work drag along. In the northern states all ties to be renewed in main track should be put in by July 1st each year, and all the better if a month earlier.

89. Renewing Ballast.—Track should be kept filled at all points, and, except in dirt ballast, there should be enough ballast on the shoulder, against the ends of the ties, to properly dress the middle of the track and the spaces between the ends of the ties after surfacing. The shoulders should be kept well filled out according to the standard form. As soon as the tie ends begin to overhang the shoulder or the spaces between the ties become only partially filled in, tamping must be done more frequently, and the track is not so easily held in line. Ballast is continually being used up in maintaining the track to surface. Whenever the track in a sag is raised, not only is ballast required to fill the space under the ties raised, but the ties to be filled in afterward are higher than they were before; hence, unless there is ballast at hand outside the tie ends (a surplus should never be left lying between the rails), there will not usually be a sufficient supply to fill in the track properly.

Broken stone ballast in time becomes foul with dirt, dust, cinders and weeds and when such is the case it should be forked over before replenishing the deficiencies. Where dirt or natural soil ballast is to be replaced by gravel, cinders, or other ballast of better quality, all the dirt should be removed from between the ties as far down as their bottoms before the new ballast is unloaded. In this way the old ballast (on fills) can be used to strengthen the shoulder, outside the tie ends, and the removal of such material will keep the ballast of good quality from getting mixed with that which is inferior. The rules of the Southern Pacific Co. for reballasting dirt track direct that where the grade stakes require a lift of less than 8 ins. the roadbed shall be dug out to get ballast of that depth under the ties, and that where the stakes require a lift of over 12 ins. the banks must be built up to such a hight that not more than this depth of ballast will be required. Where the track is to be lifted higher than the allowable depth of ballast and the roadbed is to be built up with ordinary filling, the track should first be raised and tamped with such material, so as to keep the middle of the roadbed higher than the shoulders, for drainage purposes; otherwise water which sinks through the ballast has no outlet except by the slow process of seepage through the embankment, softening the material and causing it to settle continually or to heave in winter. The cause for many a bad piece of track is a trough-shaped roadbed, the high shoulders obstructing side drainage from center. Unless an embankment is well crowned and compacted before the track is laid the tendency is to assume such a shape when settlement occurs. The practice of Roadmaster Henry Ware, of the Buffalo, Rochester & Pittsburg Ry., when renewing ballast on embankments which have settled in this manner, is to cut the shoulders down even with or a little below the sub-grade line as it stands underneath the ties. If the shoulders need strengthening, such work, called "bank edging," should be done before the ballast for renewal is unloaded. Shoulders should be replenished with dirt or natural soil and not with ballast material. The latter is the more costly and it will not remain so well in place on a slope.

Methods of handling material for ballast renewals are described and discussed in § 148, Chap. X. Before dumping ballast all spikes, bolts, splices, rails, etc., should be picked up. There is in practice to some extent a very convenient way of obtaining cinders for renewing ballast. A section of track which is in need of ballast, about a mile long, say, is selected and sign boards marked "DUMP HERE" are put up on either end of this section, on the fireman's side. As trains pass, the firemen dump their ash pans and the section men throw out the cinders as fast as they accumulate between the rails. In a little while enough cinders can be collected in this way to reballast the track or replenish the deficiency of filling material, after which the sign boards are moved ahead, or to some other point where ballast is needed. Sign boards for this purpose can be placed at two or more points on a division at the same time, and much expense in handling and hauling cinders can thereby be saved.

The work of reballasting main track which carries a heavy traffic is usually done by a large crew or extra gang. Where the lift is high in gravel or similar ballast, say 4 ins. or more, one tamping will not suffice to hold the track in even surface, and as some parts of it will need tamping the second time, a good way to plan the work is about as follows: Raise the rails up to the grade stakes and shovel tamp the ties outside and under the rails, but not between the rails. The spaces between the ties, inside the rails, may be filled in loosely and rather full and the material permitted to work itself under the ties by the jarring from the trains. In about a week the tamping crew should go over the track again, putting it in good surface and shovel tamping the ties all the way across. It may then be lined up and filled in. The advantages of this method are that the ballast supporting the ties under and outside the rails becomes compacted much harder than it does in the middle of the track, forming the firmest support where it ought to be, and in dispensing with the tamping of the middle of the ties in the first instance a good deal of labor is saved. In reballasting track it is necessary to make a run-off or gradual slope at the end of the raised portion each time a train passes, and to economize time while the work of raising is temporarily suspended the gang may be turned back and set to filling in. As already stated in another connection, the raising of a piece of track out of face presents an opportunity for the cheapest method of renewing ties.

The cost of reballasting track varies, of course, with the cost of handling and hauling the ballast and the price and efficiency of the labor in raising and tamping. The following figures are taken from carefully kept records of work in gravel, and in a general way may be of assistance in estimating labor costs. In one instance where the track was raised an average hight of 10 ins., a crew of 95 men unloaded the material and averaged 2500 ft. of track put up and finished per day, during the season. The men were divided for the work as follows: There was one gang of

50 men which raised the track and surfaced it roughly, and another gang of 45 men followed behind a day or two later, placing the track to smooth surface, lining, filling in, and dressing it up complete. These figures, it will be understood, refer to thorough work. On another railroad where the track was raised 6 to 8 ins. the average work performed by one man during the season was 40 ft. of track lifted, tamped, filled in and dressed complete, per day, including the work of a small gang following two or three days behind the raising gang to pick up the low spots and line out all the small kinks. It is a matter of common report that one man can average 60 to 65 ft. of track raised 4 to 6 ins. and completely ballasted per day.

90. Clearing Track of Grass and Weeds.—An item of quite heavy expense in maintenance work is that of clearing track of grass and weeds. There are two principal reasons making this work a necessity: first, locomotives are seriously impeded when grass or weeds get high enough to reach the wheels, for when crushed they form a sort of lubricant on the rail which vitiates the adhesion of the drivers; and more than this, grass or weeds just outside the rail wipe grease and oil from the wheels and afterward lop over and apply it to the rails; secondly, grass and weeds must be removed from between the ties in order to sight the rails for raising track; for as few as a dozen spears of grass, or two or three weeds near a rail—not to speak of a rank growth—may make its top surface at the point which is being raised almost invisible to the man sighting it. In clean broken stone or cinder ballast weeds do not usually give trouble, but they grow quite well in gravel ballast after it gets old, and in dirt ballast luxuriantly. The most common varieties of vegetation found in track are grasses, white clover and a kind of wiry joint grass sometimes called "gunbright." These varieties, it seems, will grow in track where they are not to be found in the surrounding region: explained probably by the theory that seeds are gathered up by car trucks and dropped along in places, and perhaps, too, they may be carried along by currents of air set up by moving trains. The most troublesome are the grasses and clovers, because of the tough and wiry roots. The annual cost of cutting these by hand may vary from $5 to $40 per mile, depending on the kind of ballast they grow in and the start they get. Figures commonly reported for track well ballasted with gravel run from $13 to $16 per mile, and in fertile ballast $25 per mile is not surprising. Depth of ballast is a condition of some account in the growth of vegetation in track, because in shallow ballast, although it may be clean, grasses and weeds may take root in the subsoil and grow through the ballast. Where such is the case the vegetation is hard to kill.

Attempts have been made to kill out vegetation in track and render the ballast sterile by sprinkling salt water or brine over it, but the cost of getting salt enough into the ballast to make the treatment effective renders the method rather impracticable in ordinary situations. Moreover, after the strength of the salt has departed the ground is left more fertile than before, notwithstanding that the application of a sufficient quantity of it is sure death to vegetation for a while. Permanent effects are not secured, therefore, except upon repeated applications, perhaps as often as once each year. In the vicinity of the Great Salt Lake, where very salty water can be cheaply obtained, the brine treatment has been found effective and more economical than the method of cutting the weeds by hand. An outfit that has been used by the Oregon Short Line R. R. consists of six flat cars each carrying a wooden tank of 3500 gals. capacity. The tanks are connected by 3-in. pipe and hose, above the couplers, and a sprinkling apparatus is attached at the rear of the train. It is also arranged to sprinkle the track from each car direct by means of splash boards. The best success has been with brine obtained from the lake direct. In the year 1900 experiments were made with brine produced by placing unrefined salt, in the solid condition, in the tanks and taking water from the water station most convenient to the work of sprinkling. This salt is a product which precipitates to the bottom at a temperature of 30 F. or under, and is washed on shore, where it can be easily obtained in large quantities, and at a higher temperature than that stated it can be held in solution. Experiments with this material were not altogether satisfactory.

At one time some experiments in the electrocution of vegetation in track were carried out on the Yazoo & Mississippi Valley R. R., which may be worth mentioning. A dynamo of the alternating type was set up in a box car, together with a stationary engine to drive it, the steam being supplied by hose connection with the locomotive. By a step-up transformer the voltage was raised to about 10,000. One terminal of the secondary circuit was attached to a large brush made of bare copper wires. This brush was of sufficient length to extend beyond the ends of the ties over both shoulders and it was suspended at right angles to the track from a flat car and made adjustable so as to be raised or lowered. The other terminal of the secondary circuit was grounded and the brush was trailed slowly along on the ground. Of course, the electric current found its circuit through the easiest resistance, or through the vegetation, on account of the large proportion of water contained, which, in comparison with the dry earth surface, is a fair conductor. It is said that wherever good contact was had with the vegetation every vestige of life was destroyed to the very ends of the roots, but the powerful influence did not seem to be uniformly distributed, so that it was found necessary to go over the ground a second time in order to make the work thoroughly effective. As the method seems to have been dropped it may be assumed that on the whole the experiments were not successful. Experiments have also been conducted by blowing steam into the ground from locomotives fitted up for the purpose. Such methods have been tried on the Chicago & Northwestern and the Chicago, Burlington & Quincy roads, but without the desired measure of success. The only satisfactory substitute which seems to have been found for the laborious process of grubbing grass and weeds in the track with a shovel or other primitive instrument is the oil burner. Cars equipped with this device have been put into regular service on a number of western roads where the expense of keeping vegetation down on dirt-ballasted tracks by grubbing with a shovel is a formidable figure, compared with the expense for the same work where tracks are ballasted with a good quality of gravel.

Weed-Burning Cars.—One of the earliest roads, if not the earliest, to make use of a weed-burning machine was the Minneapolis, St. Paul & Sault Ste. Marie Ry., where one was constructed on plans designed by Mr. E. A. Williams, mechanical superintendent, and first used in the spring of 1894. In the construction of this machine use was made of an ordinary flat car, on the front end of which (as it runs in service) is mounted an upright 30-h. p. boiler and pair of 7x10-in. engines. By means of a sprocket chain connection between the engine shaft and a car axle the car is made self-propelling. In order to overcome slipping due to the lopping of long weeds over the rails the two axles of the truck are connected by sprocket chain. By this means of locomotion a speed of from 10 to 12 miles per hour is easily made, as when running to sidings to meet passing trains. The water supply for

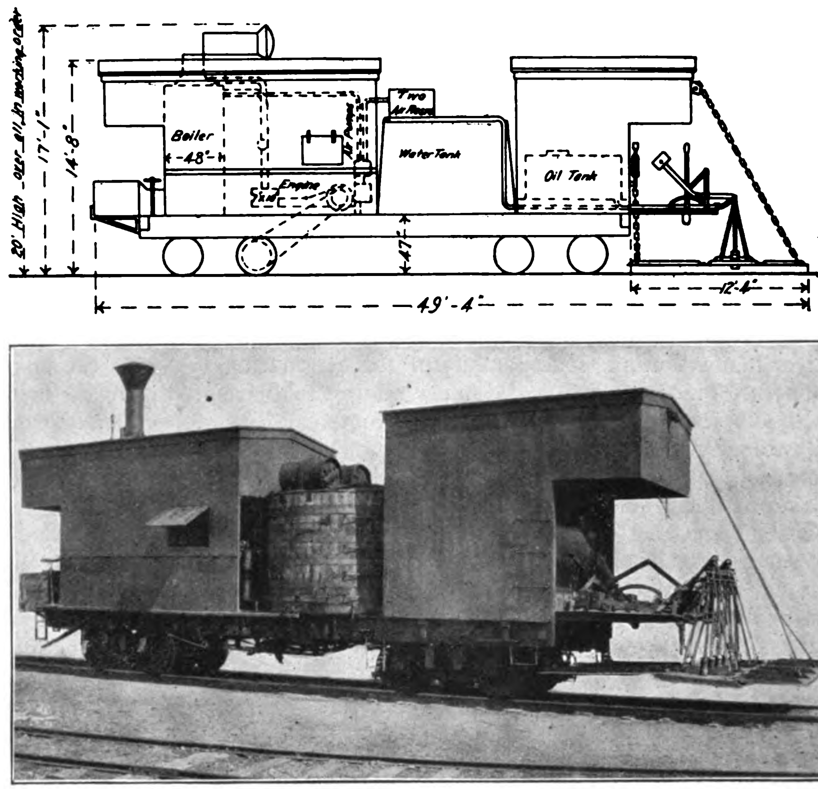

Fig. 253.—Weed-Burning Car, M., St. P. & S. St. M. Ry.

the boiler and for extinguishing fires which may be set accidentally is carried in a wooden tank in the center of the car, as seen in Fig. 253. On top of this tank there are two air reservoirs, and inside of the forward cab there are two 8-in. air pumps for creating the air pressure necessary to spray the oil into the burners. The burner rigging is suspended from a rear platform built upon four T-rails. The shield and burners are hung from the end of this platform upon bell cranks, and an old reverse lever and quadrant are used to adjust the burners to the desired hight from the rail. The burners are easily taken down when it is desired to couple the car in with a train. The tank for supplying oil to the burners is located inside the rear cab. The general appearance of the machine is shown by the reproduced photograph, while the arrangement of the machinery on the car, and the principal dimensions are shown in the line engraving. The burner shield, which is made of iron plate, covers the track around the burners, and serves the three-fold purpose of protecting the car from the heat of the burners, protecting the flame from the wind, and in confining the heat to the immediate vicinity of the ground surface. The shield has flaps, front and back, adjustable by chains attached to counterbalanced levers. There are six burners in all—four being between the rails and one outside of each rail. The burners stand $15\frac{1}{2}$ ins. apart, from centers, the burners outside of the rails being $7\frac{3}{4}$ ins. from the center of the rail. The details of these burners are shown in Fig 254, it being understood, of course, that the burner, as used on the machine, stands in the vertical position. The oil and compressed air are brought to the burner in separate pipes, the oil flowing by gravity. The car is operated

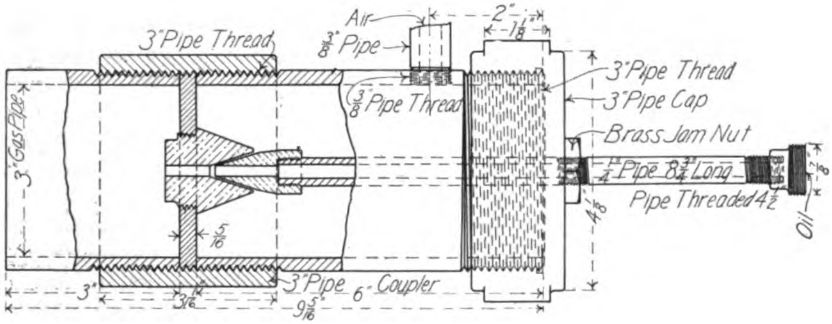

Fig. 254.—Details of Burner, M., St. P. & S. St. M. Weed-Burning Car.

by two men: one to fire the boiler and run the engine and another to operate the burners. From 10 to 13 miles of track are burned over per day, and, on an average, about 20½ gals. of crude petroleum are consumed per mile of track burned over. Ordinarily the track is burned over only once during the season, but if the burning is not started until late in the summer, or until the weeds have got a good start, or where the growth is particularly heavy, it is sometimes found necessary to burn the same ground over twice during the season. The following statement of the performance of the car in burning over 722 miles of track in one season gives the various items in detail: The total cost, including $253.49 in wages, 14,768 gals. oil at $.0389, 93,150 lbs. coal at $2.82. per ton, and $121.87 repairs, was $1081.17, or $1.50 per mile.

A weed burner used on the Chicago Great Western Ry. is arranged on a platform at the rear end of a box car (Fig. 255) which is self propelling, being driven by an 8x10-in. double cylinder mining engine connected with an axle by sprocket chain. Within the car are tanks holding the oil and other necessary supplies. There are eight burners, spaced 1 ft. apart, projecting through a metallic plate 10 ft. square, for confining the heat to the surface of the ground. The burners are distributed two outside each rail and four between the rails. The blast to the burners is furnished by compressed air at 70 lbs. pressure, supplied by two 9½-in. Westinghouse air pumps. In operation the burners are started and dropped to within about 4 ins. of the top of the rail. The car moves over the track at a

Fig. 255.—Weed Burner, Chicago Great Western Ry.

speed of about 1 mile per hour. The first time over the track the flame wilts and kills the vegetation, which is allowed to dry for several days, when the car is again run over and it is entirely consumed. Three men (an engineer, fireman and helper) are required to operate the car and burner and the section men follow along to keep fire from spreading. Crude oil is used and about 30 gallons are required per mile, each time the track is burned over.

On several other roads the weed-burning apparatus is arranged upon a flat car, which is moved over the track by means of a locomotive. In the equipment of the weed-burning car of the Northern Pacific Ry. the burners and shield are carried at the forward end of a flat car, which is pushed ahead of a locomotive. The number of burners is eighteen, arranged in three rows, with two burners in the track and two outside each rail, in each row. The shield and burners are hinged, and, by means of an air cylinder, piston and chain passed over a pulley they can be raised to a vertical position, to get them out of the way when not in use. The flat car also carries a reservoir of 16,000 cu. ins. capacity for air storage and a 1600-gal. tank for the oil supply. Air pressure is provided by a 10x14-in. "Class C" Rand compressor mounted on the locomotive pilot and taking steam from the locomotive. On its way to the burners the oil is passed through a strainer, to remove foreign matter which might clog the apparatus. The large number of burners makes the apparatus effective at faster speed than that at which the weed burners above described are worked. This car burns over about 30 miles of track per day, at a cost of $2 to $4 per mile. A weed burner used on the James river division of the Chicago, Milwaukee & St. Paul Ry. consists of a tank of 12 bbls. capacity placed on a flat car, from which pipes are led to burners at the end of the car. Of these burners there are eight—four between the rails and two outside each rail. The fuel used is crude oil, about one barrel being required per mile. The blast is furnished by compressed air supplied by air pumps on the locomotive which hauls the car; steam has also been used for this purpose with equal satisfaction. From 8 to 10 miles of track are burned over per day, and it is found that about three burnings a season are necessary in order to keep the weeds down so as not to interfere with trains. This machine will take care of about 200 miles of track. The crew necessary to operate the machine consists of two men besides the engineer and fireman—one with the burner and one to follow behind to extinguish fires which get started on the right of way outside the track. The improved machines of this road are described in §209.

The Atchison, Topeka & Santa Fe Ry. has two weed burners constructed on different ideas from those hitherto. One of the outfits consists of an iron car with an iron shield suspended between the trucks; an oil-tank car with a capacity of 4500 gals.; and an oil tank having a capacity of 800 gals., built sufficiently strong to withstand a pressure of 70 lbs. per sq. in. This tank is filled from the tank car and the oil is forced to the burners by air pressure. The shield underneath the car is 32 ft long and is provided with aprons at each side to retain the heat and prevent the flame from being blown to one side of the shield by side winds. The contrivance is put in operation by igniting the oil and lowering the shield to within 3 or 4 ins. of the rail, when the aprons on the sides of the shield are dropped and slide on the ground. When bridges are crossed the shield is lifted 12 or 15 ins. clear of the rails and the oil supply is shut off. As the oil is directed against the under surface of the shield the latter retains sufficient heat to ignite the oil for a considerable time after the oil has been shut off. In crossing culverts and cattle guards it is not found necessary to close the oil valves, since the lifting of the shield carries the flame high enough to prevent setting fire to the timbers. The amount of oil required for each of the four burners is about 8 gals. per mile. It is found that solid ties will not catch fire, but a gang of men is kept close to the car to put out such fires as may get started. The speed which the car can make depends upon the kind of vegetation worked over. In weeds not to exceed 5 or 6 ins. in hight it is practicable to run at a speed of about four miles an hour, but if the track is covered thickly with heavy, coarse grass effective work cannot be done at a speed exceeding 2½ miles per hour. It is found that only the light blades of grass and weeds are consumed, the greater portion of the vegetation being scorched, so that it soon droops and dies out. The four burners spread the flame over the whole space under the shield, which reaches about 30 ins. outside the rails. The cost of operating the car per day of 12 hours is $50, and the average length of track worked over is 20 miles per day, which makes the average expense of destroying the weeds about $2.50 per mile. The cost of the oil is not a large part of the expense, the consideration of chief importance being to keep the outfit moving. During the first year of its operation it covered more than 1500 miles of track. The cost of equipping the car with burners, building the oil tank, and the additional air pumps on the locomotives for supplying the blast, was about $1800. During another season the machine burned over 900 miles of track at an expense of $2.35 per mile.

Another weed burner used on this road was constructed by utilizing an old plate-girder turntable as the body part for an iron car. The turntable is supported by two trucks, one near one end of the table and the other about half way between the middle of the turntable and the other end, so that one end (the rear end) of the turntable overhangs the truck a considerable distance. Beneath this overhanging end there is suspended a shield 9 ft. wide and 16 ft. long, built up of two thicknesses of sheet steel spaced 6 ins. apart and filled with mineral wool to absorb the heat and prevent its radiation against the superstructure. When not in service the shield is raised 18 ins. above the rail. There are wings at the sides and at the rear end, which drag on the ground and confine the flame to the space beneath the shield. There is a cabin built upon the turntable, within which are operated three 9½-in. pumps for the air supply, taking steam from the locomotive hauling the outfit. The exhaust steam from these pumps is carried in pipes to the rear end and along the sides of the burner shield and discharged down into the ground, to quench any fires which may get started. The outfit includes a car carrying a 6000-gal. oil tank; and an extra water tender. The tank car carries a large water pump and a pump for taking oil out of stationary tanks to fill the portable one. In operation the car makes a speed of 1½ to 3½ miles per hour, according to the density and growth of the vegetation, and in light work about a barrel of fuel oil is used per mile of track burned over.

The advantage of economy seems to lie with weed-burning cars which propel themselves over the track. The daily expense of operating a locomotive exceeds that necessary to operate a self-propelling weed-burning car, and it would seem doubtful if the time to be saved in the use of a locomotive to haul the weed burner out of the way of passing trains, over that consumed by the slower moving self-propelling machine, would be sufficient to compensate for the extra cost of the locomotive operation. Especially would this seem to be the case on branch lines where the infrequency of the traffic permits the car to hold main track at comparatively long intervals. In long-distance movements, where the machine is not in service during transit, the use of the freight trains is of course available. The introduction of either type of machine must bring joy to the hearts of trackmen; for of all back-aching work the cutting of grass and weeds in track by the usual method is the worst; in a physical sense it is torture.

The almost universal, and seemingly the most satisfactory, method of disposing of vegetation in track is to cut it down as fast as it grows sufficiently high to become bothersome. This work is usually done by grubbing with the common track shovel, and on various roads it is known as "skerfing" or "sculping." The shovel seems to be the only implement in the ordinary outfit of track tools which is adapted to this work, but on humane principles something more agreeable to work with should be substituted. A steel blade about the width of an ordinary shovel blade, but shorter and thinner, fastened to a fork on the end of a long handle, on about the hang of a pitchfork, is in use to some extent for grubbing grass and weeds, one of the roads using it being the Chicago, Rock Island & Pacific. As might be expected, it is found to be a more efficient tool for

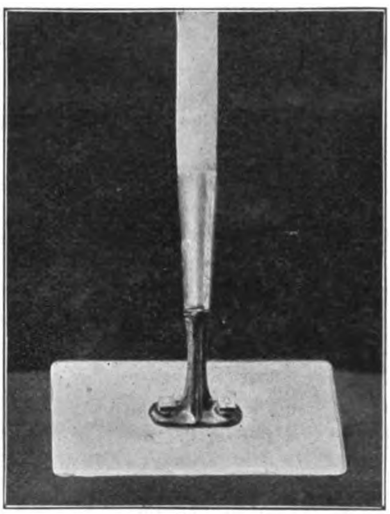

Fig. 256.—Blundell Weeding Hoe.

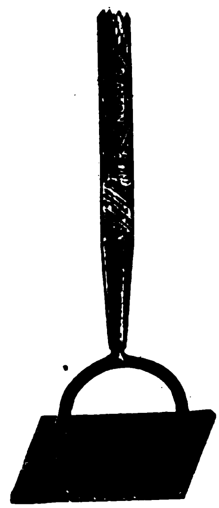

Fig. 256 A.—Weed Scuffle.

the purpose than the shovel, except in coarse gravel. A strong, wide hoe is also a better tool than the shovel for this work. A weeding hoe devised by Roadmaster E. C. Blundell, of the Chicago, St. Paul, Minneapolis & Omaha Ry., and used on that and several other roads, is shown in Fig. 256. It consists of a rectangular blade of oil-tempered steel, 9x5 ins. in size, with rounded corners. The blade is polished on both sides and has four cutting edges, beveled from top to bottom. To this blade is bolted a weighted tang, with a socket for a handle, which is 5 ft. long. This arrangement permits the substitution of a new blade when the old one is worn out. In using this weed cutter the dirt or ballast which is liable to be thrown aside in weeding with other devices remains in place in the track, or on the shoulder, and a man can stand erect and do a much larger amount of work in a day than with the ordinary track shovel, and evidently with greater ease. On the Denver & Rio Grande R. R. use is made of a weed cutter consisting of a triangular steel blade with a shank attached to a pitchfork handle. It works well in sand and dirt ballast, but not in coarse gravel, for which a shovel or heavy hoe seems best adapted. On the Evansville & Terre Haute R. R. a weed "scuffle" (Fig. 256A) is made from a piece of old shovel blade, with a long handle. The tool is made in quite large numbers at a time. The blades of old shovels are thrown into a furnace, straightened under the hammer, sheared to size, punched, sharpened, tempered and riveted to the shank. The shovels most suitable for grubbing weeds are old ones worn out for other purposes, because they are lighter. When grubbing in dirt ballast or other soft material, it helps matters along to trim the blade off squarely and then to bluntly grind it to a sharp cutting edge, but good shovels should not be ground or filed in this manner.

Vegetation in track should be cut before or during the heat of the day, so that it will wilt quickly and not need to be thrown out. Some make it a practice to scrape it into piles and throw it outside, and some give it a toss with the shovel as it is cut, thereby throwing away much ballast also. After a few cuttings in this manner the ballast on the shoulder and between the ties gradually disappears down over the bank. If the foreman is behind in his work, and there are heavy grades, he should cut the grass and weeds on the grades first. The annual contest waged against growing vegetation to maintain track in clean condition cuts into the time when much important work is on hand, and it is well to consider how far actual necessities require the work to be carried. In gravel ballast it is well to cut out as far as the gravel extends on the shoulder, or at least 3 ft. from the ends of the ties, but in dirt ballast it is hardly worth while cutting any more than the width of a shovel outside the ties, to protect them from catching fire, as this distance will usually be found sufficient for all practical purposes. Or where it is customary to burn over the right of way as soon as the grass gets dry enough in the fall, the weeds need be cut no farther than between the ties, for while burning the grass close to the track the ties can be watched. A railway company which cannot afford better ballast than dirt can ill afford to go to the expense of keeping the shoulders clear of grass and weeds. Besides, in dirt ballast the shoulder must slope from the bottom of the tie end, for drainage, and any cutting away necessarily weakens the support of the tie outside the rail.

On some roads, including the Southern Pacific, the regulations require that during the grass-growing season only so much grass and weeds shall be removed from the track as is necessary to keep the rails clear. At the end of the growing season, which is officially defined for each roadmaster's district, the grass is cut off accurately to the sod lines and after that vegetation must be kept down, between these lines, until the commencement of the next growing season. For ornamental purposes it is quite customary to preserve a nice grass line or sod line at some uniform distance from the rail. Where much weed cutting is done this grass line is liable to lead to some trouble, as the tendency is to work down the material between it and the ends of the ties and leave a shoulder at the edge of the grass to obstruct drainage. In some instances one will find channels the width of a shovel blade cut through this shoulder at intervals to drain off the water. This practice suggests that wherever the shoulders are of uniform width the grass line should be at the edge, or just over the edge, of the embankment.

Old stone ballast which has accumulated dust, cinders or dirt will grow vegetation, and when such is the case it takes an immense amount of labor to remove it and keep it down. The best way to do it is to pick up the whole filling and work it over so that the material is cleaned of dirt to a good depth. It takes time, but it is a sure method and nothing has a chance to grow in it for a long time afterward. On some roads the stone ballast is so treated every three or four years.

91. Mowing.—All grass and weeds on the right of way should be mowed each year before being allowed to go to seed. In some states the law provides a penalty for allowing Canada thistles to go to seed. The mowing should begin where the weed cutting on the shoulder leaves off, and it should usually extend to the limits of the right of way. Near wooden culverts and bridges or any kind of timber-work the grass, after drying, should be burned at the first favorable opportunity, and it is a good plan to burn over all the right of way. Vines or tall grass should not be allowed to run on or grow around trestles, telegraph poles or other timber-work. It is well, also, to cut with the shovel, the same as in the track, the grass and weeds near timber-work and telegraph poles. Around the latter it is a good plan to clear a space of at least 3 ft. radius before burning over the right of way. By taking a day when the wind is favorable the grass, brush, etc. in the vicinity of property liable to be destroyed by fire can, by watching, be burned with safety, and the danger of other fires that same year will be avoided. One way of protecting telegraph poles when burning right of way is to cut the grass around them and then throw fresh dirt around the pole. Vegetable growth at the foot of a telegraph pole hastens decay at the ground line. One way to prevent vegetation from contact with the pole is to make a small excavation around the pole and fill it with concrete. A patented device for the same purpose is a piece of sewer pipe around the pole, set into the ground socket upward, with the space between the pole and the pipe filled with screened gravel and tar or with cement. In setting new poles ordinary lengths of sewer pipe are used, but for poles already set the section of pipe is divided longitudinally into two pieces.

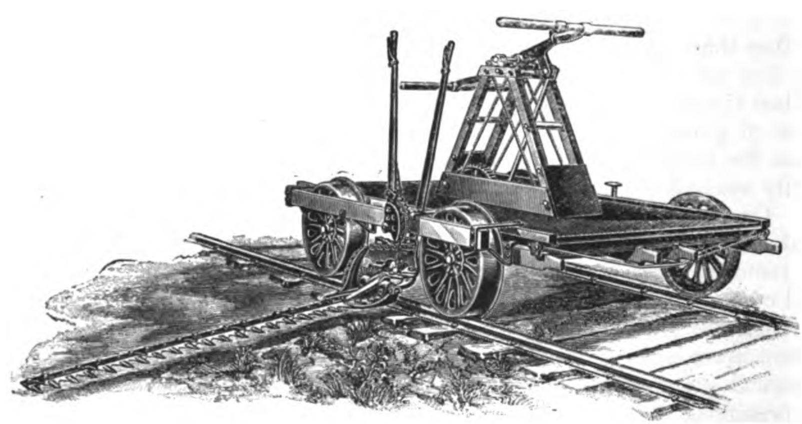

Fig. 257.—Weed-Cutting Hand Car.

In heavy grass or weeds or on rough ground the cost of mowing right of way is a considerable item—$10 to $20 per mile, $12 to $17 per mile being ordinary figures for right of way 100 ft. wide. On smooth land it sometimes pays to hire farmers to cut over as much of the right of way as possible with their mowing machines, and where there is good grass the farmers are usually willing to take the hay for compensation. In prairie country there is opportunity to make such arrangements. Some section foremen with an eye to business have prepared the right of way for machine mowing by plowing the ground, harrowing down the rough spots and seeding it with a good quality of grass, paying the farmers for the work with old ties. Each following season the farmers are then eager to mow the right of way for the hay.

On some western roads where it has been found desirable to mow only far enough from the track to clear for trains, a slow-speed hand car rigged with a side cutter bar, like a mowing machine, the sickle bar being geared to the axle of the car, is used to cut a swath each side of the track. The machine is run by a crew of four to six men, according to the density of the growth, and, when cutting, a speed of 4 or 5 miles per hour is made. Figure 257 shows a Sheffield car of this kind. The cutter bar is 6 ft. in length and is so arranged that it can be folded to a vertical position so as to pass bridges or other obstructions. The sickle bar can be thrown in or out of gear at will. The cutter bar can be adjusted to cut as low as the ends of the ties will permit and to a point 8 ft. from the rail. By a peculiar construction of the cutting arrangement it can be operated equally as well down the slope of a hill or up the face of a cut as on level ground. The weight of the car entire is 750 lbs. The car is placed in charge of one man, who looks after the mowing for a division, the crew necessary to run the machine being furnished by each section as the car comes along. Before the arrival of the car the section foremen see that old ties, stones, etc., are removed from the vicinity of the track. After the mowing season is over the cutting apparatus is taken off and the hand car is put to general use.

92. Cutting Brush.—Some railroad companies hold miles of right of way, of a width which clearly exceeds their present or future needs, for no other apparent reason than the privilege of paying taxes and cutting a crop of brush or weeds on it yearly. Around curves a wide right of way is needed, in order that the company may keep a clear space wide enough to enable trainmen to see a good distance ahead, and the usual width of 100 ft. is none too much. At public road crossings, also, and especially if the road emerges from a forest or is enclosed by trees or other objects which obstruct the view each way along the track, a wide right of way should be kept cleared. At cuts a wide right of way is necessary to provide room for snow fences, and in many cases a width of 100 ft. is insufficient. At other points, however, there is usually no need of more than 50 ft. for this purpose, and unless there is a considerable fill or cut, or a prospect of some future need of more room can be seen, there is no reason why the company should burden itself by holding a uniform width of 100 ft. everywhere, to be cut over. There is, in an extra width of 50 ft., about 6 acres of additional right of way per mile. At a cost of $2.50 to $3 per acre for brush cutting and, say, $1 per acre for mowing grass and weeds, this extra land calls for something between $6 and $18 of extra expenditure per mile, yearly. It seems almost a pity that along thousands of miles of railroad so much unused right of way should go to waste. It ought to be arranged to set the fences in closer to the track and let the farmers have the use of the land temporarily vacated .

Where the surrounding country is cleared brush must be cut the full width of the right of way in order to give an unobstructed side view from trains. Brush, when high enough, will interfere with the working of telegraph wires during damp weather, and for this reason wherever, in a wooded country, for instance, it would not be desirable to cut brush the full width of the right of way, it would be well to set the telegraph poles nearer the track than their usual location near the limit of the right of way. If set deep enough there is no danger of their falling upon the track during storms. Brush standing near the track will shade it, and oftentimes in this way it injures track by shutting out sunshine from damp places during a large portion of the day. Again, where fences are not maintained, brush close to the track forms a hiding place for cattle, horses, and other stock, from which, when frightened, they jump out and reach the track before the engineer has time to stop. It is far more sightly to cut brush the full width of the right of way, and roads on a well paying basis can do it; but on long lines through wooded and sparsely settled districts, where little business is done, the expense of cutting over the full width of the right of way every year bears heavily, and brush cutting with such roads ought, therefore, to be confined to immediate necessities only. For light brush, sprouts, etc., the brush scythe is the best tool to use, but for the heavier brush the brush hook or brush ax is best. July or August are the usual months for cutting brush. Brush cut well along in the season, or after attaining some growth, are less liable to sprout again.

93. Ditching.—The proper time to clean out ditches is in the fall, during the dry weather before the ground freezes or the winter rains set in, as the case may be. Wherever there is much material to be moved, ditches should be cleaned by the work train, especially in long through cuts. It is much cheaper to load material onto flat cars than to truck it out of cuts; besides, with the work train the material taken out can be unloaded wherever it is needed to strengthen fills, thus accomplishing two purposes with a saving of labor. If the amount of material to be moved is small the section men can do it quite well, or to expedite matters they can at least clean the ditch and scrape together the refuse in heaps before the work train arrives. All grass, weeds, sticks, stones, etc. should be cleared away so as to leave the ditch unobstructed. There are, of course, many ditches which fill frequently by washings from heavy rains in summer or by thawing in spring, so that it is not always practicable to use the work train for them, and the cleaning must therefore be done by the section men.

In side-hill cuts material taken from ditches can usually be cast across the track, but in through cuts it may be taken out on the push car, or by wheelbarrows, if the cut is not too long. There are wheelbarrows made with double flanged wheels to run on the rail, for use in cleaning out cuts. The axle of the wheel is set at a slight skew to the frame of the barrow, so that the person pushing it may walk on one side of the rail instead of astride. Aside from its special use the barrow may be run on the ground or on a plank, like any other wheelbarrow, thus enabling the man wheeling the load to dump it at desired points away from the track. For small jobs in short cuts the device is quite convenient, as it saves the time required to move a string of planks from point to point to use for a runway, such as is needed for ordinary wheelbarrows. For general ditching work, where a number of wheelbarrows are needed, it is better to use the ordinary barrow on running planks strung along on the ties outside the rail. Where it is necessary to cross the track a plank should be cut the right length to fit between the rails. Proper flangeways can be made by chamfering the ends of the plank to get them to fit under the heads of the rails. This plank may be held in place temporarily by one or two track spikes, but should be taken up in advance of fast trains and when quitting work at night. Where the view from the work is obstructed by curves or otherwise, it is dangerous to place a running plank across the rails, and even where there is a good view along straight line continual watchfulness is required. Light ditching in long cuts not deeper than 10 or 12 ft. is sometimes done by throwing the material up the bank, at one or two casts, and then moving it back out of the way; but dirt from ditches should never be thrown upon the slope of the cut or left on top of the bank, near the slope.

In cleaning out ditches the ditch should be given its proper alignment parallel with the track, or such ditches as have not previously been made straight should be trimmed up. In such work a ditch line is commonly used. The depth may be kept uniform by the use of a straightedge and level or level board, taking the rail for reference; or if the track be level the required fall may be had by allowing a certain amount of drop per rail length. To keep the ditch everywhere the same depth and shape some make use of a ditch gage, which may consist of a framework constructed of strips of board and shaped to correspond to the outline of the ditch. In use the top strip (made long enough to rest across both track rails) is held on the rail and set by the level, and the ditch is shaped to conform to the depending templet. In cleaning out a wet ditch the work should begin at the lower end, so that the water will run off as fast as the work progresses. It is important to avoid digging ditches beyond the necessary depth in places. An error of this kind is not easily remedied, for if the depression be filled up to the ditch grade line, the first hard rain will wash out the loose material and water will then stand in the ditch. Particular attention should be paid to cleaning out the surface or slope ditches around cuts, and to keep the track ditches from being obstructed by ice formed by the freezing of spring water oozing from the slopes. During heavy rain storms and when frost is coming out of the ground ditches are liable to become filled with material loosened on the slopes.

94. Shimming.—Shimming at its best is only temporary work. There are two ways of doing it, viz., shimming under the tie and shimming between the rail and the tie. The former method must be resorted to sometimes where the ground is too wet to be tamped or where no fit material is at hand with which to do the tamping, but if possible it should be avoided, as it is only a makeshift. It is cheaper in the end to throw out the wet filling and truck in dry material, if it can be had, and not to shim at all. Where this cannot be done the best way is to remove the material from between the ties, under and outside the rails, and shim for the most part with planks and boards, placing them parallel with the rails and crosswise to the ties. This manner of shimming holds much better than the method of driving short pieces under the ties lengthwise. Some will shim under the ties when the ballast is dry enough for tamping, for no better reason than that driving pieces of boards under the ties when the track is raised is more quickly done than tamping; but it is a poor plan to follow.

When the ground is frozen and the track heaved up in places there is only one convenient way of getting the rails to smooth surface, and that is by blocking or shimming between rail and tie. This is done by starting the spikes, raising the rail to proper hight and blocking it to place. The tools needed are a claw bar, hammer, pinch bar, adz, crosscut saw, handax and beetle. Blocks about 8 ins. long are cut off sound straight-grained ties, pile butts or old car timber, and out of these blocks shims of proper thickness are split to match the spaces between the rail and tie. Short blocks like these up to 1½ ins. in thickness will answer for shimming on curves, and on straight line such may be used up to 2 ins. in thickness. These shims should be split the same width as the rail base and be put under the rail base parallel to the rail, that is crosswise the tie. Some object to this method on the claim that the shims when so placed will work loose. If they are nicely fitted in and the spikes driven down again tightly to the rail flange they will not work loose; but to make sure, a 6d. or 8 d. wire nail should be driven slantwise through the shim into the tie. The shim, if thin, might for this purpose be placed the least mite skewing to the rail, so as to give the nail a hold; but if the shim is thick enough it can be toe-nailed, without projecting beyond the rail base. The nail should not be driven all the way down, but should be left so that the head may be caught by a claw hammer. The track spikes prevent the shim from swinging around sidewise and the nail prevents it from working endwise. In very extensive practice shims are placed obliquely or skewing to tie and rail, fitting between the two staggered track spikes, at right angles to the line joining them. The spikes are merely pulled and redriven in the same holes plugged, and with shims not thicker than ½ in. no nail is used to hold the shim against working out; but wherever the tie is deeply rail-cut the seat for the shim should be adzed down to an even bearing. The spikes should not be started higher than is necessary to permit the rail to be raised to surface. After placing the shim on the tie where the rail is raised the spikes should be driven home on this tie, and if the rail is surface bent and inclined to bulge up at some other point, as in the short quarter of a joint, it may be brought down even by tapping down on the spikes that have been started. No shims except the one at the raising point should be placed until the rail has been put to even surface, and then they should be driven under snugly, but without forcing to the point of lifting the rail. To fit shims to place accurately and rapidly is one of the tests of that sense of adjustments which is essential to expert trackmanship.

Some prefer to place the shim crosswise under the rail, that is lengthwise to the tie, and to secure it by pulling the track spikes and redriving them through it. To do this, holes for the spikes must be bored through the shims. The hole should be bored by an auger ⅛ inch larger in diameter than the thickness of the spike, so that the latter will not split the shim, and the holes should be spaced to crowd the spikes against the flange of the rail. This boring must be done in the block before the shims are split off, for a thin shim cannot be bored without splitting. The holes cannot therefore be bored to suit the spikes as already driven, and so this method of shimming requires that the spikes be pulled entirely out, the holes plugged and the spikes redriven through fixed holes in the shims, thus spike-killing the tie. Usually there is something of a channel or rut cut into the tie by the rail flange, so that before a shim can be placed under the rail crosswise, the tie must be adzed. The extra work of adzing, boring, pulling, plugging, and redriving spikes increases the work to many times that required to do it the other way—that is, by putting the shim crosswise the tie. By that method shims can be placed in half the time it takes to put them crosswise the rail; the tie is not injured and the work is secure. I am well aware that there are those who disapprove of this method of placing shims, but experience with both methods has taught me that if properly done it is by far the better way to do it. Shims placed crosswise the tie are more secure against splitting and displacement by derailed wheels and dragging parts than are shims placed lengthwise the tie. At suspended joints raised 1 in. or higher it is quite commonly the practice to use a long shim reaching across both joint ties.

It is quite extensively the practice to furnish the trackmen with machine-made shims, produced from waste lumber in the car repair shops or bought from manufacturers. Concerning the economy of this plan there is difference of opinion, many foremen claiming that they can do better and faster work when making their own shims. When factory or shop-made shims are used a much larger supply than is needed must usually be furnished, in order to obtain the desirable assortment of sizes. For this reason some prefer to furnish only the thin sizes from the factory—say shims from ⅛ to ⅜ in. thick—and let the trackmen make the thicker sizes themselves. Among factory shims those made of elm give best satisfaction, because they are tough and withstand pressure without splitting; and when properly fitted under the rail and the spikes driven home the rails pinch into them and hold them securely in place. Shims made by hand from almost any straight-splitting wood give satisfactory service, but red oak is considered about the best, on account of the ease with which it is worked. When shims are made by hand one man does the splitting from the blocks, waiting until the rail is raised to the desired hight before beginning on the shims for that place. After a little practice at the work men become expert, and able to estimate the required thickness so closely that accurately fitting shims can be split off rapidly. Shims should be the same thickness on both edges, and not wedge shaped, but if only a slight difference exists in this respect the thicker edge should be under the outside of the rail.

Wherever the outside rail of a curve is shimmed it should be braced. Broken splice bars answer well for this purpose, and whole bars may also be used, as they are not injured and the use is only temporary; but almost any piece of iron which has a hole through it, and which can be placed to lean against the rail, may be pressed into service; or blocks of wood may be made to do. The usual way of bracing with wood is to place a piece of board or plank at the back of the outside spike and nail it to the tie, setting two track spikes to hook over the back edge or end of the piece. By notching the piece to fit around the spike a bearing may be taken against the rail flange. It is apparent that this method of bracing is applicable only where the shims are placed lengthwise the rail; otherwise the wooden brace would have to be leaned against the web of the rail. When shimming the outside rail of curves it is well, in any case, to double-spike it on the outside, if not already secured in this manner, because the curve is all the better for being double-spiked on the outside after the shims are removed. For this purpose, spikes 6 ins. long, exclusive of head, commonly known as "frost" or "shim" spikes, can be used to advantage. In lieu of braces against the rail, where shimming is done on sharp curves, some form of bridle bar, designed for application without taking up the rails, might be used. Rails shimmed on straight line do not require bracing, since the weight of the wheels holds the rails to gage. Unless the rail is lifted more than an inch the spikes need not be pulled entirely out, but simply started up and driven down again after the shim is in place, without plugging the hole.

Where the rail is raised more than 1½ ins. on curves or 2 ins. on straight line, but not more than 3 ins., the shims should be made about 2 ft. long, preferably of plank, and placed crosswise the rail. They should be spiked to the tie with boat spikes and holes should be bored through them for the track spikes. The rail surface can then be evened up with ordinary shims. Ordinary rail braces can be spiked to these shims in the usual way, for curves. Shims 3 ins. thick and thicker should reach the whole length of the tie, under both rails, in case both rails are to be raised that high. When it comes to the use of such heavy shims it is perhaps more convenient to start the ties up from their beds with wedges and shim underneath them with pieces of plank. On some roads this method is followed in lifts of 3 ins. and higher. In adjusting the blocking to the spaces in such cases some foremen use wedges alone for some of the ties, the wedges being made from oak pieces 2 or 2½ ft. long, hacking the wedge on the top side to prevent the tie from slipping and throwing the track out of line. The appearance of wedges projecting beyond the ends of the ties is unsightly, and the arrangement is insecure, as the ties take bearing only at the end and the wedges are liable to work out. In such cases it is better to block with pieces of plank and boards of various thicknesses, shoved under the ties far enough to afford support directly under the rail. In order to avoid using very thick shims the rail is sometimes put to surface partly by shimming and partly by adzing down the high places. This practice should be discouraged as much as possible, for such injures the ties and leaves an unsightly appearance in the track as long as the ties remain.

A question which frequently arises is the proper method of shimming where tie plates are in use. With flat-top plates seated flush with the face of the tie there is no difficulty, and the shim can be placed either lengthwise or crosswise the rail, preferably crosswise, in which case it must be bored for the spikes to correspond with the punching of the tie plates. If the top of the plate is not flush with the tie face it does not seem like good practice to place the shim lengthwise the rail or at a skew with it, although some claim that thin elm shims will crush down over the edges of the plate and not work out of place. On shouldered plates it is not practicable to place the shims crosswise the rail, and if the rail seat is not flush with the tie face such plates should be removed and carefully piled where they may be had conveniently in the spring, when the shims are taken out. There is no advantage in placing tie plates on top of shims, however thick the latter; in fact it is a waste of time. As shims are intended for only temporary use the question of rail cutting is unimportant. The necessity for pulling spikes from tie plates and redriving them in the same holes, or in the same holes plugged, as is required in shimming, is a source of some trouble, for if a spike head breaks off the new spike must either drive the old stub before it or dodge and go to one side. The latter course is the one which the spike is the more liable to take. To get a good fit for the new spike in such cases it is necessary to drive the old stub entirely out of the way and plug the hole. For such work on the Michigan Central R. R. each section gang is supplied with a slender spike punch for driving the old stub down through the bottom of the tie. The punch part of this tool is $^9/_{16}$ in. square, in cross section, and 6 ins. long. The tool is also convenient for removing spike stubs from under the slots in splice bars and in the bases of switch stands, and at frogs, etc.,

All shimmed track, however the work is done, should be closely inspected by the foreman or a trustworthy track-walker at least once each day. In this connection it should be borne in mind that the parts of the track which are shimmed are not heaved, but lie adjacent to and partly on the slopes of, the heaved portions; hence the settling of the heaved portion when the frost leaves the ground leaves the shimmed portion high. At such times it is necessary to watch shimmed track very closely and remove the shims as soon as the heaved portions have settled back to place. Where very thick shims are used they should be replaced by ones of less thickness during the progress of the settlement. It is usually the case that the heaved rail will, after the thawing, settle lower than it was before heaving. It is readily seen, therefore, that after the frost has gone out, the track in such cases will remain in very uneven surface unless the shims be removed. All sound shims and extra long spikes removed in the spring should be stored for future use in or about the tool house. To avoid checking, the shims should be piled where the sun will not strike them. After removing the shims the spikes of ordinary length should, unless regaging is necessary, be driven into the tie without plugging the holes. In surfacing or ballasting track, ties on which shims may be still remaining should not be tamped until after the shims have been removed.

Wherever track heaves badly the web of the rail should be painted as a mark to identify the place, and during the following summer the roadbed should be dug out and drained or the track reballasted. The only sure cure for heaving track is to drain the roadbed and put on the proper amount of good ballast. Pockets of clay or other soggy earth under the track are a source of heaving action, and when such places are dug out and filled with better material the cavity should be drained, so that it will not hold water. In some cases of this kind the use of tile or a blind cobblestone ditch may be necessary. Two instances, happening on different roads, have come to my knowledge where the conditions did not permit disemboweling the roadbed in this manner, and the following remedy was applied: During the summer the ties over the bad spot were let down and heavy shims were placed on top of them. In the winter, when the track heaved up, the shims were taken out, thereby dropping the rails to surface.

95. Renewing and Relaying Rails.—Since the day of iron rails has passed away, occasion for frequently removing battered and broken rails from the track has also passed. Steel rails of good quality do not batter, they seldom break, and they should wear quite evenly until the head is worn out. Rails on the outside of curves wear away more rapidly than elsewhere, owing to the grinding action of wheel flanges against the side of the head; but to avoid replacing them with new rails before the rails on the tangents are worn out, it is customary to exchange places with the inside and outside rails. In many instances this work of transposition is delayed too long, or until the top bearing surface of the outer rail has been too much reduced for satisfactory service on the inner side of the curve; and on some roads it is neglected altogether.

The work of transposing rails on curves is usually done by cutting loose several hundred feet of rail in a stretch and moving the two strings of rails across the track with bars, throwing one string over the other. The rails in each string remain spliced as they lie in the track and the bolts need not be loosened or changed unless the rail head is so shallow as to allow the wheel flanges to reach the bolts; for in transposing the rails the position of the bolts with relation to the gage side of the rail is also transposed. By way of preparation for the work, it is well to pull two spikes and skip one, all along the inside of each rail, over a stretch as long as the crew can handle between trains—the whole curve if possible. This work can be done while the trains are running. The outside spikes need not be touched except where they interfere with the splice bars, but such may be pulled to best advantage after the rails are thrown over. Ties cut into by the rails will also interfere with the splice bars and at the joints they must be adzed down even with the rail seat before the rail at those places can be thrown to position. As soon as opportunity offers the two strings of rails are cut loose, the remaining inside spikes are pulled and the strings of rails are changed over. The stretch of rail thrown from the outside of the curve will be found too long for the inside, and that from the inside too short for the outside; but calculations for this difference can be made beforehand and pieces of suitable length be cut and made ready to put in. If it is desired to keep the relation of the joints on the two sides close to one of the standard methods of laying—that is, joint opposite joint (square joints) or joint opposite center (broken joints)—it will obviously be necessary to place one or more short rails in the lower side of the curve; and if there were short rails on the lower side before the change, the short rails laid after the change should be placed opposite the old short rails, now on the upper side of the curve, so as to vary the desired relative position of the joints as little as possible. As fast as one stretch of rail is thrown into the place of the other a man or two should follow and tack down spikes at the joints, quarters and centers, to hold the rail approximately to place, after which all the spikes may be driven in the old holes without plugging, except where the gage may need correcting. When renewing or transposing rails it is to some extent the custom to redrive the spikes in a new place, usually on the opposite side of the tie face from the old position, but such is wrong practice, because it cuts up the fiber of the tie without any advantage in the way that spikes are required to hold the rail. Likewise, it is a waste of time and material to plug the holes when no readjustment of the gage is necessary. As is explained more at length elsewhere, the duty of a spike is to resist side pressure from the rail, and this it can fulfill just as well when driven in the old hole without plugging as it can if the hole is plugged.

While changing or renewing rails a good opportunity is presented for making corrections in the gage or in the expansion spacings at the joints, and for righting tilted rails on the lower side of curves. Where such work is needed it should always be attended to on occasions of this kind. The necessity for looking after proper allowance for expansion when renewing rails is just as important as when laying new track. After the transposition of the rails the gage sides of the rail heads, being unworn, will be practically as good as those of new rails and the gage will be more nearly what it was when the rails were first laid, because on curves the gage is continually being widened by side wear to the head of the outside rail. Where the top corner on the outside of the inner rail is roughened or protuberant from flow of metal the precaution should be taken to have the first few trains after the transposition is made run around the curve at slow speed, for this roughened corner is then on the gage side of the outer rail, and one or two train movements are necessary to smooth it down. Unless the nuts of the track bolts interfere with the wheel flanges (which they will not do except on rails of small section) trains may be allowed to pass as soon as the sections moved over have been coupled and partly spiked, for such work as regaging and relining can be done at any time, without hindrance to the running of trains. If it is found to be necessary or desirable to change the splice bolts end for end, all but two bolts in each splice may be removed before the transposition is made and these two may be reversed one at a time, so as not to loosen the splice bars, as soon as the rails have been changed over.

In transposing stretches of rail on curves it will almost always be found necessary to move the rails longitudinally, to make a proper joint at starting, and if the track is broken-jointed the distance moved is considerable—about half a rail length. One way to do this is to arrange men along the rail at the joints, with bars, after the rail has been thrown across the track, but before it is moved into its seat at any place. In throwing with the bars the men take hold against the projecting corners of the angle plates and heave together, by the word. If, however, a work train is at hand, the locomotive may be utilized to pull the stretch of rails by attaching to one end with a switch rope and clevis. Apparently one string of rails will need to be pulled one way and the string on the other side of the track the other way; that is, one string will need to be pushed, seemingly. The pushing may be done by the locomotive, with a bumping pole; or the whole stretch of rails may be pulled a rail's length past the meeting point and the extra rail disconnected and transferred to the other end of the string. If there is intelligent supervision of the work, calculations are made beforehand, and each man understands what part he is to perform, the change can be made very rapidly and without hitch in any of the movements.

On a good many roads rails for curves up to 3 or 4 deg. are laid without curving, straight rails being sprung to the curve. After the outside rail on the curve becomes much flange worn it is sometimes taken up and reversed in place, to bring the good side of the rail head on the gage side. Ordinarily the inner and outer rails are transposed when the outer one becomes badly flange worn, as already explained, but in some cases the "fins" on the outer side of the inside rail (which would become the gage side of the outer rail if transposed) make the top corner of the rail head so rough that it would be undesirable to place the rail on the outer side of the curve. In such cases the spikes are pulled from the gage side of the outer rail and it is simply reversed in place. Rails which have been in a 4-deg. curve under traffic for several years will, as soon as released from the spikes, spring back as straight as the day they were first laid. To take up rails and swing them end for end, by carrying, requires a gang of at least eight men, but by means of a turning block that is used on the Chicago end of the Wabash R. R., by Section Foreman C. Semberg, the rail is easily turned by one man, taking hold of it with one hand. This device (Fig. 257A) is a 4x6-in. oak block about 15 ins. long, on top of which is placed a cast-iron plate with a hole in the center, and on top of this there is a flanged cast-iron plate with a hub fitting the hole in the bottom plate. Both pieces are parts taken from scrap car iron. When a rail is to be turned, the block is placed in the center of the track opposite the middle of the rail, and two men with tongs lift one end of the rail and set it upon the turning block. One man then takes hold of the rail and walks around with it, swinging the opposite end into the rail seat on the ties, and then two men with tongs lift the other end and set it against the spikes. With this device a crew of only two men can work to advantage.

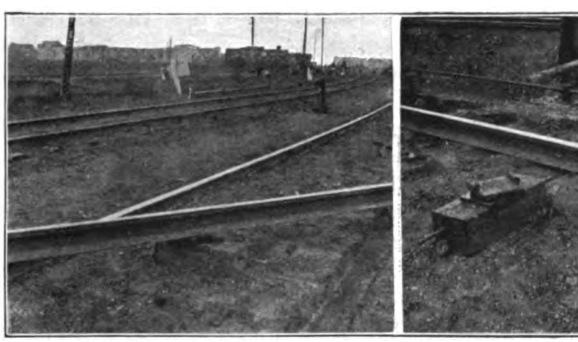

Fig. 257 A.—Rail Turning Block, Wabash R. R.

Renewing Rails.—The detail work of renewing old rails with new ones, sometimes called "changing out" rails, is much the same as when transposing rails on curves. The new rails may be laid on the ties alongside and outside the old rails and the splices be put on and partly or wholly bolted before the old rails are disturbed. Care should be taken to start the joints right with the first new rail. Along straight line new rails may be spliced together in this way to fit closely enough the space occupied by the old rails coming out, for almost any distance; but it is well not to attempt to lay around more than one curve at a time, owing to the variation in length between the old rails and the new rails as they lie parallel to each other before the change. Allowance for the difference in length may be made in the joint openings. For instance, if the new rails are spliced together in a string placed 1 ft. c. to c. of heads from the rails in the track, the difference in length over the same arc of the curve will be about 0.21 inch per degree of curve per 100 ft. of curve, or say ⅕ inch. It would be well, therefore, to distribute this allowance among the joint openings of the new rails, increasing the space with the string lying outside the outer rail of the curve and decreasing it with the string lying outside the inner rail of the curve. The bolts should then be left loose enough to permit the rails to shove through the splices and adjust themselves to the proper opening, upon being thrown to place. If, however, no allowance is made at the joints, the bolts should be turned on tightly, so as to hold the proper spacing against the binding or hauling of the string of rails while it is being thrown to place. This arrangement of course makes the rails hard to move and on long curves the plan will not work; it is better to make allowance in the spacing and leave the splices somewhat loose until the rails are moved to place, after which the rails should be adjusted to an even spacing. If the rails are to be curved, but are not so prepared when unloaded, the most expeditious method is to curve them with lever and sledge, in place, as they lie strung out along the track, carrying two ties along for use, as described in § 24, Chap. III. In considerable practice, however, the plan of unloading the rails in piles, at points along the curve where there is clear space for convenience of curving, is followed. After being curved the rails are distributed with a push car.

As already pointed out, part of the spikes should be pulled and everything possible should be got ready before the time arrives for the change to begin. The spikes pulled beforehand should include such as are driven slantwise, or in any other manner to cause them to pull hard, as, for instance, the spikes in the slots of splice bars. All such spikes, if in the rows of spikes that are being pulled, should be removed, and if necessary to hold the rail, redriven at one side of the slots, where they can be readily drawn the day of the change. In the winter season, when the ties are frozen, spikes start hard. In preparing to renew rails when such a condition prevails some remove part of the spikes and at the same time start the remaining ones and drive them down again, so that they will start easy when the time comes for quick work. If the base of the new rail is wider than that of the old one, all rail-cut ties must be adzed, and this can be done beforehand—several days, if desired—as can also such work as driving down spike stubs, etc. For the work last named a punch is a convenient tool. A machine used on the Pere Marquette R. R. to groove rail-cut ties in preparation for adzing out the rail seat when renewing with a rail of wider base, is described and illustrated in connection with the subject "Laying Tie Plates"—§ 106 of this chapter. Ballast, cinder droppings and other material lying on the ties near the rails or between the ties and higher than the rail base and near it, should be cleared away before the work of renewal, proper, is begun and, in the same connection, there should be a man with a broom to sweep away any dirt that may be kicked into places where it will interfere with the proper bearing of the new rails.

As soon as everything is ready and opportunity offers the spikes are pulled and the string of old rails is cut loose and shoved into the middle of the track, where it may lie indefinitely, if the ballast does not cover the ties; if, however, it must be thrown outside the track before trains may be permitted to pass, it may as well be thrown there in the first place, throwing the old rail over the new. It is best to renew only one side at a time, and if the base of the new rail fits the seat of the old one and there is not such difference in width of heads as to tighten the gage appreciably, trains may be allowed to pass after one side is renewed and made safe. At any rate, it is best not to remove the old rail from both sides until the new rail on one side has been moved into its place and part of the spikes are driven to hold it there, because with both rails removed from the ties at the same time the ties are easily jarred out of place in their beds, particularly where the ballast is not filled in at their ends. In renewing rails on side-track, however, where there is usually more time for the work and where the general excellence of the work is not so important, it is well to combine the work of tie renewing with that of renewing rails, in which case both of the old rails are first thrown from the ties, so as to permit the unsound ties to be upended and thrown out. The new ties may be placed either before or after the new rails are placed—preferably before, if digging must be done outside the track in order to get the ties in. In renewing rails in side-track the best plan is to throw the old rails out in a string and to splice the new rails after they are set into place, one at a time. Nothing can be gained by splicing the rails together in a string on the ends of the ties, as is done in preparation for renewing rails on main track. In driving the spikes for the new rails, all ties down from the rail should be held up with a bar, so that the spike heads may be driven snugly against the rail flange. The occasion for nipping the ties when spiking is greatest where the track is badly out of surface, and for this reason, as well as for the good of the new steel, rough places in the track surface should be attended to before the work of laying new steel begins.

It is better to pull the inside, rather than the outside, spikes when changing or renewing rails, for whenever track gets out of gage it is always a widening, and not a narrowing of the gage that takes place; for this reason the outside spikes should be disturbed as little as possible. But if the base of the rail going in differs in width from that coming out, the new rails cannot be laid to the same gage as the old ones by pulling the inside row of spikes from both rails. In order to lay the new rails to the same gage, the outside spikes must be pulled from one rail and the inside spikes from the other (in curves it should be the *outside* spikes from the *inner rail* of the curve and the *inside* spikes from the *outer rail* of the curve). This rule does not apply, however, to new rails and old rails differing much in width of head, in which case three lines of spikes must be pulled—that is, both outside and inside spikes must necessarily be pulled from one of the rails (in a curve, the inner rail, of course); but one of the four rows of spikes may, and should, remain undisturbed, and obviously it is against this row that the new rail laid first should be spiked. Wherever, as in such cases, the spikes must be pulled from both sides of one of the rails, not more than two-thirds of the spikes should be pulled from either side while the trains are running over the track, and the spikes that remain temporarily should be left in sets of three on the same tie; that is to say, two thirds of the ties will have only one spike remaining (the spike which comes in the row that is not pulled), while at least every third tie should have all four spikes remaining. In exchanging rails of different base width where tie plates are used, the old plates will not answer unless the use of the same with the rail of wider section was anticipated and the plates punched for spike holes accordingly; if such has not been done all four rows of spikes must be pulled. In a case of this kind the aim should be, in setting the new plates, to drive at least one row of spikes in the old holes without plugging, before placing the rail on the plates. In this connection it should be pointed out that tie plates double punched in anticipation of a change of rail section should be so punched and laid that it will not be necessary to change the position of the plates when laying the new rails to gage.

Wherever, for any reason, the spikes cannot be redriven in the old holes, the holes should be plugged. Plugs made to fit the holes snugly should be distributed along the track before the work of renewing begins, and being required in such large quantities it is cheapest and most convenient to get machine-made plugs. If the base of the new rail be not much wider or narrower than that of the old one, the spike may be driven in the same plugged hole, on that side of the plug which will operate to crowd the spike up to the rail, if the base be narrower, and away from the rail, if the base be wider, than the old one. Where both rows of spikes must be pulled from one of the rails in order to lay the new rails to proper gage, it is necessary, of course, while spiking the new rail laid last, to use the gage, as in spiking new track; but in any event the gage should be run along on the new rails as the final spikes are being driven and all points out of gage should be corrected there and then, as previously stated in another connection. Adverting to the work of preparation, it should be stated that the old rails, if in bad alignment, should be lined before the change is made, and it will usually be found necessary to reline the track after the new rails are in, especially if the gage has been corrected in places. After the new rails are laid it is usually necessary to respace the joint ties.

The old rails thrown to the middle of the track may lie there until it is convenient to remove the splices, when, if there is any assortment to be made, the better class of rails should, for convenience of loading, be placed on one side of the track and the poorer class on the other side. If, however, the strings of old rails are thrown upon the shoulders it will cost less to make the assortment when loading the rails on the cars. It is well, however, to inspect and mark the rails in advance of the loading time if an assortment is desired. It is quite frequently the case that the best of the rail removed from main track on the trunk lines is relaid on branch lines, where the traffic is lighter; and rail that is even much worn in main track is usually good for still further use in side-tracks and yards. When old steel is sorted for further service one should be careful to keep rails of the same condition of wear together. Rails removed from curves should not be mixed with those taken from tangents, and rails taken from the outer side of curves should be kept separate from those taken from the inner side. It sometimes occurs that old rail taken from main track is to be relaid in a parallel side-track. In such cases a good deal of labor can be saved by throwing the rails over bodily, in long sections, with lining bars, without removing the splices. In relaying old steel the unworn side of the rail should be used for the gage side; and in laying old curved rails on straight line the curve should be "shaken" out or else the rails on the two sides should lie oppositely bowed, so as to neutralize the tendency of the track to assume a scolloped or serpentine alignment.

The object in splicing together long stretches of rails preparatory to laying them is to do as much work as possible while trains are running, and then to be able to get as much rail as possible into the track during the interval between trains. Where, however, the intervals between trains are very short, or where the track may be abandoned for a large part of a day, as is sometimes done with one of the tracks of a double-track road, between stations or designated crossovers, this practice is not always followed. On roads where the intervals between trains are short, a crew of moderate size, say 12 men, exclusive of flagmen, can make fair headway at rail renewing. Stretches of old rail of such length as can be properly handled during the time available are cut loose and thrown out and the new rails are set in one at a time and spliced afterward; or if the rails are placed along on the ends of the ties and properly spaced they may, with equal facility, be spliced two and two and moved into place with bars. Another plan which is followed to advantage is to put a splice on the end of each rail as it lies on the shoulder, placing the bolts for half the splice but not screwing the nuts on tightly. As the rails are set into the track one by one they are heeled into the splice behind, and it is then necessary to tighten only one bolt to make the splice secure. By this method there need be no delay in fumbling splices during the interval when time is most valuable. When the plan of placing the rails one at a time is followed it pays to renew the ties while changing the rails, but in such event the force should consist of at least 20 men, if the trains run close. If the old ties are cut into deeply by the rails, so that their beds must be deepened in order to get the new ties in, the new ties had better be hauled in after the new rails are laid, but otherwise, or if the ties are in a narrow cut or obstructed at their ends in any manner, it will pay to dress out the old beds and lay the new ties in place before laying the rails, thus saving much digging. If ties are renewed just previous to the time contemplated for renewing the rails, the new ties put in on straight track, if not too close together, should not be spiked until the new rails are laid, thus saving some labor in pulling spikes when the time comes to renew the rails.

Connections.—For closing up temporarily to let a train pass, a switch point (preferably reinforced) is a convenient thing to have on hand; and in order to have it handy when needed it should be carried on a push car just in advance of the old rail that is being thrown out. To make the closure the switch point is heeled against, and spliced to, either the last new rail laid or the last old one, so that the train will trail it, and the split end is spiked down and braced against the mating rail spread outward like the stock rail of a switch. As the latter is not bent sharply it is necessary that the switch point should lie a trifle loose for gage. If both sides of the track are connected in this manner the closure rails should not stand opposite. To lift the outer flange of guttered tires over the spread rail the switch point should stand a little higher than its mate. If the new rail is of larger section than the old one the point rail should preferably be of the new section, so that it may be made to match up against the old rail a little high, without slide plates or shims. To provide for quickly coupling a switch point to an old rail of smaller section, a piece of the old rail may be spliced to an extra switch point carried on the push car; or if an old switch point is to be used for making temporary connection a piece of the new rail may be spliced to a point piece for heeling against the new rail when such becomes necessary. For quickly securing the point piece to the stock rail a special clamp is sometimes used. It is considered that in quitting work for the day it is safer practice to close with a cut rail than with a switch point to be left in the track over night, and on single track such is undoubtedly true; and perhaps so in any case, for if a derailed wheel should trail through such a temporary connection it would very likely tear something out. Nevertheless in closing up for the night on a tangent or on the inside of a curve there are some who will make the connection with a switch point. On the Louisville & Nashville R. R. the use of switch points for making closures is forbidden under any circumstances. In work of this kind the matter of cutting a rail to make closure is not as objectionable as is the practice of cutting rails in general, because the required piece can be cut from one of the old rails.

When switches are encountered during the progress of laying steel, a large crew should not be halted at the switch, but measurements should be taken with a steel tape to start the joints right beyond the turnout and the work continued, leaving a small crew to change the points, frog and lead rails, if such is immediately required, or else to connect the joints one rail length from frog and switch with suitable splices to answer until a more convenient time. As stated in another connection, turnouts should be laid with rails of the same section as those in main track, and such rails should extend at least one length beyond the frog, so as to avoid the use of compromise splices on the switch ties.

In making a permanent connection between rails of different hights and shapes the joint should be a supported one and both a step plate and a step splice should be used—the former to insure an even bearing and the latter to properly join the rails of different section. As step or compromise splices do not, as a rule, fit as closely as ordinary straight splices, it is considered that a supported joint under such conditions will generally give better satisfaction than a suspended one. In Fig. 258 there are shown three methods of joining rails of different section, described by Mr. C. P. Sandberg, an eminent European rail expert. Figure 1 of the views shows a cast steel step splice of angular section joining a 68-lb. with a new 80-lb. rail, as used on the Swedish State line. The weight is about 56 lbs. per pair, and the cost is about $3 per joint. This arrangement has been in use on the Swedish State railways for many years, and is the one used in most approved practice in this country. Figure 2 shows a cast steel "tapered" rail junction designed by Mr. C. W. Kinder, engineer-in-chief of the Imperial Chinese railways, for joining an old 60-lb. with a new 85-lb. rail, the

FIG. 3. FORCED STEEL STEP FISHPLATE

Fig. 258.—Compromise Splicing Arrangements.

ordinary splices for each section being used to make the connection. It is about 27 ins. long, weighs 56 lbs. and costs about the same as the splice shown in Fig. 1. Figure 3 of the views shows an 86-lb. bullhead rail joined with a 100-lb. T-rail by plain rolled step fish plates weighing only 34 lbs. per pair. These are made from a bar rolled to the larger section and planed, or sometimes by forging in a die, under a steam hammer or press. On general principles the steel rail junction shown in Fig. 2 is not a good style of connection, being a piece of rail too short for use in main track. A rolled steel rail of standard length tapered down to the smaller section at one end would undoubtedly give better satisfaction. On the Southern Pacific road tapered junction rails made from ordinary rolled steel rails are in standard service. The piece of rail is 7½ ft. long and the reduction in section is made gradually, in a length of 15 ins., near one end of the piece, by heating and forging. In reducing the width of the rail head the gage side is kept straight and the taper is made on the outside. On each side of the web of the rail, covering the tapered portion, there is riveted a reinforcing strap 2 ft. 10 ins. long. An "offset" splice is one having a lateral jog in the bars, for connecting rails having different widths of head, it being necessary, of course, to hold the gage side of the heads in line, as well as to hold the tops of the same even. In making connection with an offset splice care should be taken to have no lip on the gage side of the head. If the heads do not match right for this they may be brought into line by applying a thin strip of oak wood of proper thickness to the outside of the web of the rail of smaller section and to the inside of the web of the rail of larger section and then bolting on the splice bars over the wood strips (See also §27 and §212).

Rail Renewing Crews.—An important question which arises in connection with rail renewing is whether the work should be done by the section crews or by an extra gang. To do the work to advantage a crew of at least 12 or 15 men, besides the foreman, is required, and if undertaken by the section crews this means either the hiring of extra men temporarily or the combining of the forces of adjoining sections. The former plan is not always practicable just at the time the men are wanted, and the latter plan cannot very well be carried out during the summer season without delaying or disarranging the regular work. The most available time to do the work with the section crews is during the late fall or winter, when other work is not pressing, but if the ground is frozen there is no opportunity to take up simultaneously, or to follow with, certain other work of track improvement, such as tie renewing, respacing joint ties or lining. And finally, when the work is done by the section crews it is likely to progress in patches, at several points on a division at the same time, and consequently with greater tendency to disturb the train service, for a train may be flagged several times in getting over the division. Undoubtedly the best arrangement is to work an extra gang of good size, beginning at one end of the division or of the section of track on which the rails are to be renewed, and working continuously. By this plan the train service is interrupted at only one point, and in striving to apply uniform methods to all the work the roadmaster has only one foreman to deal with. Where the work proceeds continuously there is a better opportunity to keep the old material picked up behind the work and do what is considered a "clean job" than is the case where the work moves at slower pace here and there and the whole division is strewn with old material at intervals.

By whatever plan the new rails are laid they should be distributed continuously. Where the work has been done by the section crews it has frequently happened that the new steel would be distributed first to those sections where the foremen were ready to take up the work, and then something would happen to cut short the supply of new material until another year. In this way stretches of poor rail would become isolated between sections laid with new rails and have to be retained in service another year or perhaps longer. When finally these sections of poor rail came to be renewed there existed a difference of a year's service on adjoining sections and it may also have chanced that the rails supplied later were of better quality than the first, so that in course of years the condition of rail wear on comparatively short subdivisions of the road, taken at random, was somewhat variable and of an alternating character. The result is that when it comes to renewing rails the second time in such cases, it is necessary to remove some of the old rail prematurely in order to lay the new rail continuously. If the new rail is of heavier section than the old one or of different pattern there are certain advantages to be had in laying it continuously, such as a uniform stiffness in the track structure, which is readily observed in the riding of the cars; and the opportunity to reduce the patterns for switch points, frogs, tie plates etc. to a single standard in each case.

On roads where Sunday work is the rule, laying new steel is usually done on that day, when there are fewer trains to bother. The preliminary work is carried out on the day, or during the few days, previous by the section crews, aided by the work-train crew and floating gangs, perhaps, and on the day the change is made a large force is employed. It is seldom imperative to use this day for the work, however, for a large force may be employed on any day or with any of the various methods in practice. On the Boston & Albany R. R. it has been the practice for the train department to give up a section of one of the two tracks and operate the trains on single track past the stretch where rail renewing is under way. Rail-cut ties are adzed and some other work is done before the actual operation of laying begins. Out of a crew of 200 men about 40 are put at pulling spikes, this gang being divided into three lines—one for each row of spikes pulled. One set of men in each line use straight claw bars with a heel of small radius, starting the spike up an inch or more above the rail flange, while another set are provided with goose-neck bars or with bars having a heel of long radius, for pulling the spike the remainder of the way out. Six or eight men with pinch bars throw out the old rails in a string and 25 to 30 men complete the work of adzing the ties, sweeping and otherwise preparing the seat for the rail. The "setting in" gangs are two in number, of 16 men each, who handle the rails with tongs. In case the rails are spliced in pairs beforehand the number of men in these gangs is doubled. The remainder of the crew work as strappers, spikers and nippers.

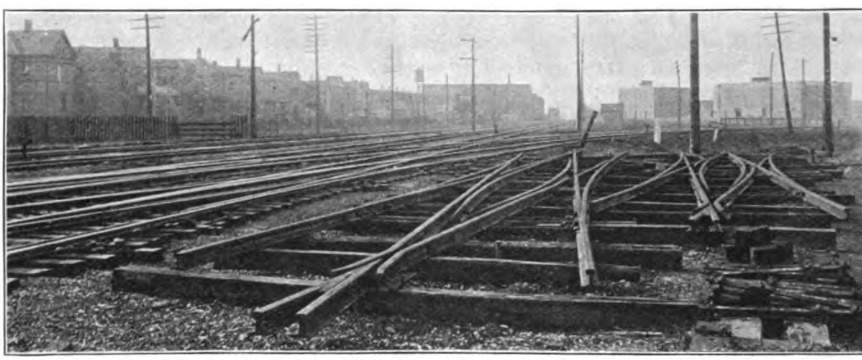

Fig. 258 A.—Crossings and Double Slip Switches Assembled in Preparation for Renewal, Chicago & Western Indiana R. R.

With a view to present data to be used as a basis of estimation, the following records of carefully planned work at rail renewing may be of service. On a road of crooked alignment, curves of 1 to 5 deg. being almost continuous, over which was moved a traffic of 83 trains daily, crowded pretty close together in the morning and late afternoon, a gang of 47 men renewed the rails on an average of 1 mile of track per day. The new rail was of heavier pattern than the old, requiring a readjustment of $\frac{1}{2}$ in. in the gage. The men were distributed for the work in the following manner: 2 flagmen, 6 pulling spikes, 3 throwing out old rail, 5 adzing ties, 8 carrying rails with tongs, 1 applying expansion shims, 1 holding rail up to spikes with bar, 6 spikers, 1 pulling spikes for new splices, 1 adzing ties for new splices, 12 strappers (6-bolt angle bars), 1 spiking new joint ties. This record was submitted to the Roadmasters' Association of America by Mr. J. B. Dickson.

In another instance, on a single-track road carrying rather light traffic, a record of 3.2 miles of track relaid with 75-lb. rails replacing 61-lb. rails, was made in 9 hours with a crew of 98 men. The rails were full bolted with 38-in. 6-hole angle bars and full spiked on curves, of which there were four. On straight line only alternate ties were spiked, except that spikes were driven in all slotted angle bars which came right to catch a tie, which was the case with about two thirds of the joints. This is a record of rush work, and is not supposed to be repeated as an average result.

In another instance where the work was carefully planned, but not rushed, 12,000 ft. of rail (one side of the track) was relaid with 85-lb. 60-ft. rails in 6½ hours including an intermission of ½ hour for dinner, 12 trains passing while the work was in progress. As a matter of preparation, the adzing of the rail-cut ties had been done 2 months previously, and, on the day before, alternate spikes were pulled from one side of the rail, it being necessary to pull only one line of spikes to make the renewal. In making the change the old rail was thrown out without unbolting the splices and the new rails were set in one at a time. Every other tie was spiked exclusive of as many joint ties as came right for the splices, which were 6-bolt angle bars. Two to four bolts were placed in each splice. The rails were spiked ahead of the strappers, and in this way their ends were brought even for splicing. The crew consisted of 41 men distributed along the track in the following order: 1 man pushing a hand car carrying a switch point, bolts and nut locks, who distributed bolts and nut locks—7 men pulling spikes—4 men moving out old rail—14 men setting in new rails with tongs —1 man placing expansion shims—2 men holding new rail up to the spikes—5 men spiking alternate ties—1 man taking out shims and putting on splice bars—5 men tightening bolts—1 flagman, who, by the way, had tools to keep himself busy correcting errors and supplying deficiencies. By dividing the work in the foregoing manner each man was assigned particular duty and did nothing else.

Renewing Crossings and Switches.—In renewing the rails and frogs at crossings, crossovers or in a network of switches on parallel tracks, it is to some extent the practice to couple up the various pieces of lead rails, frogs, switches, movable-point frogs etc. in the order in which they will lie in the track, laying them on skids of old rails or old switch ties placed on the right of way opposite the point where they will go into the track when the change is made. In making the change the old devices are taken up and the new parts are shoved laterally into position, bodily, with bars, then coupled up at the ends and spiked to place. In this way changes can be quickly made, and at points where busy traffic must be taken care of the plan is a means of saving considerable time. In renewing crossings it is also the practice on a number of roads to handle the frogs, already connected, with a derrick car. On the Chicago & Western Indiana R. R. the crossing frogs on two tracks and one rail of a third parallel track, at a long-angle crossing, solidly bolted together in one piece, have been lifted out with a derrick car, and as many frogs for the new crossings, all bolted up for service, set into place by the same means. An account of some of the work of renewing crossings and switches on this road will serve to bring out the details.

The particular piece of work selected for description was the renewal of crossings and slip switches where a double-track line makes junction with four tracks of the main line of the Chicago & Western Indiana R. R. This junction consists of a double leader crossing three of the four Chicago & Western Indiana tracks, making a double slip switch connection with two of them. The work of renewal consisted in replacing the crossings and slip switches on the two westerly tracks of the C. & W. I. R. R. The four tracks of the road at this point are used by a number of tenant companies, and a heavy freight traffic is handled by the C. & W. I. R. R. itself, so that to do the work satisfactorily, it was found to be necessary to abandon the two tracks mentioned while the work of renewal was under way. For doing this work two Sundays were selected, one crossing and double slip switch being renewed on each day. Preparatory to the work of renewal, the crossing frogs, movable point frogs and slip switches were laid out and assembled on switch ties, each opposite its final place in the track, as shown in Fig. 258A. On each day of renewal the tracks were abandoned early in the day, the interlocking connections were broken, the old rails, frogs, switch points, interlocking parts,.etc., and the unserviceable ties were taken up and carried out of the way, and the new crossing and double slip switch was thrown in bodily with lining bars. To hold the parts to proper gage while being thrown the rails were spiked to two long planks near each end, and at the middle of the crossing the rails were solidly blocked apart, making the whole piece, weighing something like 7½ tons, rigid enough to be thrown bodily.

The work of renewal on the first day included the replacing of a crossing and double slip besides a single plain crossing. After the old material had been taken up and carried away the decayed ties were replaced with new ones and three skid rails were put into position and oiled for launching the new work into place. Figure 258B is a view showing the launching operation in progress. In order to move the slip endwise and get it into exact position it was jacked up and skid rails were laid longitudinally underneath four points of the crossing diamond, namely, under

Fig. 258 B.—Moving a Crossing and Double Slip Switch Bodily into Place, Chicago & Western Indiana R. R.

the end frogs and under the point-rail heel castings. After moving the new work into place it was spliced to the old track rails and spiked down, and then surfaced up on new rock ballast. In the meantime an interlocking crew was busy at making the necessary connections for restoring operation from the tower. All connections of this kind necessary to put the tracks into regular service were completed by evening of the day of change. The facing-point locks were not put on until the following day, and to insure safety of operation during the night a watchman was stationed at the crossing and the switches, when thrown for the high-speed movements, were spiked. The working force numbered about 65 men, including three extra gangs of trackmen and an interlocking crew of ten men.

Changing Gage.—Leaving roads of 4 ft. 9 ins. gage out of consideration the mileage of roads of other than standard gage is comparatively very small, in this country; but there are a considerable number of narrow-gage roads and branch lines of short length, 3 ft. being the gage of nearly all. The building of narrow-gage roads in this country has practically ceased and those that remain are fast becoming standardized, either as a means of increasing the capacity or to discontinue the inconvenience and costly work of transferring freight at junction points with standard-gage roads. The work of changing track from narrow to standard gage is in many respects similar to that just considered and may properly receive attention here.

Preparatory to changing the gage of track it is usually necessary to widen fills and cuts, modify and strengthen bridges and trestles for the heavier rolling stock, and renew at least a portion of the ties with longer ones for the increased gage, 6 ft. being the common length of tie for track of 3-ft. gage. Such preparation is accomplished most economically if carried out gradually, during several years, beginning as soon as there is any certainty that the change will be made, and working with the contemplated end in view, as opportunity is seen. In following such a plan much can be done in the course of ordinary repairs, thus avoiding expense which might accrue from waste of materials discarded should the substitution of the same be attempted within a short time before the final change. In renewing the ties of the narrow-gage track with longer ones either of two methods may be followed: the tie may be laid to project equally beyond both rails, in which case both rails must be moved when widening the gage; or the tie may be laid with reference to one of the rails only, projecting beyond it the proper distance for standard-gage track, in which case only one of the rails need be moved when the gage is changed. The latter method obviously shifts the center line of the track, and on bridges could not be permitted without moving the bridge, as it would produce an unequal distribution of the load upon the trusses of the bridge or upon the posts of a trestle bent; and if the track center was to remain the same on the bridge but not elsewhere, a new alignment would have to be made each way from the bridge for some distance. The method also requires that the widening of the roadbed for the longer ties be made on one side of the track, which might not always be feasible without moving the track; as along a side-hill cutting in rock, for instance, where it might be cheaper to move the track than to widen the cut. As a general proposition there is probably nothing to be gained by this method and the usual practice is to widen the gage by moving both rails. Otherwise the bearing for the changed rail is partly upon a strip of newly formed roadbed or newly tamped ballast, which might make it difficult to maintain the track in level and surface for awhile, besides giving trouble from center binding. If both rails are to be changed it is not necessary that all of the ties of the narrow-gage track should be replaced by those for standard gage, except perhaps on sharp curves. On straight line, two thirds of the short ties, and on ordinary curves half of the short ties, if sound enough for further service, may remain. The supporting power of the short tie is, of course, inferior to that of the longer one, and projecting a shorter distance outside of the rail, its spike-holding efficiency is less, but if the long ties are somewhat uniformly distributed no serious trouble will arise from matters of this kind.

The preparation made immediately before the final change is begun usually consists in pulling part of the spikes, preparing new seats for the rails and in driving part way down a row or line of spikes for one or both the rails in the new position. On straight line two thirds of the spikes may be pulled from each side of both rails before traffic is discontinued; on light curves half the spikes might be pulled from both sides of the inner rail and from the inside of the outer rail; on heavy curves, say half the spikes from the inside of the inner rail. Ties with warped upper face, ties cut into deeply by the rail and "bellied" ties with the ends curving upward outside the rails should be adzed down, to give the rail an even bearing when it is moved over. A gage for testing the uniformity of this work may consist of a piece of board or narrow wooden strip notched (say ½ inch) to fit over the narrow-gage rails, with depending blocks or lugs of proper depth to mark the position of the rail base. In standardizing the gage of 110 miles of 3-ft. track on the Flint & Pere Marquette Ry., in 1898-99, the seats for the rails in their new position were cut by a traveling tie spotting machine described under the section (§ 106) on "Laying Tie Plates," further along in this chapter. A record of the work which there appears presents an interesting comparison with figures given in connection with the present subject. When widening the gage of the Burlington & Western and the Burlington & Northwestern roads, from Burlington to Oskaloosa and Washington, Ia. (123.1 miles), on June 29, 1902, the rail seats had been prepared during the two weeks previous by a portable sawing machine similar to the one above referred to, working over 12 to 15 miles of track per day.

The best gage for driving a row of spikes for the new rail is a short piece of hard-wood board of proper width, the board being used edgewise against the web of the rail and the spike driven against its outer edge. To secure neat gage it is perhaps best to drive only one row of spikes for a guide line, the second rail being spiked to the gage after the first rail has been secured, as in spiking new track. The spikes in the row or rows driven as a guide line should be taken from those pulled from the ties, so as to minimize the demand for new spikes.

All the work of preparation being completed, traffic is abandoned for a time and a large force is set to work pulling spikes, moving over the rails and spiking them to the new gage and changing the switches and turnout leads. On tangent the track can be made safe enough temporarily for the passage of trains by driving every third spike, but each tie that is spiked should receive all the spikes (four) for both rails. At first only such work as may be necessary to allow the trains to pass need be done, but as soon as possible thereafter the rails should be fully spiked and lined, the old spike holes plugged, all old material picked up, rubbish cleared away, etc. If the steel is to be renewed at the time of changing the gage the final work can be much simplified, for the new rails may be spiked to the proper gage outside the old rails, using spikes pulled from the old rails, without interfering with the traffic. The traffic need then be delayed only while the breaks are being closed at the switches. If, therefore, a change of gage is in contemplation at a time when the rails are poor or beginning to show the worse for wear, it may pay to either delay the rail renewing or to hasten it, as the case may be, so that both jobs may be done at the same time.

It may help to a better understanding of the conditions involved to state briefly the facts concerning some actual cases of changing gage. One instance of this kind was the widening of 57 miles of track on the Columbia & Puget Sound R. R. and branches (Pacific Coast Company), from a 3-ft. gage to standard gage, on Nov. 14 and 15, 1897. The idea of making the road standard gage had been in the minds of the management for some years, and timely preparation was made. The preliminary work of standardizing began in June, 1897. Several Howe truss spans were rebuilt and the bridges strengthened, wherever necessary, for the increased loads. Twenty thousand 8-ft. ties were put into the track which, with those already in, replaced practically all the narrow-gage ties on the line; and 11 miles of 56-lb. rail was laid in place of 30-lb. rail remaining. On account of a demand at the company's mines for the 30-lb. rail at this time, the 56-lb. rail had to be laid to 3-ft. gage, so that the light rail could be released. This stage of the preliminary work was practically complete on Nov. 1. A gang of 75 men was then put to work on the track pulling all the spikes which could be spared with safety, and in preparing lead rails for use with standard-gage switches. The new ties had been laid symmetrically in the 3-ft. track, so that it was necessary to move both rails. To facilitate this work some of the spikes pulled were driven in line by gage, so that they would be in the right place on the outside of one of the rails when put to standard gage. The gage used consisted of a board 8x12½ ins., shod on each end with sheet iron. One end was placed against the web of the rail and the spike driven half way into the tie at the other end of the gage, thus forming a line against which one rail could be moved out when the track was spread. This work was finished on Nov. 13, and on the same day the necessary switch rods and a supply of new spikes, to take the place of broken or bent spikes, were distributed. By midnight all the narrow-gage cars and engines were unloaded and stored, all traffic having been run to the full capacity during the day.

It was estimated that an average of five men to each mile could spread the track and lay the necessary switches in two days, one day being Sunday, when little traffic would ordinarily be handled. This number, therefore, was sent out on Saturday and divided into four gangs, and each gang given a certain district and certain switches to complete. Each gang of men was divided into three parts: The first pulled spikes, the next threw the rails out with lining bars and the third gaged and spiked, the number of men in each squad being so regulated that they kept well together. After the rails were spread each gang went back over its own district and full-spiked the rails, put on curve braces and changed what switches had been omitted during the first two days. In the matter of tools the men had 150 claw bars, 100 lining bars, 150 spike mauls and 50 track gages. The change was begun at 7 a. m. Sunday, and the track was spread, quarter-spiked and the switches put in by Monday night, when the first through train passed over the road. By forcing matters a little in train service, before and after the change, there was very little loss in the volume of traffic, and outside of delays for a few days in running trains at reduced speed over a quarter-spiked track, the change was not materially felt.

The best record made was by a gang of 36 men, who spread both rails on 12 miles of track, about one third of which was on curves, and put in three switches, in 24 hours. The track around the curves was all changed by this gang without cutting a rail. The rail was freed for a mile at a time, the splices loosened and a curve to the left worked into a curve to the right, thus compensating the expansion and contraction necessary to move the rail in and out with respect to the curves. That is to say, the stretches of rail moved were so chosen that what was gained in length on one curve was compensated by the necessary decrease in length on another curve turning in an opposite direction. On sinuous location with short distances between the curves, the practicability of the scheme is apparent, and by loosening the splices no difficulty should be experienced in carrying from one curve to the other whatever length the rail might run over or fall short by being moved over to a curve of slightly shorter or longer radius. It might here be suggested that the same method of procedure could be employed to advantage in the work of transposing rails from the outer to the inner side of a series of curves, if the curves are not too far apart. Where the curves are some distance apart the most rapid method would probably be to take care of the lengthening of the outside rail temporarily by opening the joints, and provide in advance for the shortening of the inside rail by cutting a piece of proper length to connect in when the change is made.

Another instance of widening gage, of particular interest because of the unusual conditions existing and of the novel method of doing the work, was the standardizing of the Columbia & Western Ry., from Trail to Rossland, British Columbia, in 1899 (This road has since become a part of the Canadian Pacific Ry. system). The peculiar features of the line are its steep grades and sharp curves, the road rising 2300 ft. in its length of 13.6 miles. The grade on all tangents was 4 per cent and the curves were compensated .04 per cent per degree. The maximum curves were 25-deg., of which there were 38, the aggregate length of which was approximately 3 miles; and there were two switch-backs. The track, of 3-ft gage, was laid with 6-ft. ties and 28-lb. steel rails. The cuts were 10 ft. wide and embankments 9 ft. in width. In addition to widening the gage the road was to a large extent reconstructed, the maximum curvature being reduced to 20 deg., cuts widened to 16 ft. and embankments to 14 ft. Four out of eleven trestles were filled and the others were strengthened. The grading was done during the fall of 1898. The work was done under the immediate direction of Mr. F. P. Gutelius, superintendent of the Rossland branch of the Canadian Pacific Ry. The plan of the work was different from usual practice, in that not only were new 60-lb. rails laid in connection with the widening of the gage, but new 8-ft. ties were also laid at the same time, thus entirely rebuilding the track upon a widened roadbed. The change was carried out gradually by tearing up the old track and laying an entirely new track, at the rate of about ½ mile per day, meanwhile carrying the narrow-gage rolling stock upon one of the rails of the new standard-gage line and a third rail laid temporarily to serve as the other side of the narrow-gage track. The narrow-gage switches were temporarily retained in service, so that all that remained to be done, as soon as the new track was laid, was to go back and lay the switches of the standard-gage track. The conditions being such that traffic could be accommodated by a night schedule for a few weeks, the usual custom of abandoning traffic for one or more days during the period of transition from one gage to the other was avoided.

Some of the details of this work may be useful information. As the old track had been laid but three years there had been no tie renewals and consequently no opportunity to gradually replace the short ties with ones of standard length in the course of ordinary repairs. The material for the new track was delivered by narrow-gage work trains, just ahead of the workmen, in the day time. The system of renewing out of face was adopted, thus allowing joint ties to be properly placed and rails to be full spiked as the new track was being laid. By this method a gang of 40 men would remove 2500 ft. of old track and replace it with standard track each day, the best record made for any one day being 3800 ft. The third rail put down for narrow-gage operation was only half spiked. Each evening the new track laid that day was connected to the undisturbed narrow-gage track, over which the narrow-gage trains were run during the night. The operation of narrow-gage trains on one 28-lb. rail and one 60-lb rail was not attended with any difficulty or accident. Rails were cut for standard-gage switches for all spurs, passing sidings and switch-backs, although temporary narrow-gage switches were laid as the work progressed, except in case of the Smelter Junction yard, where the tracks were arranged for use of both gages. Here a combination switch was used, and a movable-point frog operated by bell cranks attached to the regular switch stand was used (where the lead rail of the standard-gage turnout crossed the narrow-gage rail) instead of a double-point rigid frog. By June 14 the entire standard-gage track had been laid except for the substitution of standard for narrow-gage switches, of which there were fourteen. These switches were changed on June 15 by 100 men, in six gangs. The work of changing the switches was started at 7 o'clock, after all the narrow-gage equipment had been unloaded and taken to Smelter Junction, where it was stored. At 13 o'clock the first standard-gage passenger train started and by 15 o'clock it had passed over the road.

Referring to examples of more extensive changes, but not so much in detail, in the period between May 22 and June 2, 1886, the gage of more than 12,000 miles of track on various roads in the South was changed without interrupting the trains for more than a single day in any case. This change was from broad (5-ft.) to standard and 4-ft. 9-in. gage, and included 1806 miles of Louisville & Nashville main line and side-tracks, which was accomplished in a single day, May 30. The force employed on this occasion averaged 4 men to each mile of main line and siding and 5 men to each mile in the terminal yards, the total number of workmen employed being 8763. Preparation for the change at the crossings was made by cutting out at the middle of each side the requisite length of rail and then holding this piece in place by splice bars until the day of the change, when the cut pieces were removed and the sides of the crossings moved in to the newly adopted gage.

On July 9, 1885, the Mobile & Ohio R. R. changed the gage of its entire track of more than 500 miles in less than 12 hours, interfering with the movement of only one passenger train and a few freight trains. In this instance the cost was $27.99 per mile. The time required to do the preparatory work, such as adzing ties even with the rail seat and setting gage spikes, averaged 53 days' labor per section of 8 miles, and for pulling spikes just previous to the change, 20 days more. Only one rail was changed—the west rail—the east rail remaining undisturbed. Gage spikes for the new position of the west rail were driven to within 1½ ins. of the top of the tie. On the day before the change every other spike was drawn from the west rail and straightened and three new spikes were distributed to each rail. On the day of the change every other spike was driven on the outside of the changed rail and the gage spikes previously set on the inside were driven down. Switch rods adjustable at the center, by cutting in halves and overlapping (Engraving *H*, Fig. 145), had been gradually put on the switches before the change of gage commenced, and preparation had also been made for moving all switch stands located on the west side of the track. Precaution had been taken to provide each section with standard gage hand and push cars. The organization of each section crew on the day of the change was as follows: 4 men pulling inside spikes, 1 man driving down stubs of spikes from which the heads were broken in pulling, 3 men throwing out rail, 12 spikers working in pairs, 2 extra spikers, 1 nipper, 3 men shoving cars and doing miscellaneous work; or 26 men in all, besides the foreman. One day's supply of cooked provisions for the entire force on each section, water, spikes and extra tools were carried on the push cars, of which there were two—one car of 5 ft. gage pushed ahead of the work and a standard-gage hand car following after. At alternate meeting points between the sections two gangs began together and worked away from each other until meeting the next gang. The work commenced at 4 a. m. and was finished at about 4 p. m. or earlier. The pay of each laborer on this day was $1.50 and rations. Enough side-track was changed at each station to accommodate at least one freight train. The best record made was 5 miles of track changed in 5½ hours. To put the track into final shape, after the change, required about 50 days' labor per section of 8 miles, exclusive of superintendence.

96. Broken and Bent Rails.—Rails are most liable to break during very cold weather. One reason for this is that the ground may heave irregularly in places and make the support for the rail inelastic and uneven; another reason is that loss of heat has a tendency to make the metal brittle. There are those who dispute the latter statement on the ground that steel shows the same tensile strength at low temperatures that it does at ordinary atmospheric temperatures, but most trackmen know how difficult it is sometimes to break a rail during a hot day by notching and dropping it, and how much easier a rail can be broken in the same way during cold weather. Again, at even a moderate heat, far below red heat, steel rails may be bent quite sharply without breaking. A variation between 150° F. above zero and 40° F. below zero, must show some difference in the brittleness of the rail, if not in its tensile strength. Some experiments on steel rails by Mr. C. P. Sandberg, made in Sweden in 1888, showed that out of 21 specimens put to the drop test under a 1-ton ball, ten broke at —22° F. and only one at +90° F. The specimens were taken in pairs from the same piece of rail, one of each pair being tested at the lower temperature and the other at the higher temperature stated. In another instance reported by the same authority, specimens of rails requiring a drop of 39 ft. to break them at 84° were broken with the same weight falling only 11 ft. when the thermometer stood at 10°. Mr. P. H. Dudley has pointed out that cold weather has the effect of decreasing the ductility of the

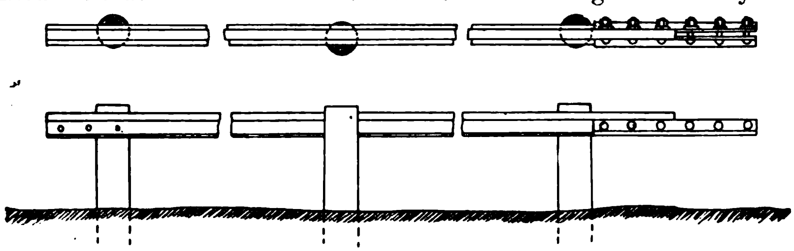

Fig. 259.—Rail Rest.

metal of the rails, but slightly increasing its tensile strength, elastic limit and modulus of elasticity. He also directs attention to heavy tensile stresses which may exist in the rails at low atmospheric temperatures, due to the tendency of the metal to contraction when the ends of the rails refuse to render in the splice bars. Such stresses might be sufficient, when combined with stresses from the moving loads, to start fracture at some flaw or gag mark. Straight pulling tests in the testing machine on two pieces of 95-lb. rail spliced with 20-in. angle bars showed that the metal could be stressed more than 12,000 lbs. per sq. in. before the rail would slip in the splice bars.

The danger from broken rails depends upon circumstances and the character of the break. If the break occurs over a tie support on straight line, or on the inside rail of a curve, and is a square break, derailment is not liable to occur; nevertheless there is danger; but if the break is between tie supports, or occurs on the outside rail of a curve, there is much danger of derailment. If the break occurs between tie supports when the ground is frozen deeply there is danger that a piece of rail may be broken out, which, if it occurs, will result almost surely in derailment. It is likely that in many cases of derailment from broken rails, the rail is broken by the very train to which the derailment happens. Rails break perhaps most frequently within the splice bars; but if the broken-off piece is not longer than 6 ins. or so and the break is square, so that the splice holds it, there is no danger. The tendency for rails to break most frequently near the end is undoubtedly due to the heavier stresses there arising from the greater deflection at the joint and to the pounding effect of the loads on low joints. It is also suggested by students of the metallurgical side of the matter that the greater tendency to break near the end than at intermediate points may in some measure be due to the metal in that portion of the rail having come from material too near the end of the ingot, in rolling, in which case seamy or brittle metal would be expected.

Whenever a dangerous broken rail is found, trains should be stopped and passed over it slowly until after it is temporarily repaired or another rail has been put in its place. The quickest way to make safe at a broken rail is to drill two holes and bolt on a splice. If the break is found in the night or the section crew, for any reason, is hard to find, or no spare rail is near, this is by all means the best thing to do; because all the tools and materials can be carried by one man, the work can be done by one man in a few minutes, and the rail is thereby made practically as safe as before the break. If the fracture is a "clean break"—that is, squarely across the rail or nearly so—and not too near a joint, the spliced pieces, fully bolted, may remain permanently, in lieu of laying another rail in their place. If a rail should be broken in more than one place, however, another rail should be laid in its stead as soon as possible. It is well to always measure, in some way, the length of the rail broken before going for a new one; if it is on a curve it may be one of the short rails. When a broken rail is taken out of the track the rail laid in its place should be one of the same pattern or section, and as nearly as may be in the same condition of wear. A broken joint splice leaves the track in a condition equivalent to that of a broken rail, although it does not usually create the same degree of excitement among the track men. In case a frog is broken beyond repair in place, and there is no spare frog on hand, a piece of rail may be laid in place of the frog. When such is done the switch should be spiked and the roadmaster and the train dispatcher promptly notified to that effect.

Rail Rests—Spare rails, sometimes called "emergency" rails, should be kept on hand at convenient points about a mile apart—say at every mile post. They are needed to replace broken rails occasionally and are handy to draw from when rails are needed at a wreck. These rails, if left lying on the shoulder half sunken into or half covered by the ballast, will, when wanted in a hurry some cold night, be found "tied fast" or perhaps covered with snow. Spare rails should be placed at least 18 ins. from the ground, on some kind of support located convenient to the track and in a clear space. Rail rests are made in a variety of forms, almost any of which are good enough for the purpose. A very common arrangement is to set two or three posts on a line parallel with the track and notch the tops to hold a rail in the inverted position (head down). In some instances spare rail posts set in this way are notched deep enough to hold a second rail laid on top of the other, base to base, or drift bolts are set into the sides of the posts to serve as pegs for supporting a second or third rail. Very frequently the middle post is set slightly out of line with the two end ones and the notching is done as in Fig. 259, to permit the rail to rest on its base. Rail rests for 60-ft. rails on the Pittsburg, Cincinnati, Chicago & St. Louis Ry. consist of four posts 10 ins. square set 16 ft. apart and notched according to the arrangement in Fig. 259, half the width of the post and two rails deep. Another arrangement, where it is desired to keep more than one rail at a place, is to set old bridge ties in a leaning position and notch out a series of seats or steps to hold the rails, on the inclined upper sides of the ties. Similarly, heavy planks are sometimes set in a vertical position and stepped out on the edge, to hold two or three rails.
